Liquidity Rules and Credit Booms*

July 2017

Abstract

We show that stricter liquidity standards can trigger unintended credit booms. Attempts to arbitrage the regulation change the allocation of savings across banks, eliciting strategic responses that also change the allocation of lending across markets. More credit is generated per unit of savings in the new equilibrium. Applying our model to China, we find that a move to stricter liquidity standards in the late 2000s accounts for one-third of the unprecedented credit boom that followed. A quantitative extension allowing for other, non-regulatory shocks also identifies variation in liquidity rules as the dominant force behind observed co-movements in market-determined interest rates.

*We thank Jeff Campbell, Jon Cohen, Doug Diamond, Gary Gorton, Narayana Kocherlakota, Randy Kroszner, Gary Richardson, Rich Rosen, Martin Schneider, Aleh Tsyvinski, Harald Uhlig, and seminar participants at various institutions and conferences for helpful comments. Financial support from Chicago Booth and CUHK is gratefully acknowledged.
1 Introduction

Seeking to mitigate booms and busts, many countries regulate bank lending in relation to the quantity and composition of bank liabilities. Proponents insist that business cycle fluctuations would be more severe without these regulations but policy-makers remain wary of unintended consequences. In the words of Stanley Fischer, Vice Chairman of the U.S. Federal Reserve, a “tightening in regulation of the banking sector may push activity to other areas – and things happen.” Exactly what happens, Fischer argues, is difficult to predict with existing models as there is limited theoretical work on the interactions between regulated and unregulated institutions and the economic incentives that drive them.\footnote{Speech delivered at the 2015 Financial Stability Conference, Washington D.C., December 3, www.federalreserve.gov/newsevents/speech/fischer20151203a.htm.} In this paper, we develop a theoretical framework that helps fill the gap between existing models and the models requested by policy-makers. We then establish the quantitative relevance of the theory with an application to China, one of the world’s largest economies.

Our model is one where banks engage in maturity transformation, borrowing short and lending long. This leaves them vulnerable to idiosyncratic withdrawal shocks, giving rise to an ex post interbank market where banks with insufficient liquidity can borrow from banks with surplus liquidity at an endogenously determined price.

We add to this environment two features. First, there are both big and small banks, namely a big bank that internalizes the impact of its choices on the rest of the economy and a continuum of individually small banks that do not. Second, banks can choose whether to manage all of their activities on a regulated balance sheet or whether to move some activity to a less regulated off-balance-sheet vehicle.

We then use our framework to explore the effects of a regulation that restricts bank lending in relation to bank deposits. Loans to non-financial borrowers are among the least liquid financial assets on a bank’s balance sheet so the regulation we consider is a liquidity minimum which requires each bank to keep its ratio of liquid assets to short-term funding above some threshold.

Our model predicts that the big bank will want a higher liquidity ratio than the small banks, regardless of regulation. This is because the small banks are interbank price-takers whereas the big bank takes into account the impact of its liquidity on the interbank price. Small banks are therefore endogenously more affected by the introduction of a liquidity minimum. In response, they find it optimal to offer a new savings instrument and manage the funds raised by this instrument in an off-balance-sheet vehicle that is not subject to regulation and that can therefore make the loans the bank cannot make on its balance sheet.
without violating the liquidity minimum. This constitutes shadow banking: it achieves the same type of credit intermediation as a regular bank without appearing on a regulated balance sheet. It also achieves the same type of maturity transformation as a regular bank, with long-term assets financed by short-term liabilities.

As small banks push to attract savings into off-balance-sheet instruments, our model predicts that they raise the interest rates on these instruments above the interest rates on traditional deposits. On the margin, the premium that small banks are willing to pay for off-balance-sheet funding is exactly equal to the tax implicitly imposed on their deposits by a binding liquidity minimum.

All else constant, the emergence of a savings instrument that pays a premium relative to traditional deposits poaches some deposits away from the big bank. Our model predicts that the big bank responds to this loss of funding in two ways. First, it issues its own high-return savings instruments, competing directly with the small banks. Second, it decreases the amount of liquidity it makes available to the interbank market. The second response involves a more subtle form of competition, wherein the big bank uses its price impact on the interbank market to change the incentives of the small banks. Naturally, the incentive to evade a liquidity minimum is weaker when liquidity is expected to be expensive. Therefore, by tightening the interbank market and making liquidity more expensive, the big bank can compel the small banks to behave less aggressively in their quest for off-balance-sheet business and thus lessen the extent to which they poach deposits.

The new equilibrium is characterized by an unintended credit boom, with more credit per unit of savings relative to the pre-regulation equilibrium. There are two channels behind this result. First, the migration of some savings from deposits at the big bank to the higher-return off-balance-sheet instruments of the small banks increases credit because the small banks, as interbank price-takers, lend more per unit of funding than the big bank. Second, the strategic response of the big bank on the interbank market contributes directly to the credit expansion: rather than sitting idly on the liquidity that it intends to withhold from the interbank market, the big bank lends more to non-financial borrowers.

We call the increase in credit that culminates from these two channels a supply-side credit boom because it originates from the banks themselves. These channels would not operate if the interbank market were purely Walrasian with ex ante identical banks. They would also not operate if off-balance-sheet vehicles were precluded, as small banks would have to mechanically switch from loans to more liquid assets in order to comply with the liquidity minimum.

The result that a credit boom can be born out of stricter liquidity regulation is startling. However, the theory generates it under a minimal set of assumptions, namely accounting
standards that do not outlaw off-balance-sheet business and heterogeneity in interbank market power. The first of these assumptions is satisfied around the world\footnote{The legality of off-balance-sheet vehicles reflects the discretion available in accounting rules (e.g., U.S. GAAP, IFRS standards, etc). Banks can capitalize on this discretion, changing the form of an activity for reporting purposes without changing the true economic substance. For this reason, accounting assets and liabilities can differ from economic assets and liabilities.} while the second is easily satisfied in countries (or time periods) where the central bank does not target a short-term policy rate. To elaborate on the latter point, most countries have at least some banks that are large enough to shift the demand for liquidity relative to the supply, leading to sudden changes in the price that clears the interbank market. If the central bank does not automatically offset all such changes by targeting the interbank rate, big banks will have a much greater price impact than small banks and the assumption of heterogeneity in interbank market power will be satisfied.

The relevance of the model is therefore potentially quite broad so we want to take it to the data to assess its quantitative performance. We choose China as the setting for our quantitative analysis. Between 2007 and 2014, the ratio of debt to GDP in China exploded from 110% to 200%. The ratio of private credit to private savings, sometimes a more conservative gauge, also rose markedly from 65% to 75% over the same period. This credit boom appears to have occurred on the heels of stricter liquidity regulation. Around 2008, Chinese regulators began enforcing an old but hitherto neglected loan-to-deposit cap which forbade banks from lending more than 75% of their deposits to non-financial borrowers. Our model predicts that some credit booms are caused by stricter liquidity regulation so we are interested to know whether stricter liquidity regulation can account for at least part of the Chinese experience.

We use a rich, transaction-level dataset to establish that there is a high degree of heterogeneity in interbank market power among China’s commercial banks. We then calibrate the model to Chinese data. The calibrated version of our model shows that loan-to-deposit enforcement alone generates one-third of the increase in China’s aggregate credit-to-savings ratio between 2007 and 2014. We then pursue a quantitative extension that allows for multiple shocks to the Chinese economy: shocks to liquidity regulation, shocks to loan demand stemming from the fiscal stimulus package announced by China’s State Council in late 2008, and money supply shocks. We find that loan demand shocks and money supply shocks produce counterfactual correlations between key market-determined interest rates, specifically interbank interest rates and spreads on the high-return savings instruments offered by small versus big banks. Allowing for all three shocks simultaneously, the quantitative extension matches a broad set of empirical moments almost perfectly, while still assigning a dominant
role to variation in loan-to-deposit rules.

Our paper contributes to the literature on financial regulation. Of particular relevance for the issues we study are Farhi, Golosov, and Tsyvinski (2007, 2009) who theoretically analyze the effect of liquidity regulation on market interest rates in a broad set of specifications and Gorton and Muir (2016) who provide a historical record of arbitrage during the U.S. National Banking Era to evaluate whether the BIS liquidity coverage ratio might work. We contribute to this literature by showing how the effect of liquidity regulation depends on interbank market structure and by developing a theory of unintended credit booms.

Our paper also relates to a growing strand of research in economic history that highlights the importance of understanding interbank markets. Mitchener and Richardson (2016) show how a pyramid structure in U.S. interbank deposits propagated shocks during the Great Depression, Gorton and Tallman (2016) show how cooperation among members of the New York Clearinghouse helped end pre-Fed banking panics, and Frydman, Hilt, and Zhou (2015) show how a lack of cooperation with and between New York’s trust companies became problematic during the Panic of 1907. Our paper relates to this literature as well as a recent line of work by Corbae and D’Erasmo (2013, 2014) on the industrial organization of banking, although our focus is on understanding how liquidity regulation can be endogenously undermined.

The rest of our paper is organized as follows. Sections 2 and 3 focus on the model. To help isolate the effect of interbank market structure, Section 2 lays out a benchmark model with only small banks and studies the equilibrium properties. Section 3 extends the benchmark to include a large bank, studies how the equilibrium properties are affected, and presents the main analytical results. All proofs are in Appendix A. Section 4 then applies the model to China, presenting the calibration results along with a structural estimation to evaluate the importance of various shocks. Section 5 concludes.

2 Benchmark Model

There are three periods, \( t \in \{0, 1, 2\} \), and a unit mass of risk neutral banks, \( j \in [0, 1] \). Let \( X_j \) denote the funding obtained by bank \( j \) at \( t = 0 \). Each bank can invest in a project which returns \( (1 + i_A)^2 \) per unit invested. Projects are long-term, meaning that they run from \( t = 0 \) to \( t = 2 \) without the possibility of liquidation at \( t = 1 \). To introduce a tradeoff between investing and not investing, banks are also subject to short-term idiosyncratic liquidity shocks which must be paid off at \( t = 1 \). More precisely, bank \( j \) must pay \( \theta_j X_j \) at \( t = 1 \) in order to continue operation. The exact value of \( \theta_j \) is drawn from a two-point distribution:
\[ \theta_j = \begin{cases} \theta_t \text{ prob. } \pi \\ \theta_h \text{ prob. } 1 - \pi \end{cases} \]

where \( 0 < \theta_t < \theta_h < 1 \) and \( \pi \in (0, 1) \). Each bank learns the realization of its shock in \( t = 1 \). Prior to that, only the distribution is known.

### 2.1 Bank Liabilities

The liquidity shocks just described can be fleshed out using Diamond and Dybvig (1983). Specifically, the economy has an aggregate endowment \( X > 0 \) at \( t = 0 \) and banks attract funding by offering liquidity services to the owners of this endowment (ex ante identical households). The liquidity service offers households more than the long-term project if liquidated at \( t = 1 \) but less than this project if held until \( t = 2 \).

The traditional liquidity service is a deposit. To set notation, a dollar deposited at \( t = 0 \) becomes \( 1 + i_B \) if withdrawn at \( t = 1 \) and \((1 + i_D)^2 \) if withdrawn at \( t = 2 \). In Diamond and Dybvig (1983), banks choose \( i_B \) and \( i_D \) to achieve optimal risk-sharing for households. In Diamond and Kashyap (2015), banks take \( i_B \) and \( i_D \) as given and, with \( i_B = i_D = 0 \), the traditional deposit is equivalent to storage.

In our model, each bank \( j \) can offer a liquidity service which delivers storage plus a return \( \xi_j \). To ease the exposition, suppose \( \xi_j \) accrues at \( t = 2 \). As we will explain in Section 2.4, bank \( j \) chooses \( \xi_j \) at \( t = 0 \) to maximize its expected profit subject to household demand for liquidity services. If bank \( j \) chooses \( \xi_j = 0 \), then it is content offering storage. If bank \( j \) chooses \( \xi_j > 0 \), then it is choosing to offer more than storage.\(^3\)

In practice, banks may have more elaborate liability structures, where they pay different prices for different units of funding. What matters for the analysis are the spreads so it suffices to fix characteristics and price for one type of funding and let the rest vary relative to it. To this end, we allow each bank \( j \) to simultaneously offer storage and another liquidity service that pays an endogenously chosen \( \xi_j \geq 0 \). We refer to the other liquidity service as a deposit-like product (DLP), with a choice of \( \xi_j = 0 \) implying that no DLPs are offered. The shock \( \theta_j \) represents the fraction of households that withdraw funding from bank \( j \) at \( t = 1 \).

Let us now specify how households allocate their endowment at \( t = 0 \) conditional on interest rates. Denote by \( D_j \) the funding attracted by bank \( j \) in the form of storage. The funding attracted in the form of DLPs is denoted by \( W_j \), with \( X_j = D_j + W_j \) and \( \int X_j d\mu_j = X \).

\(^3\)Offering \( \xi_j < 0 \) would create an incentive for early withdrawals and cannot be an equilibrium outcome. We will be focusing on parameters such that a choice of \( \xi_j = 0 \) indicates a desire by bank \( j \) to offer exactly \( \xi_j = 0 \), as opposed to indicating that bank \( j \) would offer \( \xi_j < 0 \) if there were no concern about creating incentives for early withdrawals.
Appendix B sketches a simple household optimization problem with transactions costs which motivates the following functional forms:

\[ W_j = \omega \xi_j \]  
\[ D_j = X - (\omega - \rho) \xi_j - \rho \bar{\xi} \]

where \( \omega \) and \( \rho \) are non-negative constants and \( \bar{\xi} \) denotes the average DLP return offered by other banks. Intuitively, \( \omega \) captures the substitutability between liquidity services within a bank while \( \rho \) governs the intensity of competition among banks. To see this, sum equations (1) and (2) to write bank \( j \)'s funding share as:

\[ X_j = X + \rho (\xi_j - \bar{\xi}) \]

If \( \rho = 0 \), then bank \( j \) perceives its funding share as fixed, shutting down competition. If \( \rho > 0 \), then bank \( j \) perceives a positive relationship between its funding share and the DLP return it offers relative to other banks.

Each individual bank will take \( \bar{\xi} \) as given when making decisions. In a symmetric equilibrium, \( \bar{\xi} \) will be such that the profit-maximizing choice of \( \xi_j \) equals \( \bar{\xi} \) for all \( j \).

### 2.2 Bank Assets and the Interbank Market

We now elaborate on how banks allocate their funding. The maturity mismatch between investment projects and liquidity shocks introduces a role for reserves (i.e., savings which can be used to pay realized liquidity shocks). As we will explain in Section 2.4, the division of \( X_j \) into investment and reserves is chosen at \( t = 0 \) to maximize expected profit.

Let \( R_j \in [0, X_j] \) denote the reserve holdings of bank \( j \) at \( t = 0 \). If \( \theta_j < \frac{R_j}{X_j} \), then bank \( j \) has a reserve surplus at \( t = 1 \). If \( \theta_j > \frac{R_j}{X_j} \), then bank \( j \) has a reserve shortage at \( t = 1 \). An interbank market exists at \( t = 1 \) to redistribute reserves across banks. A market in which banks can share risk and obtain liquidity also exists in Allen and Gale (2004).

The interbank interest rate in our benchmark is denoted by \( i_L \). Banks in the continuum are atomistic so they take \( i_L \) as given when making decisions. However, \( i_L \) is endogenous and adjusts to clear the interbank market. Interbank lenders (borrowers) are banks with reserve surpluses (shortages) at \( t = 1 \). In practice, central banks also serve as lenders of last resort so we introduce a supply of external funds, \( \Psi(i_L) \equiv \psi i_L \), where \( \psi > 0 \).

We will focus on symmetric equilibrium, in which case \( R_j \) and \( \xi_j \) are the same across the unit mass of banks. Notice that symmetry of \( \xi_j \) in equation (3) implies \( X_j = X \). The
condition for interbank market clearing is then:

\[ R_j + \psi i_L = \bar{\theta} X \]  

(4)

where \( \bar{\theta} \equiv \pi \theta_c + (1 - \pi) \theta_h \) is the average liquidity shock. The left-hand side of (4) captures the supply of liquidity at \( t = 1 \) while the right-hand side captures the demand. Total credit in this economy is the total amount of funding invested in projects, \( X - R_j \).

### 2.3 Liquidity Regulation and Possible Arbitrage

We now allow for the possibility of a government-imposed loan limit on each bank. This limit can also be viewed as a liquidity rule which says the ratio of reserves to funding must be at least \( \alpha \in (0,1) \). Given the structure of our model, reserves are meant to be used at \( t = 1 \) so enforcement of the liquidity rule is confined to \( t = 0 \). If the government does not enforce a liquidity rule, then \( \alpha = 0 \).

Importantly, the liquidity rule only applies to activities that the bank reports on its balance sheet. To model this, we allow banks to choose where to manage DLPs and the projects financed by those DLPs. If fraction \( \tau_j \in [0,1] \) is managed in an off-balance-sheet vehicle, then bank \( j \)'s reserve holdings only need to satisfy:

\[ R_j \geq \alpha (X_j - \tau_j W_j) \]  

(5)

Off-balance-sheet vehicles can be viewed as accounting maneuvers that legally shift activities away from regulation without changing the nature of those activities. Such maneuvers capitalize on the discretion available in accounting rules and constitute regulatory arbitrage.4

Notice that bank \( j \) does not need to use off-balance-sheet vehicles if just attempting to change its funding share in equation (3). This is because \( \xi_j \) and \( \tau_j \) are separate decisions. If bank \( j \) chooses \( \xi_j > 0 \) and \( \tau_j = 0 \), then it is simply offering a deposit with a competitive interest rate to boost its funding share. If it chooses \( \xi_j > 0 \) and \( \tau_j > 0 \), then it is offering this product to lessen the burden of the liquidity rule and hence engaging in regulatory arbitrage. The value of \( \tau_j \) thus reveals the source of any spread between DLP returns and storage.

---

4 Adrian, Ashcraft, and Cetorelli (2013) define regulatory arbitrage as “a change in structure of activity which does not change the risk profile of that activity, but increases the net cash flows to the sponsor by reducing the costs of regulation.” In principle, we could introduce a small cost to pursuing the accounting maneuvers that permit regulatory arbitrage. We do not do this here as it would clutter the exposition without producing much additional insight.
2.4 Optimization Problem of Representative Bank

The expected profit of bank $j$ at $t = 0$ is:

$$
\Upsilon_j \equiv (1 + i_A)^2 (X_j - R_j) + (1 + i_L) R_j - \left[ i_L \overline{\theta} X_j + X_j + (1 - \overline{\theta}) \xi_j W_j \right] - \frac{\phi}{2} X_j^2
$$

(6)

where $W_j$ and $X_j$ are given by (1) and (3) respectively. The first term in (6) is revenue from investment. The second term is revenue from lending reserves on the interbank market. The third term is the bank’s expected funding cost, namely the expected cost of borrowing reserves on the interbank market and the expected payments to households. The fourth term is a general operating cost (with $\phi > 0$) which is quadratic in the bank’s funding share. Operating costs will play a minimal role until Section 3.

The representative bank chooses the attractiveness of its DLPs $\xi_j$, the intensity of its off-balance-sheet activities $\tau_j \in [0, 1]$, and its reserve holdings $R_j$ to maximize $\Upsilon_j$ subject to the liquidity rule in (5). The Lagrange multiplier on (5) is the shadow cost of holding reserves. We denote it by $\mu_j$. The multipliers on $\tau_j \geq 0$ and $\tau_j \leq 1$ are denoted by $\eta_j^0$ and $\eta_j^1$ respectively. The first order conditions with respect to $R_j$, $\tau_j$, and $\xi_j$ are then:

$$
\mu_j = (1 + i_A)^2 - (1 + i_L) 
$$

(7)

$$
\eta_j^1 = \eta_j^0 + \alpha \mu_j W_j 
$$

(8)

$$
\xi_j = \frac{(1 - \overline{\theta}) i_L + (1 - \alpha) \mu_j - \phi X_j}{2 (1 - \overline{\theta})} \times \frac{\rho}{\omega} \bigg\{ \text{competitive motive} \bigg\} + \frac{\alpha \mu_j}{2 (1 - \overline{\theta})} \times \tau_j \bigg\{ \text{reg. arbitrage motive} \bigg\}
$$

(9)

The first term on the right-hand side of equation (9) captures what we will call the competitive motive for DLP issuance. If this term is positive, then bank $j$ wants to offer higher DLP returns in order to attract more funding. Recall that bank $j$’s total funding, $X_j$, is given by equation (3). Each bank takes $\overline{\xi}$ as given so increasing $\xi_j$ relative to $\overline{\xi}$ increases $X_j$. The second term on the right-hand side of equation (9) captures what we will call the regulatory arbitrage motive for DLP issuance. In the absence of a liquidity rule ($\alpha = 0$), there is no regulatory arbitrage motive. There is also no such motive when the interbank rate is high enough to make the shadow cost of holding reserves ($\mu_j$) zero.

2.5 Results for Benchmark Model

We now study the equilibrium properties of the benchmark model.
We start by establishing the existence of an equilibrium where banks are content offering only storage (i.e., $j^*_j = 0$, where asterisks denote equilibrium values). We have already established that there is no regulatory arbitrage motive for DLP issuance without liquidity regulation ($\alpha = 0$). The following proposition establishes the conditions under which there is also no competitive motive:

**Proposition 1** Suppose $\phi \leq \bar{\phi}$ where $\bar{\phi}$ is a positive threshold that depends on parameters other than $\alpha$ and $\rho$. If $\alpha = 0$ and $\phi < \bar{\phi}$, then $j^*_j = 0$ if and only if $\rho = 0$. If $\alpha = 0$ and $\rho > 0$, then $j^*_j = 0$ if and only if $\phi = \bar{\phi}$.

With $\rho = 0$, there is no competitive motive for DLP issuance because each bank perceives its funding share as fixed. With $\rho > 0$ and a high operating cost (i.e., $\phi = \bar{\phi}$), there is also no competitive motive because banks do not want to get bigger. Therefore, $\alpha = 0$ with either one of these parameterizations delivers an equilibrium where only storage is offered.

Suppose the economy starts in such an equilibrium. Proposition 2 shows that increasing $\alpha$ above a threshold value $\bar{\alpha}$ triggers the issuance of off-balance-sheet DLPs. The benchmark model thus delivers a shadow banking sector after the introduction of a sufficiently strict liquidity rule:

**Proposition 2** Suppose $\rho = 0$. There is a unique $\bar{\alpha} \in [0, \bar{\phi})$ such that $j^*_j = 0$ if $\alpha \leq \bar{\alpha}$ and $\xi^*_j > 0$ with $\tau^*_j = 1$ otherwise.

The incentive to issue DLPs in Proposition 2 does not come from competition since $\rho = 0$ eliminates the competitive motive. Instead, DLPs are issued because they can be booked off-balance-sheet, away from the binding liquidity rule. Similar intuition can be delivered with $\rho > 0$ and $\phi$ sufficiently high.

Consider now the aggregate effects. Proposition 3 shows that introducing a liquidity minimum into the benchmark model lowers both the interbank rate and total credit in equilibrium:

**Proposition 3** Fix all parameters except for $\alpha$. For any $\rho \geq 0$, the equilibrium under $\alpha = 0$ has a higher interbank rate and more total credit than the equilibrium under any $\alpha > 0$. It can also be shown, fixing all parameters except for $\alpha$ and $\rho$, that the equilibrium under $\alpha = 0$ and $\rho = 0$ has a higher interbank rate and more total credit than the equilibrium under any combination of $\alpha > 0$ and $\rho > 0$.

Proposition 3 is effectively the market mechanism at work. The interbank market in the benchmark model is Walrasian so all banks are price-takers. Suppose there is no government
intervention ($\alpha = 0$). At low interbank rates, none of these price-taking banks will find it profitable to hold reserves. Instead, they will all want to invest heavily in the long-term project to earn a return, relying on the interbank market for cheap liquidity to pay off liquidity shocks. Liquidity demand at $t = 1$ will then exceed liquidity supply, which cannot be an equilibrium. The equilibrium interbank rate must therefore be high to incent banks to hold reserves when $\alpha = 0$. The introduction of a liquidity minimum by the government ($\alpha > 0$) substitutes somewhat for this market-based discipline and the equilibrium interbank rate falls.$^5$ The result on total credit then follows immediately from equation (4), given that total credit equals $X - R_j$.

3 Full Model: Heterogeneity in Market Power

We now extend the benchmark model to include a big bank. By definition of being big, this bank will internalize how all of its choices affect the equilibrium.

We keep the continuum of small banks, $j \in [0, 1]$, and index the big bank by $k$. DLP demands are $W_j = \omega \xi_j$ and $W_k = \omega \xi_k$, similar to equation (1). The funding attracted by each bank is an augmented version of equation (3), namely:

$$X_j = 1 - \delta_0 + \delta_1 (\xi_j - \bar{\xi}_j) + \delta_2 (\xi_j - \bar{\xi}_j)$$

(10)

$$X_k = \delta_0 + \delta_1 (\xi_k - \bar{\xi}_j)$$

(11)

where total funding in the economy has been normalized to $X = 1$ and $\bar{\xi}_j$ is the average return on small bank DLPs. Here, $\delta_1$ is the competition parameter between the big and small banks while $\delta_2$ affects the competition among small banks. Small banks take $\bar{\xi}_j$ and $\xi_k$ as given, along with being interbank price-takers. In a symmetric equilibrium, the profit-maximizing choice of $\xi_j$ equals $\bar{\xi}_j$.

The big bank does not take $\bar{\xi}_j$ as given. It is also not an interbank price-taker. As a result, the interbank rate will depend on the big bank’s realized liquidity shock. This makes the big bank’s shock an aggregate shock so, in Appendix C, we show that adding aggregate shocks to the benchmark model with only small banks does not change Proposition 3. It is therefore the strategic nature of the big bank’s decision-making that will drive the substantive differences between the results of the full model being considered here and the results of the benchmark model considered earlier.\footnote{Another way to think about this is as follows: the government intervention makes reserves more scarce, on the margin, which drives down their yield. See Farhi, Golosov, and Tsyvinski (2009) for a different environment in which a liquidity minimum decreases interest rates.}
Let \( i_L^s \) denote the interbank rate when the big bank realizes \( \theta_s \) at \( t = 1 \), where \( s \in \{ \ell, h \} \). The interbank market clearing condition for \( s = h \) is:

\[
R_j + R_k + \psi i_h^L = \bar{\theta} X_j + \theta_h X_k
\]

(12)

The left-hand side of (12) captures the supply of liquidity while the right-hand side captures the demand for liquidity, in an equilibrium where small banks are symmetric. All decisions are made at \( t = 0 \) so it will be enough for the big bank to affect the expected interbank rate, \( i_L^s \equiv \pi i_L^s + (1 - \pi) i_h^L \). We can therefore simplify the exposition by fixing \( i_L^s = 0 \) and letting \( i_L^h \) move with \( i_h^L \), where \( i_L^h \) is determined as per equation (12). It will be verified in the proposition proofs that \( i_L^s = 0 \) does not result in a liquidity shortage when the big bank realizes \( \theta_L < \theta_h \) in this class of equilibria.

### 3.1 Optimization Problem of Big Bank

At \( t = 0 \), the big bank’s expected profit is:

\[
\Upsilon_k \equiv (1 + \alpha)^2 (X_k - R_k) + [1 + (1 - \pi) i_h^L] R_k - [(1 - \pi) i_L^h \theta_h X_k + X_k + (1 - \bar{\theta}) \omega \xi_k^2] - \frac{\phi}{2} X_k^2
\]

The interpretation is similar to equation (6): the first term is revenue from investment, the second term is the potential expected revenue from lending reserves, the third term is the big bank’s expected funding cost, and the fourth term is an operating cost.

The big bank chooses \( R_k, \tau_k, \) and \( \xi_k \) to maximize \( \Upsilon_k \) subject to three sets of constraints. First are the aggregate constraints, namely funding shares as per (10) and (11) and market clearing as per (12). The market clearing equation connects \( R_k \) and \( i_h^L \) so saying that the big bank chooses \( R_k \) with \( i_L^h \) determined by (12) is equivalent to saying that it chooses \( i_L^h \) with \( R_k \) determined by (12). This is the sense in which the big bank is a price-setter on the interbank market.

The second set of constraints are the first order conditions of small banks. The representative small bank solves essentially the same problem as before. Its objective function is still given by (6) but with \( (1 - \pi) i_L^h \) as the interbank rate and \( X_j \) as per equation (10). It is also still subject to the liquidity rule in (5) with \( \tau_j \in [0, 1] \). The results in Section 2.5 on which we want to build involved \( \xi_j \geq 0 \) so we will add this as an explicit condition here.

The last set of constraints on the big bank’s problem are inequality constraints, namely a liquidity rule for the big bank and non-negativity conditions:

\[
R_k \geq \alpha (X_k - \tau_k W_k)
\]
\[ \tau_k \in [0, 1] \]
\[ \xi_k \geq 0 \]
\[ \mu_j \geq 0 \]

where \( \mu_j \) is the shadow cost of reserves or, equivalently, the Lagrange multiplier on the liquidity rule in the small bank problem. Each inequality constraint listed above can be either binding or slack.

### 3.2 Results for Full Model

An equilibrium in the full model is characterized by the first order conditions from the small bank problem, the first order conditions from the big bank problem, and interbank market clearing.

Following Section 2.5, we first discuss the equilibrium where all banks offer only storage. We know from our analysis of the benchmark model that small banks will have a competitive motive for DLP issuance if (i) they do not take their funding shares as given and (ii) operating costs are low enough that they want to expand. Notice from equation (10) that small banks will not take their funding shares as given if \( \delta_1 + \delta_2 > 0 \).

If instead \( \delta_1 + \delta_2 = 0 \), with \( \delta_1 \geq 0 \), then equation (10) simplifies to:

\[ X_j = 1 - \delta_0 + \delta_1 (\bar{\xi}_j - \xi_k) \]

In a symmetric equilibrium, \( \xi_j = \bar{\xi}_j \) so there is still an indirect effect of \( \xi_j \) on the funding share \( X_j \). However, small banks are not setting \( \xi_j \) to exploit this effect. Instead, small banks take their funding shares as given and the first order conditions from their optimization problem deliver:

\[ \mu_j \left[ R_j - \alpha (X_j - \omega \xi_j) \right] = 0 \text{ with complementary slackness} \quad (13) \]

\[ \mu_j = (1 + i_A)^2 - [1 + (1 - \pi) i^h_L] \quad (14) \]

\[ \xi_j = \frac{\alpha \mu_j}{2 (1 - \theta)} \quad (15) \]

with \( \tau_j = 1 \) for the reasons discussed at the beginning of the proof of Proposition 2. In words, these first order conditions say that small banks are content offering only storage unless there is a liquidity rule \( (\alpha > 0) \) and a shadow cost to holding reserves \( (\mu_j > 0) \). With \( \alpha > 0 \) and \( \mu_j > 0 \), small banks would also offer off-balance-sheet DLPs, which is the same
regulatory arbitrage motive for DLP issuance seen in equations (8) and (9) of the benchmark model.

Clearly, $\alpha = 0$ will be enough to deliver an initial equilibrium without regulatory arbitrage so that small banks do indeed offer only storage at the combination of $\alpha = 0$ and $\delta_1 + \delta_2 = 0$. To simplify the analytical exposition and develop clear intuition, this section will study a move from $\alpha = 0$ to $\alpha > 0$, assuming $\delta_1 + \delta_2 = 0$. In Section 4.2, we will calibrate the starting and ending values of $\alpha$ to data and allow $\delta_1 + \delta_2 > 0$. We will then calibrate an operating cost parameter for small banks ($\phi_j$) that is consistent with minimal DLP issuance in the initial steady state.\(^6\)

The property that the big bank offers only storage when $\alpha = 0$ can also be delivered in one of two ways. The first approach is to set $\delta_1 = 0$ in equation (11) so that the big bank’s funding share is fixed at $X_k = \delta_0$. The second approach is to keep the funding share endogenous ($\delta_1 > 0$) and set a sufficiently high operating cost parameter which eliminates any incentive for the big bank to increase its funding share (and hence issue DLPs) at the configuration of parameters in the initial equilibrium. We will present analytical results for both approaches to isolate how, if at all, an endogenous funding share affects the big bank’s decision-making. When considering the second approach in the analytical results below, we will set $\phi$ so that, in the initial equilibrium, $\xi_k$ is exactly zero as opposed to being constrained by zero. The quantitative analysis in Section 4.2 will also follow the second approach and allow $\delta_1 > 0$. We will then calibrate a $\phi_k$ for the big bank to distinguish it from the $\phi_j$ for the small banks mentioned above.

Having explained the defining features of the initial equilibrium, let us consider the distribution of reserves between big and small banks in this equilibrium. The distribution of reserves across banks was not a consideration in the benchmark model because all banks were ex ante identical price-takers. Now, however, we have a big bank who is a price-setter so its reserve choice may differ from that of small banks.

Proposition 4 Suppose $\alpha = 0$. Consider $\delta_1 + \delta_2 = 0$ and either $\delta_1 > 0$ with $\phi$ sufficiently positive or $\delta_1 = 0$ so that the initial equilibrium has $\xi_j^* = \xi_k^* = 0$. If $i_A$ lies within an intermediate range, then the initial equilibrium also involves $\mu_j^* > 0$, $R_j^* = 0$, and $R_k^* > 0$.

Proposition 4 says that reserves in the initial equilibrium are held disproportionately by the big bank when the returns to investment ($i_A$) are moderate. The big bank’s willingness to hold liquidity reflects its status as an interbank price-setter. In particular, the big bank

\(^6\)With $\delta_1 + \delta_2 = 0$, small banks never have a competitive motive for DLP issuance. With $\delta_1 + \delta_2 > 0$ and $\phi_j$ sufficiently high, they have no such motive at the initial equilibrium. The second approach imposes weaker conditions than the first but the main qualitative results do not depend on which approach is used.
understands that not holding enough liquidity will increase its funding costs should it experience a high liquidity shock. In contrast, the price-taking small banks invest all their funding in projects and rely on the interbank market, which now includes the big bank, to honor short-term obligations.

We saw in Section 2.5 that introducing a liquidity minimum into the benchmark model with only small banks decreased both the interbank rate and the total amount of credit. In other words, regulation had the intended effect. We want to see whether this is still the case in the full model with big and small banks or whether there are conditions under which the result is reversed.

To make the policy experiment concrete, suppose the government moves from $\alpha = 0$ to $\alpha = \overline{\alpha}$. As shown next, introducing a liquidity minimum into the full model can lead to an increase in the interbank rate, in sharp contrast to the benchmark prediction:

**Proposition 5** Keep $\delta_1 + \delta_2 = 0$ as in Proposition 4. The following are sufficient for the equilibrium under $\alpha = \overline{\alpha}$ to have a higher interbank rate $i_h^* \geq i_L^*$ than the equilibrium under $\alpha = 0$, while preserving slackness of the big bank’s liquidity rule ($R_k^* > \alpha X_k^*$), bindingness of the small bank liquidity rule ($\mu_j^* > 0$), and feasibility of $i_L^* = 0$:

1. Suppose $\delta_1 = 0$ so that the big bank’s funding share is fixed. The sufficient conditions are: $\pi$ sufficiently high, $\theta_\ell$ and $\frac{w}{\omega}$ sufficiently low, and $i_A$ within an intermediate range.

2. Suppose $\delta_1 = \omega > 0$ so that the big bank’s funding share is endogenous. Also set $\phi$ so that $\xi_k^*$ is exactly zero at $\alpha = 0$ for the reasons discussed earlier in this section. The sufficient conditions are: $\pi$ sufficiently high, $\theta_\ell$ and $\frac{w}{\omega}$ sufficiently low, and $i_A$ and $\delta_0$ within intermediate ranges.

There is a non-empty set of parameters satisfying the sufficient conditions in both 1 and 2. All else constant, the model with an endogenous funding share generates a larger increase in the interbank rate than the model with a fixed funding share.

We devote Section 3.2.1 to explaining the interbank rate results just established. Section 3.2.2 will then establish several other results that distinguish the full model from the benchmark, including the effect of liquidity regulation on total credit.

### 3.2.1 Intuition for Interbank Rate Response

To explain Proposition 5, it will be useful to summarize all the forces behind the big bank’s choice of $i_h^*$. Differentiating the big bank’s objective function with respect to $i_h^*$, we get:
The equilibrium $i_L^b$ solves $\frac{\partial Y_k}{\partial i_L^b} = 0$ when the relevant inequality constraints in the big bank’s problem are slack. This is the appropriate case given the statement of Proposition 5. We will start by explaining the three motives identified in (16). We will then explain how the strength of each motive varies with $\alpha$ in order to understand why moving from $\alpha = 0$ to $\alpha = 0$ generates a higher interbank rate.

First is the direct motive. The big bank has reserves $R_k$ and a funding share $X_k$. Its net reserve position when hit by a high liquidity shock is therefore $R_k - \theta_h X_k$. Each unit of reserves is valued at an interest rate of $i_L$ when the big bank’s shock is high so, on the margin, an increase in $i_L$ changes the big bank’s profits by $R_k - \theta_h X_k$.

Second is the reallocation motive. The idea is that changes in $i_L$ also affect how many reserves the big bank needs to hold in a market clearing equilibrium. If $\frac{\partial R_k}{\partial i_L} < 0$, then an increase in $i_L$ elicits enough liquidity from other sources to let the big bank reallocate funding from reserves to investment. On the margin, the value of this reallocation is the shadow cost of reserves, hence the coefficient on $\frac{\partial R_k}{\partial i_L}$ in (16).

Third is the funding share motive. The idea is that changes in $i_L$ also affect how much funding the big bank attracts when funding shares are endogenous. If $\frac{\partial X_k}{\partial i_L} > 0$, then an increase in $i_L$ decreases the shadow cost of reserves and curtails the DLP offerings of small banks by enough to boost the big bank’s funding share. The coefficient on $\frac{\partial X_k}{\partial i_L}$ in (16) captures the marginal value of a higher funding share for the big bank. We will discuss this coefficient in more detail below.

To gain some insight into how changes in $\alpha$ will affect the solution to $\frac{\partial Y_k}{\partial i_L} = 0$ through each motive, we start with the case of fixed funding shares ($\delta_1 = 0$). Consider first the direct motive. Using the market clearing condition:

$$R_k - \theta_h X_k \overset{\delta_1=0}{\Rightarrow} \bar{\theta} (1 - \delta_0) - \psi i_L^b - \alpha \left( 1 - \delta_0 - \frac{\alpha \omega (1 - \pi)}{2 (1 - \bar{\theta})} \left( 1 + i_A \right)^2 - \frac{1 - \phi X_k}{1 - \pi} - i_L^b \right)$$

For a given value of $i_L^b$, the magnitude of the direct motive in (17) depends on $\alpha$ through the reserve holdings of small banks. There are two competing effects. On one hand, higher $\alpha$ forces small banks to hold more reserves per unit of on-balance-sheet funding. On the
other hand, higher $\alpha$ can compel small banks to engage in regulatory arbitrage, decreasing their on-balance-sheet funding as they offer off-balance-sheet DLPs ($\xi_j > 0$ with $\tau_j = 1$). The net effect is ambiguous so we must look beyond the direct motive to fully understand Proposition 5.

With fixed funding shares, the only other motive is the reallocation motive, where:

$$\left. \frac{\partial R_k}{\partial i^h_L} \right|_{\delta_1=0} = -\psi - \frac{\alpha^2 \omega (1 - \pi)}{2 \left( 1 - \theta \right)} < 0 \tag{18}$$

This expression is negative for two reasons. First, and as captured by the first term in (18), a higher interbank rate will attract more external liquidity, allowing the big bank to hold fewer reserves. Second, and as captured by the second term in (18), small banks will increase their reserves when the interbank rate increases, also allowing the big bank to hold fewer reserves. The effect of $i^h_L$ on $R_j$ that underlies the second term in (18) works through the regulatory arbitrage motive of small banks: there is less incentive to circumvent a liquidity minimum when liquidity is expected to be expensive. We can also infer from the second term in (18) that the effect of $i^h_L$ on $R_j$ strengthens with $\alpha$. This is both because $R_j$ is more responsive to changes in $\xi_j$ at high $\alpha$ (see equation (13)) and because $\xi_j$ is more responsive to changes in $i^h_L$ at high $\alpha$ (see equations (14) and (15)).

This discussion helps explain the first bullet in Proposition 5: when funding shares are fixed, high $\alpha$ makes it easier for the big bank to use high interbank rates to incent small banks to share the burden of keeping the system liquid.

Does the same intuition extend to the case of endogenous funding shares? No, because:

$$\left. \frac{\partial R_k}{\partial i^h_L} \right|_{\delta_1=\omega} = -\psi + \frac{\alpha \omega \pi (\theta_h - \theta_l) (1 - \pi)}{2 \left( 1 - \theta \right)} \tag{19}$$

An increase in $i^h_L$ still decreases $\xi_j$ but now a decrease in $\xi_j$ also decreases how much funding $X_j$ small banks attract in equilibrium, which then decreases how many reserves they hold. This effect is strong enough to make the second term in (19) positive, in contrast to the second term in (18) which was negative.

We must therefore turn to the funding share motive to fully understand why introducing a liquidity minimum can increase the equilibrium interbank rate when funding shares are endogenous. Recall from (16) the expression for the funding share motive and note:

$$\left. \frac{\partial X_k}{\partial i^h_L} \right|_{\delta_1=\omega} = \frac{\alpha \omega (1 - \pi)}{2 \left( 1 - \theta \right)} > 0 \tag{20}$$

We already know from the discussion of (19) that an increase in $i^h_L$ decreases $\xi_j$ which
then decreases how much funding \( X_j \) small banks attract in equilibrium. Total funding is normalized to one so the decrease in \( X_j \) implies an increase in the big bank funding share \( X_k \). The expression in (20) is therefore positive. The magnitude of this expression increases with \( \alpha \) because \( \xi_j \) is more responsive to changes in \( i^h_L \) at high \( \alpha \) (see again equations (14) and (15)). It is therefore easier for the big bank to increase its funding share by increasing \( i^h_L \) when \( \alpha \) is high.

There is, of course, a difference between the ability to increase funding share and the desire to do so. To complete the intuition, let us reconcile the big bank’s desire to increase its funding share when \( \alpha \) is high with the existence of convex operating costs. Return to the coefficient on \( \frac{\partial X_k}{\partial i^h_L} \) in (16). All else constant, moving from \( \alpha = 0 \) to \( \alpha = \overline{\theta} \) will trigger regulatory arbitrage by small banks (\( \xi_j > 0 \) with \( \tau_j = 1 \)). The presence of \( \xi_j > 0 \) will then erode the big bank’s funding share \( X_k \), lowering its marginal operating cost \( \phi X_k \).

We can now understand the second bullet in Proposition 5 as follows: when funding shares are endogenous, high \( \alpha \) makes it easier for the big bank to use high interbank rates to stop small banks from encroaching on its funding share. The last part of Proposition 5 establishes that sizeable increases in the interbank rate are most consistent with this sort of asymmetric competition, wherein the big bank uses its price impact on the interbank market to fend off competition from small banks and their off-balance-sheet activities.

### 3.2.2 Credit Boom and Cross-Sectional Predictions

We have now explained how the full model can deliver an increase in the equilibrium interbank rate when a liquidity minimum is introduced. Next, we establish how the introduction of this regulation changes the liquidity ratios of big and small banks, the liquidity services they provide, and the total amount of credit generated in equilibrium:

**Proposition 6** Invoke the parameter conditions from Proposition 5. The equilibrium under \( \alpha = \overline{\theta} \) has higher total credit \( (1 - R^*_j - R^*_k) \) and a smaller gap between the on-balance-sheet liquidity ratios of big and small banks at \( t = 0 \) than the equilibrium under \( \alpha = 0 \). Moreover, \( \xi^*_j > \xi^*_k \) at \( \alpha = \overline{\theta} \), with \( \xi^*_j > 0 \) if and only if funding share is endogenous. This is in contrast to \( \xi^*_j = \xi^*_k = 0 \) at \( \alpha = 0 \).

In sharp contrast to the benchmark model with only small banks, Proposition 6 shows that introducing a liquidity minimum into the full model increases total credit. There are several channels behind this result and, as we will see below, all rely on the ability of the big bank to affect the interbank market through its reserve holdings.

As was the case in the benchmark model, small banks move into off-balance-sheet DLPs after the introduction of a sufficiently strict liquidity minimum. As they push to attract
funding into these products, the small banks offer interest rates that exceed the rates on traditional deposits (storage). Effectively, the tightening of liquidity rules implies a higher regulatory burden for on-balance-sheet activities relative to off-balance-sheet activities and, when the rule is strict enough to constrain the small banks, they are willing to pay higher interest rates for off-balance-sheet DLPs relative to storage.

Under the parameter conditions in Proposition 5, which are also the parameter conditions in Proposition 6, the liquidity minimum is strict enough to constrain the small banks but not strict enough to constrain the big bank. The big bank can unilaterally affect the interbank market so it internalizes the impact of its reserve holdings on the expected price of interbank liquidity. Compared to the small banks, then, the big bank always undertakes less long-term investment per unit of funding attracted. In other words, the big bank has a higher liquidity ratio than the small banks at $t = 0$. This is why a liquidity minimum can introduce a binding constraint on small banks without also introducing one on the big bank.

The big bank thus has no incentive to offer off-balance-sheet DLPs after the liquidity minimum in Propositions 5 and 6 is introduced. If its funding share is fixed, the big bank also has no incentive to offer on-balance-sheet DLPs, hence the statement in Proposition 6 that $\xi_k^* > 0$ if and only if funding share is endogenous. However, as discussed in Section 3.2.1, tougher liquidity regulation makes the interbank rate a more powerful tool for getting the small, price-taking banks to share the burden of keeping the system liquid. All else constant, the interbank market at $t = 1$ will be less liquid, and the expected interbank rate will rise, if the big bank holds fewer reserves at $t = 0$. Proposition 6 shows that the gap between the on-balance-sheet liquidity ratios of big and small banks narrows after the liquidity minimum is introduced. The liquidity ratio of small banks, as measured on balance sheet, must rise to comply with the regulation. The liquidity ratio of the big bank, however, falls as the big bank shifts from reserves to investment to tighten the interbank market. On net, total liquidity falls and total credit rises on the heels of the big bank’s strategy.

Consider now the more general case where the big bank’s funding share is endogenous. All else constant, some funding will migrate from the big bank to the small banks, as the latter begin offering off-balance-sheet DLPs that pay higher interest rates than storage. We have already explained that the big bank internalizes the impact of its reserve holdings on the expected price of interbank liquidity and hence has a higher liquidity ratio than the small banks. Therefore, the reallocation of funding from the big bank to the small banks, as the latter poach from the former, decreases total liquidity and increases total credit. This is one of two channels for the credit boom when funding shares are endogenous.

The big bank can respond to its loss of funding by offering its own DLPs with high interest rates. Naturally, this is costly because of the high rates. Proposition 6 shows that
the big bank engages in some of this activity ($\xi_k^* > 0$), but not to the same extent as the small banks ($\xi_k^* < \xi_j^*$). Moreover, unlike the small banks who are constrained by the liquidity minimum and therefore issue all of their DLPs off-balance-sheet ($\tau_j^* = 1$), the big bank is not constrained and is therefore indifferent between any $\tau_k^* \in [0, 1]$.

The big bank can also respond to its loss of funding by using its price impact on the interbank market. We discussed this motive and its implications for the interbank rate in Section 3.2.1. Small banks have less incentive to skirt the liquidity minimum if they expect liquidity to be expensive. The big bank therefore tightens the interbank market to make small banks scale back their issuance of DLPs. The gap between the on-balance-sheet liquidity ratios of big and small banks again narrows but, unlike the case with fixed funding shares, the big bank is now using its price impact on the interbank market to fight the competitive pressures that arise as the small banks engage in regulatory arbitrage. While this strategy by the big bank curbs some of the increase in total credit from the first channel, it also boosts credit directly because the big bank is shifting from reserves to investment to tighten the interbank market. This is the second channel for the credit boom when funding shares are endogenous.

4 Quantitative Analysis

We have focused so far on qualitative predictions of the theory. We now want to study quantitative implications. We choose China as the setting for our quantitative analysis. In addition to being one of the world’s largest economies, China has experienced a near doubling of its debt-to-GDP ratio over the past decade, along with unprecedented growth in its ratio of private credit to private savings. Our model predicts that some credit booms are caused by stricter liquidity regulation so we are interested to know whether stricter liquidity regulation can account for at least part of the Chinese experience.

Liquidity rules in China involve reserve requirements and, until late 2015, a loan-to-deposit cap. The loan-to-deposit cap was introduced in 1995 to prevent banks from lending more than 75% of the value of their deposits to non-financial borrowers. The remaining 25% had to be kept liquid, with reserve requirements dictating how this liquidity was to be divided between pure reserves and other liquid assets. In practice, enforcement of the 75% loan-to-deposit cap was lax until 2008, when the China Banking Regulatory Commission (CBRC) announced a tougher stance and began increasing the frequency of its loan-to-deposit monitoring. The enforcement action began with CBRC monitoring the end-of-year loan-to-deposit ratios of all banks more carefully. CBRC then switched to monitoring end-
of-quarter ratios in late 2009, end-of-month ratios in late 2010, and average daily ratios in mid-2011. The increasing frequency of CBRC’s loan-to-deposit enforcement was also complemented by a rapid increase in the reserve requirements set by the central bank. We refer the reader to Hachem and Song (2017) for more on China’s regulatory environment and financial institutions.

Heterogeneity in interbank market power was central to our theory of unintended credit booms in Section 3. Credit did not increase after the introduction of a liquidity minimum in the benchmark model with a Walrasian interbank market. We would therefore like to establish that large commercial banks in China can impact the interbank market to a much greater extent than small commercial banks before applying the model to China. This is done in Section 4.1. We then calibrate the model to Chinese data in Section 4.2. We use the calibrated model to study how large a credit boom our model can produce (Section 4.3) and present a structural estimation to evaluate the importance of various shocks (Section 4.4).

4.1 Interbank Market Structure in China

The Chinese economy is served by both big and small banks. The small banks include twelve joint-stock commercial banks (JSCBs) which operate nationally, as well as over two hundred city banks operating in specific regions. Many rural banks have also emerged. The JSCBs are typically larger than the city and rural banks but all of these banks are still individually small when compared to China’s big banks (the Big Four). The Big Four are the four commercial banks established by the central government after the Cultural Revolution. Market-oriented reforms initiated in the 1990s made the Big Four almost entirely profit-driven and removed government involvement from day-to-day operations. However, a legacy of minimal competition between these four banks remains. China’s banking sector is therefore well approximated by a model with one big bank and many small banks.

Importantly, this big bank, as represented by the Big Four, is large enough to impact prices on the interbank market. China has both an interbank repo market and an uncollateralized money market. We will focus on the repo market since it is vastly larger. To better understand the market structure and the relative importance of the Big Four, we obtained anonymized data on each individual trade that took place in China’s interbank repo market during June 2013. The majority of transactions had either an overnight or a seven-day maturity and there was not much variation in collateral or haircuts so we can focus on interest rates and loan amounts.

The main sample for the analysis excludes June 20 and 21. There was a dramatic spike in interbank interest rates on June 20, which many observers characterized as either a market
liquidity crisis or a failure by the government to respond. In Appendix D, we conduct a
detailed analysis of China's interbank repo market around this spike and demonstrate that
the traditional narrative is incorrect: agents of the government provided generous amounts
of liquidity but interbank rates did not fall because the funds were absorbed by the Big
Four and re-intermediated at much higher interest rates. This is a concrete example of
price-setting by the Big Four and we will refer back to it in what follows.

Figure 1 graphs the interbank network for the main sample. Each node represents a
group of banks. In addition to the Big Four, the JSCBs, and other smaller players, China
has three policy banks which participate in the interbank repo market. The policy banks are
the agents of the government referred to above. They are not commercial banks. Instead,
they raise money on bond markets and take directives from the central government about
where to invest. The flow of funds between the nodes in Figure 1 is indicated by the direction
of the arrows, with thicker arrows signifying more trade.

Eigenvector centrality is one way to put numbers on the approximate importance of
each of the nodes in Figure 1. It is based on the idea that a central node is connected
to other central nodes. We only need to specify an adjacency matrix $A$ that summarizes
the connections between the nodes. The centrality of node $i$ is then the $i^{th}$ element of the
eigenvector associated with the largest eigenvalue of $A$. The first column in Table 1 reports
the results when the connection from node $i$ to node $s$ in the adjacency matrix is based on
average daily lending from $i$ to $s$. The second column reports the results when the connection
from $i$ to $s$ is based on average daily borrowing by $i$ from $s$. It is clear from these two columns
that the policy banks and the Big Four are the central lending nodes in the main sample.

The third and fourth columns of Table 1 repeat the eigenvector centrality analysis with
adjacency matrices constructed using data from June 20, as opposed to the main sample.
We know from the analysis in Appendix D that the spike in interbank rates on June 20 was
driven by the Big Four. The results in Table 1 show minimal change in the centrality of the
policy banks on June 20 relative to the main sample. In contrast, the Big Four became much
less central on the lending side and much more central on the borrowing side. Therefore, the
lending and borrowing decisions of the Big Four have a dramatic effect on the tightness of
the interbank market, even if the policy banks remain a central lending node.

We can also compare the ability of each node in Figure 1 to impact interbank conditions
by calculating the elasticity of total lending by the interbank market with respect to the
money that each of these nodes brings into the market. The procedure for computing the
elasticities is described in Appendix E and the results using the main sample are reported in
the last column of Table 1. An elasticity of 0.29 for the Big Four means that, on an average
trading day in the main sample, a 1 percent increase in the amount of money brought into
the interbank market by the Big Four leads to a 0.29 percent increase in total lending by this market. This is 3.7 times the elasticity for the JSCBs and 0.5 times the elasticity for the policy banks, which is substantial given the quantity adjustments that the Big Four can make. The scale of these adjustments was apparent on June 20. Policy banks brought 72 percent more money into the interbank market than they did on an average trading day in the main sample. Total lending by the interbank market should have then increased by 41 percent, given the elasticity of 0.57 in Table 1. However, the Big Four brought 183 percent less money into the interbank market than they did on an average trading day in the main sample and, with an elasticity of 0.29, this leads to a 53 percent decrease in total lending by the interbank market, more than enough to offset the efforts of the policy banks.

4.2 Calibration

We calibrate the model to data from 2014. Our primary dataset is the Wind Financial Terminal, supplemented by data from bank annual reports.

We take the time from \( t = 0 \) to \( t = 2 \) to be a quarter, with all interest rates quoted on an annualized basis. China’s central bank (PBOC) set benchmark interest rates for traditional deposits in China until late 2015. Recall from Section 2.1 that our model has a normalized liquidity service called storage with \( i_B = i_D = 0 \). In the calibration, we will re-normalize storage to be a traditional deposit that has \( i_B > 0 \) and \( i_D > 0 \) as set by the PBOC. Any DLPs offered in equilibrium will pay an additional return relative to these positive rates.

We set \((1 + i_D)^2 = 1.026\) to match the average benchmark interest rate of 2.6% for 3-month deposits in China. We set \((1 + i_B)^2 = 1.004\) to match the average benchmark interest rate of 0.4% for demand deposits. The central bank’s benchmark interest rate for loans with a maturity of less than six months averaged 5.6%. We set \((1 + i_A)^2 = 1.05\) since banks can offer a discount of up to 10% on the benchmark loan rate.\(^7\)

We set the liquidity regulation to \( \alpha = 0.25 \) since CBRC was strictly enforcing the 75% loan-to-deposit cap in 2014. We then calibrate the average liquidity shock, \( \bar{\theta} \equiv \pi \theta_e + (1 - \pi) \theta_h \), to get an average interbank rate of 3.6% when \( \alpha = 0.25 \). The 3.6% target is the weighted average seven-day interbank repo rate in 2014. The seven-day rate is the longest maturity for which there is significant trading volume. It is difficult to target the level of shorter-term (e.g., overnight) repo rates since there are two model periods and each period must be long enough to match reasonable data on the level of loan returns \( (i_A) \). This is merely a level effect: the correlation between the overnight and seven-day repo rates is around 0.95.

\(^7\)We are assuming the same return \( i_A \) for all banks. In practice, different banks may invest in different sectors but, adjusting for political risk, the returns are roughly comparable in China. Some anecdotal evidence can be found in Dobson and Kashyap (2006).
We normalize the low liquidity shock to $\theta_L = 0$ and set its probability to $\pi = 0.75$. The calibration of $\bar{\theta}$ then pins down the high liquidity shock $\theta_H$.

To set the external liquidity parameter ($\psi$), we look at data on monetary injections by the PBOC over a sufficiently long horizon, namely 2002 to 2014. A 1 percentage point increase in the weighted average interbank repo rate predicts that the PBOC will inject liquidity on the order of 0.5% of total savings. We therefore set the external liquidity parameter to $\psi = 0.5$. We will allow $i_L^e = i_B > 0$ in the calibration since surplus reserves can earn a small interest rate from the central bank. We then redefine $\Psi(i_L) \equiv \psi(i_L - i_B)$ to preserve $\Psi(i_L^e) = 0$.

The competition parameters ($\delta_1$ and $\delta_2$) and the DLP demand parameter ($\omega$) are calibrated to match funding outcomes in 2014. The DLPs in our model are well approximated by wealth management products (WMPs) in China. In 2005, the Chinese government expanded the range of financial services banks could provide. This led to the advent of WMPs which represent a liquidity service provided by banks at endogenous interest rates. Banks can also choose where to report their WMPs by choosing whether or not to provide an explicit principal guarantee. Any WMPs issued with an explicit principal guarantee must be reported on-balance-sheet. Absent such a guarantee, the WMP and the assets it invests in do not have to be consolidated into the bank’s balance sheet. These unconsolidated WMPs are instead invested off-balance-sheet. The lack of explicit guarantees on off-balance-sheet WMPs is only for accounting purposes though: there is a general perception that all WMPs are at least implicitly guaranteed by traditional banks (Elliott, Kroeber, and Qiao (2015)).

We target a big bank funding share of $X_k = 0.45$ when $\alpha = 0.25$ since roughly 45% of total savings in China (i.e., traditional deposits plus WMPs) were held at the Big Four in 2014. We also target DLP issuance of $W_j = 0.10$ and $W_k = 0.05$ for small and big banks respectively when $\alpha = 0.25$. WMPs represented 15% of total savings in China at the end of 2014. Small banks accounted for roughly two-thirds of WMPs issued and were also much more involved in off-balance-sheet issuance than the Big Four (Hachem and Song (2017)).

To calibrate $\delta_0$, we target an aggregate credit-to-savings ratio $(1 - R_j - R_k)$ of 75% when $\alpha = 0.25$. We get this target from the data as follows. Commercial banks in China for which Bankscope has complete data collectively added RMB 40 trillion of new loans between 2007 and 2014. As a result, the ratio of traditional lending to GDP increased by 20 percentage points. Hachem and Song (2017) estimate that the ratio of off-balance-sheet WMPs to GDP increased by 15 percentage points over the same period and show that this accounts for the majority of the growth in broader measures of shadow banking that can be constructed using data from China’s National Bureau of Statistics. Adding the growth of the traditional and shadow sectors, we get a 35 percentage point increase in the ratio of total credit to GDP.
from 2007 to 2014, which translates into a roughly 10 percentage point increase in China’s credit-to-savings ratio. The ratio of private credit to private savings was 65% in 2007. This is easy to calculate since WMP issuance was minimal prior to 2008 and all the relevant information was therefore reported on bank balance sheets (Hachem and Song (2017)). It then follows that the credit-to-savings ratio in China was roughly 75% in 2014.

Finally, we allow big and small banks to have different operating cost parameters, $\phi_k$ and $\phi_j$ respectively. China has around 200 commercial banks so, with a funding share of 45% for the Big Four in 2014, a big bank was on average 40 times as large as a small one (i.e., $\frac{0.45}{0.55} \approx 40$). In the context of our model, this size difference implies that the big bank faces $\phi_k$ below $\phi_j$. To match the observed size difference in 2014, we set $\phi_j = 40 \phi_k$ so that marginal operating costs are the same across banks.\(^8\) We then calibrate $\phi_k$ to match a loan-to-deposit ratio of 0.70 for the Big Four when $\alpha = 0.25$, which is the loan-to-deposit ratio observed in 2014 data. We will see below that the resulting operating cost parameters are high enough to deliver minimal WMP issuance in 2007, consistent with the initial equilibrium considered in the theoretical analysis.\(^9\)

4.3 Policy Experiment

We now use the calibrated model to predict what would have happened in 2007 had the only difference between 2007 and 2014 been the strength of CBRC’s loan-to-deposit enforcement. Recall that 2007 is just prior to China’s adoption of stricter liquidity rules. Comparing the predicted change in the aggregate credit-to-savings ratio between 2007 and 2014 to the actual change observed in the data, we get an estimate of the quantitative importance of stricter liquidity rules.

The results are summarized in Table 2. Recall that the calibration targeted the 2014 values of all the variables in this table. To obtain the predictions for 2007, we decreased the liquidity rule from $\alpha = 0.25$ to $\alpha = 0.14$, keeping all other parameters unchanged. We chose $\alpha = 0.14$ because the loan-to-deposit ratio of small banks in China was 86% in 2007, suggesting that CBRC was willing to tolerate a ratio of 86% in 2007 despite the 75% cap having existed since 1995. In contrast, the loan-to-deposit ratio of small banks in China was just under 75% in 2014, consistent with $\alpha = 0.25$ after CBRC’s decision to begin strict enforcement of the cap. All loan-to-deposit ratios reported here are calculated using the average balances of loans and deposits during the year, not the year-end balances, because

\(^8\) Differences in $\phi$ can be interpreted as differences in retail networks that stem from exogenous social or political forces. In robustness checks, we found that cutting the $\frac{\phi_j}{\phi_k}$ ratio to five (based on the size difference between the Big Four and only the JSCBs) and re-calibrating the model generates very similar results.

\(^9\) The calibrated parameters are $\omega = 126.84$, $\delta_0 = 0.55$, $\delta_1 = 266.36$, $\delta_2 = 0.374$, $\phi_k = 0.0335$, $\overline{\theta} = 0.1325$. 

25
the ultimate target of CBRC’s enforcement action was the average loan book of each bank. See Hachem and Song (2017) for more on the importance of using average balance data.

Table 2 shows that our model generates most of the rise in WMPs in China between 2007 and 2014. It also delivers a 7 percentage point decrease in the Big Four’s funding share, which is most of the 10 percentage point decrease observed in the data.

We also obtain a large increase in the Big Four’s loan-to-deposit ratio, from 58% in 2007 to the targeted 70% in 2014. This is slightly bigger than the increase from 62% to 70% in the data, but the general pattern is clearly consistent. Also notice the large difference between the 2007 loan-to-deposit ratios of big and small banks in China: 62% for the big versus 86% for the small. Stricter enforcement of the 75% cap starting in 2008 therefore introduced a binding constraint on China’s small banks but not on the Big Four. This is exactly the type of liquidity regulation considered in Propositions 5 and 6.

Table 2 also shows that our model generates a 25 basis point increase in the interbank interest rate between 2007 and 2014. This is half of the 50 basis point increase in the average seven-day interbank repo rate observed in the data. Since yearly averages can mask some of the most severe events, it is also useful to consider the peak interbank rates observed in daily data before and after CBRC’s enforcement action. The peak rate before the enforcement began was 10.1% while the peak rate after was 11.6%. Of this 150 basis point increase in the data, our model delivers 90 basis points.

Finally, we obtain a sizeable 3.2 percentage point increase in the aggregate credit-to-savings ratio between 2007 and 2014. The credit boom in the data is roughly 10 percentage points, as explained earlier. The calibrated version of our model therefore generates one-third of China’s overall credit boom as the outcome of stricter liquidity regulation.

4.4 Simulation Results

We now subject the calibrated model to various shocks to see how well it matches empirical moments not targeted in the calibration. We are interested in (i) the overall ability to match these moments and (ii) the relative importance of each shock in doing so.

Table 3 reports observed correlations between the interbank repo rate and the returns to WMPs issued by small and big banks. These are the key market-determined interest rates in China and their correlations were not targeted in the calibration.

The correlations in Table 3 are calculated using monthly data from January 2008 to December 2014. The time series for $i_L$ is the average interbank repo rate weighted by transaction volume. The time series for $\xi_j$ and $\xi_k$ are the average returns promised by small and big banks respectively on 3-month WMPs. Since Wind has only partial data on
the amount of funding raised by each WMP, \( \xi_j \) and \( \xi_k \) are unweighted averages. We will introduce error terms to absorb imperfections in the measurement of \( \xi_j \) and \( \xi_k \).

Table 3 shows that \( i_L \) is positively correlated with each of \( \xi_j \), \( \xi_k \), and \( \xi_j - \xi_k \). It also shows that \( \xi_j \) is positively correlated with each of \( \xi_k \) and \( \xi_j - \xi_k \) while the correlation between \( \xi_k \) and \( \xi_j - \xi_k \) is negative but not highly significant. We would like to know the extent to which our calibrated model can replicate the correlations in Table 3. We start by considering three shocks separately: shocks to liquidity regulation, shocks to loan demand, and money supply shocks. We then simulate the model allowing for all three shocks simultaneously.

### 4.4.1 Shocks to Liquidity Regulation

We allow \( \alpha \), the parameter governing liquidity regulation, to be drawn from a normal distribution:

\[
\alpha = \bar{\alpha} + \varepsilon_\alpha
\]

where \( \varepsilon_\alpha \) is normally distributed with mean 0 and variance \( \sigma_\alpha^2 \). We set \( \bar{\alpha} = 0.195 \), which is the midpoint between the \( \alpha \) that generates the loan-to-deposit ratio of small banks in 2007 (\( \alpha = 0.14 \)) and the \( \alpha \) that generates the regulated ratio (\( \alpha = 0.25 \)).

We draw values of \( \alpha \) using equation (21) and simulate the model for each value to generate the average interbank rate, \( \pi i^L + (1 - \pi) i^H_L \), the WMP returns offered by small banks, \( \xi_j + \varepsilon_{\xi_j} \), and the WMP returns offered by big banks, \( \xi_k + \varepsilon_{\xi_k} \). Here, \( \varepsilon_{\xi_j} \) and \( \varepsilon_{\xi_k} \) denote measurement errors which are drawn from two independent normal distributions with mean 0 and variances \( \sigma_{\xi_j}^2 \) and \( \sigma_{\xi_k}^2 \) respectively.\(^{10}\) We then use Simulated Method of Moments to estimate the three unknown parameters \( \sigma_\alpha \), \( \sigma_{\xi_j} \), and \( \sigma_{\xi_k} \). Appendix F describes the estimation procedure in more detail.

The first column of Table 4 reports the estimated parameter values (Panel A) and predicted correlations (Panel B). The observed correlations from Table 3 appear in the last column of Panel B. Notice that \( \sigma_\alpha \) is quantitatively large and highly significant. Also notice that the estimated model matches very well the observed correlations between \( i_L \) and each of \( \xi_j \), \( \xi_k \), and \( \xi_j - \xi_k \). Shocks to \( \alpha \) are therefore important for generating the right correlations between the interbank rate and WMP returns. At the same time though, the estimated model matches less well the magnitudes of the pairwise correlations among WMP returns. It will thus be useful to also allow for other shocks, as is done next.

\(^{10}\) All distributions are truncated to avoid abnormal values of \( \alpha \), \( \xi_j \), and \( \xi_k \).
4.4.2 Loan Demand Shocks

Shocks to loan demand are introduced by allowing $i_A$ to exceed a floor $\bar{i}_A$. Specifically:

$$i_A = \bar{i}_A + |\varepsilon_{i_A}|$$

where $\varepsilon_{i_A}$ is normally distributed with mean 0 and variance $\sigma_{i_A}^2$. The floor represents the benchmark loan rate after the highest permissible discount is applied. Loan demand shocks have their own importance in China given that fiscal stimulus was undertaken in 2009 and 2010. The stimulus package sought to combat negative spillover from the global financial crisis by providing a direct boost to aggregate demand. To the extent that stimulus increased loan demand, it did so at all banks in a largely uniform way (Bai, Hsieh, and Song (2016)). An increase in $i_A$ relative to $\bar{i}_A$ captures this.

We simulate the model for different values of $i_A$ while holding $\alpha = \bar{\alpha}$. The results are reported in the second column of Table 4. The estimated value of $\sigma_{i_A}$ in Panel A is not significantly different from zero and the overall fit in Panel B is much worse than the model with only variations in $\alpha$.

Intuitively, banks will want more funding when investment opportunities become more attractive, as is the case when higher loan demand raises $i_A$. Funding shares are given by equations (10) and (11) so, all else constant, small banks will increase $\xi_j$ and the big bank will increase $\xi_k$ following an increase in $i_A$. However, when $\delta_1 + \delta_2 > 0$ as allowed in the calibrated model, the big bank understands that an increase in $\xi_k$ will push small banks to increase $\xi_j$ even further. All else constant, higher $\xi_k$ lowers the small bank funding share $X_j$ in (10). The first order condition for $\xi_j$ in equation (15) was derived under $\delta_1 + \delta_2 = 0$ so, to understand the response of $\xi_j$ to $X_j$ when $\delta_1 + \delta_2 > 0$, we can just go back to equation (9) when $\rho > 0$. There, we easily see that a decrease in $X_j$ elicits an increase in $\xi_j$ through the competitive motive for DLP issuance. Therefore, the big bank internalizes that an increase in $\xi_k$ elicits an increase in $\xi_j$, forcing the big bank to increase $\xi_k$ by even more in order to change its funding share in (11). Each individual small bank takes the actions of other banks as given so there is no similar ratchet effect when the small banks choose $\xi_j$. This makes the response of $\xi_k$ to $i_A$ more dramatic than the response of $\xi_j$ to $i_A$. As a result, the correlation between $i_L$ and $\xi_k$ is stronger than the correlation between $i_L$ and $\xi_j$ in the model with only shocks to $i_A$. The correlation between $i_L$ and $\xi_j - \xi_k$ in the second column of Table 4 is then negative, contradicting the positive correlation in the data.

Shocks to liquidity regulation generated a positive correlation between $i_L$ and $\xi_j - \xi_k$ in Section 4.4.1. The response of $\xi_k$ to $\alpha$ was less dramatic than the response of $\xi_j$ to $\alpha$. The
difference relative to $i_A$ arises because the small banks, as interbank price-takers, want lower liquidity ratios than the big bank and are therefore endogenously more constrained than the big bank following an increase in $\alpha$. Accordingly, they respond more than the big bank, even though they do not internalize any ratchet effects when choosing $\xi_j$.

### 4.4.3 Money Supply Shocks

Money supply shocks are introduced by allowing for exogenous variation in external liquidity:

$$
\Psi(i_L) = \psi(i_L - i_B) + \varepsilon
$$

where $\varepsilon$ is normally distributed with mean 0 and variance $\sigma^2_{\psi}$. We simulate the model for different draws of $\varepsilon$ while holding $\alpha = \bar{\alpha}$ and $i_A = \bar{i}_A$. Note that $i_L$ is endogenously determined for each draw.

The results are reported in the third column of Table 4. As was the case with only loan demand shocks, the estimated value of $\sigma_{\psi}$ in Panel A is not significantly different from zero and the overall fit in Panel B is much worse than the model with only variations in $\alpha$.

All else constant, a decrease in external liquidity increases $i_L$ but reduces both $\xi_j$ and $\xi_k$. Intuitively, the increase in $i_L$ reflects the fact that the central bank is tightening the interbank market by removing liquidity, the decrease in $\xi_j$ reflects the fact that small banks have less of a regulatory arbitrage motive when the interbank rate is high, and the decrease in $\xi_k$ reflects the fact that the big bank is competing against less aggressive products by the small banks. Money supply shocks thus generate negative correlations between the interbank rate and WMP returns, contradicting the positive correlations in the data.

Shocks to liquidity regulation generated these positive correlations in Section 4.4.1. All else constant, an increase in $\alpha$ increases the regulatory arbitrage motive of small banks so $\xi_j$ (where $\tau_j = 1$) goes up. The big bank responds to the resulting loss in its funding share by increasing $\xi_k$ and $i_L$. The increase in $i_L$ tempers the increase in $\xi_j$, but $\xi_j$ still increases on net because of the increase in $\alpha$.

### 4.4.4 Multiple, Simultaneous Shocks

Now consider a version of the quantitative model which has shocks to liquidity regulation, shocks to loan demand, and money supply shocks, all at the same time. The shocks ($\varepsilon_{\alpha}$, $\varepsilon_{i_A}$, and $\varepsilon_{\psi}$) and measurement errors ($\varepsilon_{\xi_j}$ and $\varepsilon_{\xi_k}$) are drawn from the relevant distributions, all of which are assumed to be independent of each other. We are able to separately identify $\sigma_{\alpha}$, $\sigma_{i_A}$, and $\sigma_{\psi}$ since shocks to liquidity regulation, loan demand, and external liquidity imply
different correlations between $i_L$, $\xi_j$, and $\xi_k$, as discussed above.

The results are reported in the fourth column of Table 4. The quantitative model with three shocks matches the six empirical correlations almost perfectly. Moreover, $\sigma_\alpha$, $\sigma_{i_A}$, and $\sigma_\Psi$ are all statistically significant, indicating that all three shocks are relevant.\[^{11}\] However, as we saw when we considered each shock separately, shocks to liquidity regulation play a much more important role than shocks to either loan demand or external liquidity when it comes to getting the right signs for the correlations.

To this point, we also find that variations in $\alpha$ explain 46% of the variance of $i_L$ in the data while variations in $i_A$ and the intercept of $\Psi(\cdot)$ explain only 21% and 33% respectively. This complements our finding in Section 4.3 that changes in liquidity regulation can explain about half of the increase in the interbank repo rate between 2007 and 2014, along with explaining one-third of the increase in the aggregate credit-to-savings ratio.

5 Conclusion

This paper has developed a theoretical framework to study the endogenous response of the banking sector to liquidity regulation and the implications for the aggregate economy. We showed that stricter liquidity standards can generate unintended credit booms. The mechanism we uncovered is as follows. Liquidity minimums are endogenously more binding on a small bank than on a large one. In response, small banks find it optimal to offer a new savings instrument and manage the funds raised by this instrument in an off-balance-sheet vehicle that is not subject to liquidity regulation. As small banks push to attract savings into off-balance-sheet instruments, they raise the interest rates on these instruments above the rates on traditional deposits and poach funding from the big bank. The big bank responds to this competitive threat both by issuing its own high-return savings instruments and by tightening the interbank market for emergency liquidity against small banks. The new equilibrium is characterized by more credit as savings are reallocated across banks and lending is reallocated across markets.

Applying our framework to China, we found that a regulatory push to increase bank liquidity and cap loan-to-deposit ratios in the late 2000s accounts for one-third of China’s unprecedented credit boom between 2007 and 2014. A quantitative extension that allowed for other, non-regulatory shocks also identified variation in liquidity rules as the dominant force behind observed co-movements in market-determined interest rates.

\[^{11}\]This can also be seen from estimated measurement errors: $\sigma_{\xi_j}$ becomes statistically insignificant and the magnitude of $\sigma_{\xi_k}$ is less than a quarter of the previous estimates.

Appendix A – Proofs

Proof of Proposition 1

By contradiction. Suppose $\mu_j > 0$. If $j > 0$, then $R_j = 0$ so (4) implies $i_L = \frac{\bar{X}}{\psi}$. Substituting into (9) then implies $\xi_j > 0$ if and only if $\phi < \frac{(1 + i_A)^2 - 1}{X} - \frac{\bar{\psi}}{\psi} \equiv \bar{\phi}_1$ (where we have used $X = X$ in symmetric equilibrium). If instead $\mu_j = 0$, then (7) implies $i_L = (1 + i_A)^2 - 1$. Substituting into (9) then implies $\xi_j > 0$ if and only if $\phi < \frac{\bar{\psi}}{X} [(1 + i_A)^2 - 1] \equiv \bar{\phi}_2$. The condition for $\bar{\phi}_1 > \bar{\phi}_2$ is also the condition for $\mu_j > 0$. Defining $\bar{\phi} \equiv \max \{\bar{\phi}_1, \bar{\phi}_2\}$ completes the proof.

Proof of Proposition 2

With $\rho = 0$, the equilibrium is characterized by (4), (7), and:

$$\xi_j = \frac{\alpha \mu_j}{2(1 - \bar{\theta})}$$

$$\mu_j \left[R_j - \alpha (X - \omega \xi_j)\right] = 0$$

with complementary slackness

There is an implicit refinement here since we are writing $\xi_j = \frac{\alpha \mu_j}{2(1 - \bar{\theta})}$ instead of $\xi_j = \frac{\alpha \mu_j \tau_j}{2(1 - \bar{\theta})}$. Both produce $\xi_j = 0$ if $\alpha \mu_j = 0$ so the refinement only applies if $\alpha \mu_j > 0$. Return to equations (8) and (9) with $\rho = 0$ and $\alpha \mu_j > 0$. If $\xi_j > 0$, then $\eta^1_j > 0$. This implies $\tau_j = 1$ which confirms $\xi_j > 0$. If $\xi_j = 0$, then $\eta^1_j = \eta^0_j$. This implies $\tau_j \in [0, 1]$. However, any $\tau_j \in (0, 1]$ would return $\xi_j > 0$, violating $\xi_j = 0$. We thus eliminate $\xi_j = 0$ by refinement.

Instead, $\alpha \mu_j > 0$ is associated with $\xi_j > 0$ and thus $\tau_j = 1$. For this reason, we write $\xi_j = \frac{\alpha \mu_j}{2(1 - \bar{\theta})}$. We can now proceed with the rest of the proof. There are two cases:

1. If $\mu_j = 0$, then $\xi_j = 0$ and $1 + i_L = (1 + i_A)^2$. Equation (4) then pins down $R_j$. To ensure that $R_j \geq \alpha (X - \omega \xi_j)$ is satisfied, we need $\alpha \leq \bar{\theta} - \frac{\psi [(1 + i_A)^2 - 1]}{X} \equiv \bar{\alpha}_1$. We have now established $\xi_j = 0$ if $\alpha \leq \bar{\alpha}_1$.

2. If $\mu_j > 0$, then complementary slackness implies $R_j = \alpha (X - \omega \xi_j)$. Combining with the other equilibrium conditions, we find that $\mu_j > 0$ delivers:

$$i_L = \frac{\alpha^2 \omega [(1 + i_A)^2 - 1] - 2(1 - \bar{\theta})(\alpha - \bar{\theta})X}{\alpha^2 \omega + 2 \psi (1 - \bar{\theta})}$$

(22)

Verifying $\mu_j > 0$ is equivalent to verifying $1 + i_L < (1 + i_A)^2$. This reduces to $\alpha > \bar{\alpha}_1$.

If $\bar{\alpha}_1 \geq 0$, then we have established $\xi_j > 0$ with $\tau_j = 1$ for any $\alpha > \bar{\alpha}_1$.
Defining $\tilde{\alpha} = \max \{\alpha_1, 0\}$ completes the proof. ■

**Proof of Proposition 3**

Consider $\alpha = 0$. If $\mu_j = 0$, then (7) implies $i_L = (1 + i_A)^2 - 1$ which is the highest feasible interbank rate. If instead $\mu_j > 0$, then the liquidity rule binds. In particular, $R_j = \alpha (X_j - \tau_j W_j)$ which is just $R_j = 0$ when $\alpha = 0$. We can then conclude $i_L = \frac{\tilde{\alpha} X}{\psi}$ from equation (4). Note that $\mu_j > 0$ is verified if and only if $\frac{\tilde{\alpha} X}{\psi} < (1 + i_A)^2 - 1$.

Based on the results so far, we can see that the interbank rate at $\alpha = 0$ is independent of $\rho$. Let $i_{L0}$ denote the interbank rate at $\alpha = 0$. Let $i_{L1}(\rho)$ denote the interbank rate at some $\alpha > 0$, allowing for any $\rho \geq 0$. From (4), we know $i_{L1}(\rho) = \frac{\tilde{\alpha} X}{\psi} - \frac{R_{j1}(\rho)}{\psi}$, where $R_{j1}(\rho)$ is reserve holdings at the $\alpha > 0$ being considered. The rest of the proof proceeds by contradiction. In particular, suppose $i_{L1}(\rho) > i_{L0}$. Then $\alpha = 0$ must be associated with $\mu_j > 0$, otherwise $i_{L0}$ would be the highest feasible interbank rate and the supposition would be incorrect. We can thus write $i_{L0} = \frac{\tilde{\alpha} X}{\psi}$ and $i_{L1}(\rho) = i_{L0} - \frac{R_{j1}(\rho)}{\psi}$. The only way to get $i_{L1}(\rho) > i_{L0}$ is then $R_{j1}(\rho) < 0$ which is impossible. We can now conclude $i_{L0} > i_{L1}(\rho)$.

The result on total credit follows immediately. Total credit equals $X - R_j$, with $R_j$ as per (4). Therefore, under $\psi > 0$, combinations of $\alpha$ and $\rho$ that deliver higher $i_L$ in equilibrium also deliver higher total credit. If instead $\psi = 0$, then total credit is constant and independent of either $\alpha$ or $\rho$. Either way then, total credit does not increase. ■

**Proof of Proposition 4**

Start with general $\alpha$. The derivatives of the big bank’s objective function are:

\[
\frac{\partial Y_k}{\partial \xi_k} \propto -\frac{2\omega (1 - \theta)}{1 - \pi} \xi_k - \left[ \frac{(1 + i_A)^2 - 1}{1 - \pi} - i_L^h \right] \frac{\partial R_k}{\partial \xi_k} + \left[ \frac{(1 + i_A)^2 - 1 - \phi X_k}{1 - \pi} - \theta_h^L \right] \frac{\partial X_k}{\partial \xi_k}
\]

\[
\frac{\partial Y_k}{\partial i_L^h} \propto R_k - \theta_h X_k - \left[ \frac{(1 + i_A)^2 - 1}{1 - \pi} - i_L^h \right] \frac{\partial R_k}{\partial i_L^h} + \left[ \frac{(1 + i_A)^2 - 1 - \phi X_k}{1 - \pi} - \theta_h^L \right] \frac{\partial X_k}{\partial i_L^h}
\]

It will be convenient to reduce these derivatives to a core set of variables ($\xi_j$, $\xi_k$, and $i_L^h$). If $\mu_j > 0$, then the complementary slackness in equation (13) implies:

\[
R_j = \alpha (X_j - \omega \xi_j)
\]  

(23)

With $\delta_1 + \delta_2 = 0$ and $\overline{\xi}_j = \xi_j$, equations (10) and (11) are:

37
\[ X_j = 1 - \delta_0 + \delta_1 (\xi_j - \xi_k) \]  
\[ X_k = \delta_0 + \delta_1 (\xi_k - \xi_j) \]  
(24)
(25)

Substitute (23) to (25) into equation (12) to write:

\[ R_k = \delta_0 \theta_h + (1 - \delta_0) (\bar{\theta} - \alpha) + \delta_1 (\theta_h - \bar{\theta} + \alpha) (\xi_k - \xi_j) + \alpha \omega \xi_j - \psi i^h_L \]  
(26)

Finally, combine equations (14) and (15) to get:

\[ \xi_j = \frac{\alpha (1 - \pi)}{2 (1 - \bar{\theta})} \left[ \frac{(1 + i_A)^2 - 1}{1 - \pi} - i^h_L \right] \]  
(27)

We can now write \( \frac{\partial \Upsilon_k}{\partial \xi_k} = 0 \) as:

\[ \xi_k = \frac{\delta_1 (1 - \theta_h + \bar{\theta} - \alpha) [(1 + i_A)^2 - 1] - \phi \delta_0 + \phi \delta_1 \xi_j - (\bar{\theta} - \alpha) (1 - \pi) i^h_L}{2 \omega (1 - \bar{\theta}) + \phi \delta_1^2} \]  
(28)

We can also write \( \frac{\partial \Upsilon_k}{\partial i^h_L} = 0 \) as:

\[ i^h_L = \frac{2 \psi + \frac{\alpha (1 - \pi)}{2 (1 - \bar{\theta})} \left[ \alpha \omega + \delta_1 (\bar{\theta} - \alpha) \right] - (1 - \delta_0) (\bar{\theta} - \alpha) - \frac{\alpha \delta_0 \delta_1}{2 (1 - \bar{\theta})} + \alpha \omega \xi_j - \delta_1 \left[ (\bar{\theta} - \alpha) + \frac{\alpha \delta_1}{2 (1 - \bar{\theta})} \right] (\xi_k - \xi_j)}{2 \psi + \frac{\alpha (1 - \pi)}{2 (1 - \bar{\theta})} \left[ \alpha \omega + \delta_1 (\bar{\theta} - \alpha) \right]} \]  
(29)

Note that the second order conditions are:

\[ \frac{\partial^2 \Upsilon_k}{\partial (\xi_k)^2} = -\phi \left( \frac{\partial X_k}{\partial \xi_k} \right)^2 - 2 (1 - \bar{\theta}) \omega < 0 \]

\[ \frac{\partial^2 \Upsilon_k}{\partial (i^h_L)^2} = - \left[ 2 (1 - \pi) \theta_h + \phi \frac{\partial X_k}{\partial i^h_L} \right] \frac{\partial X_k}{\partial i^h_L} + 2 (1 - \pi) \frac{\partial R_k}{\partial i^h_L} \]

For \( \frac{\partial^2 \Upsilon_k}{\partial (i^h_L)^2} < 0 \), we need:

\[ \frac{\partial R_k}{\partial i^h_L} < \left[ \theta_h + \frac{\phi}{2 (1 - \pi)} \frac{\partial X_k}{\partial i^h_L} \right] \frac{\partial X_k}{\partial i^h_L} \]

or, equivalently:
\[ \vartheta \delta_1 + \alpha (\omega - \delta_1) + \frac{2\psi (1 - \vartheta)}{\alpha (1 - \pi)} > - \frac{\alpha \phi \delta_1^2}{4 (1 - \vartheta)} \]

This is certainly true for \( \delta_1 = 0 \). It is also true for \( \delta_1 = \omega \) which is the other case we will take up in Proposition 5.

**Remark 1** If the big bank’s inequality constraints are non-binding, the equilibrium is a triple \( \{ \xi_j, \xi_k, i^h_L \} \) that solves (27), (28), and (29). It must then be veriﬁed that the solution to these equations satisﬁes \( \xi_k \geq 0 \) along with \( R_k > \alpha X_k \) and \( \mu_j > 0 \). The big bank is technically indifferent between any \( \tau_k \in [0, 1] \) if its liquidity rule is slack so, for analytical convenience, consider \( \tau_k = 0 \). We also need to check \( W_j \leq X_j \) and \( W_k \leq X_k \) so that deposits are non-negative. Finally, we want to check that \( i^h_L = 0 \) does not result in a liquidity shortage when the big bank realizes \( \vartheta \) at \( t = 1 \).

The rest of this proof focuses on \( \alpha = 0 \). Notice \( \xi_j = 0 \) from (27). As discussed in the main text, we also want \( \xi_k = 0 \). Subbing \( \alpha = 0 \) and \( \xi_j = \xi_k = 0 \) into (28) and (29) yields:

\[
\delta_1 \left[ \frac{(1 - \theta_h + \bar{\theta}) [(1 + i_A)^2 - 1] - \vartheta \delta_0}{\bar{\theta} (1 - \pi)} - i^h_L \right] = 0
\]

\[
i^h_L = \frac{(1 + i_A)^2 - 1}{2 (1 - \pi)} + \frac{\bar{\theta} (1 - \delta_0)}{2 \psi}
\]  

To verify \( \xi_k = 0 \), we must verify that (30) holds when \( i^h_L \) is given by (31). This requires either \( \delta_1 = 0 \) or:

\[
\phi = \frac{1}{\delta_0} \left[ 1 - \theta_h + \bar{\theta} \right] [(1 + i_A)^2 - 1] - \frac{\bar{\theta}^2 (1 - \pi) (1 - \delta_0)}{2 \psi \delta_0} \equiv \phi^* \]

In other words, we can use either \( \delta_1 = 0 \) or the combination of \( \delta_1 > 0 \) and \( \phi = \phi^* \) to get \( \xi_k \) exactly zero at \( \alpha = 0 \). Note that \( W_j \leq X_j \) and \( W_k \leq X_k \) are trivially true with \( \xi_j = \xi_k = 0 \). We now need to check \( R_k > \alpha X_k \) and \( \mu_j > 0 \). Using (14) and (31), rewrite \( \mu_j > 0 \) as:

\[
\frac{(1 + i_A)^2 - 1}{1 - \pi} > \frac{\bar{\theta} (1 - \delta_0)}{\psi}
\]  

Note that condition (33) is also suﬃcient for \( \phi^* > 0 \). With \( \mu_j > 0 \) veriﬁed, we can substitute \( \alpha = 0 \) into equation (23) to get \( R_j = 0 \). The next step is to check \( R_k > \alpha X_k \) which is simply \( R_k > 0 \) at \( \alpha = 0 \). Recall that \( R_k \) is given by equation (26). Use \( \alpha = 0 \) and \( \xi_j = \xi_k = 0 \) along with \( i^h_L \) as per (31) to rewrite equation (26) as:
\[ R_k = \theta_k \delta_0 + \frac{\bar{\theta} (1 - \delta_0)}{2} - \psi \frac{(1 + i_A)^2 - 1}{2 (1 - \pi)} \]  

(34)

The condition for \( R_k > 0 \) is therefore:

\[ \frac{(1 + i_A)^2 - 1}{1 - \pi} < \frac{\bar{\theta} (1 - \delta_0)}{\psi} + \frac{2 \delta_0 \theta_h}{\psi} \]  

(35)

The last step is to check that there is sufficient liquidity at \( t = 1 \) when the big bank's liquidity shock is low. The demand for liquidity in this case will be \( \overline{\theta} X_j + \theta_\ell X_k \). The supply of liquidity will be \( R_j + R_k \) since we have fixed \( i_L^\ell = 0 \). We already know \( \xi_j = \xi_k = 0 \) at \( \alpha = 0 \). Therefore, \( X_j = 1 - \delta_0 \) and \( X_k = \delta_0 \). We also know \( R_j = 0 \) and \( R_k \) as per (34). Therefore, \( R_j + R_k \geq \overline{\theta} X_j + \theta_\ell X_k \) can be rewritten as:

\[ \frac{(1 + i_A)^2 - 1}{1 - \pi} \leq \frac{2 \delta_0 (\theta_h - \theta_\ell)}{\psi} - \frac{\bar{\theta} (1 - \delta_0)}{\psi} \]  

(36)

Condition (36) is stricter than (35) so we can drop (35). We now just need to make sure that conditions (33) and (36) are not mutually exclusive. Using \( \bar{\theta} \equiv \pi \theta_\ell + (1 - \pi) \theta_h \), this requires:

\[ \theta_\ell < \left[ 1 - \frac{1 - \delta_0}{\delta_0 + \pi (1 - \delta_0)} \right] \theta_h \]  

(37)

The right-hand side of (37) is positive if and only if:

\[ \pi > \frac{1 - 2 \delta_0}{1 - \delta_0} \]  

(38)

Therefore, with \( \theta_\ell \) sufficiently low and \( \pi \) sufficiently high, conditions (33) and (36) define a non-empty interval for \( i_A \), completing the proof. □

**Proof of Proposition 5**

**Fixed Funding Share** Impose \( \alpha = \overline{\theta} \) and \( \delta_1 = 0 \) on equations (27), (28), and (29). The resulting system can be written as \( \xi_k = 0 \) and:

\[ \xi_j = \frac{[(1 + i_A)^2 - 1] \bar{\theta} \psi}{2 \psi (1 - \bar{\theta}) + \omega \bar{\theta}^2 (1 - \pi)} \]  

(39)

\[ i_L^h = \frac{(1 + i_A)^2 - 1}{2 \psi (1 - \bar{\theta}) + \omega \bar{\theta}^2 (1 - \pi)} \left[ \psi \frac{1 - \bar{\theta}}{1 - \pi} + \omega \bar{\theta}^2 \right] \]  

(40)
With \( \delta_1 = 0 \) in equations (24) and (25), the funding shares are \( X_j = 1 - \delta_0 \) and \( X_k = \delta_0 \). Impose along with \( \alpha = \overline{\theta} \) on equations (23) and (26) to get:

\[
R_k = \theta_h \delta_0 + \omega \overline{\theta} \xi_j - \psi i_L^h
\]

\[
R_j + R_k = \overline{\theta} (1 - \delta_0) + \theta_h \delta_0 - \psi i_L^h
\]

where \( \xi_j \) and \( i_L^h \) are given by (39) and (40) respectively. We now need to go through all the steps in Remark 1 to establish the equilibrium for \( \alpha = \overline{\theta} \) and fixed funding shares. Using equations (14) and (40), we can see that \( \mu_j > 0 \) is trivially true. Using \( \mu_k = 0 \) and \( X_k = \delta_0 \), we can also see that \( W_k \leq X_k \) is trivially true. The condition for \( W_j \leq X_j \) is:

\[
\frac{(1 + i_A)^2 - 1}{1 - \pi} \leq \frac{2(1 - \delta_0)}{\psi} \left[ \overline{\theta} + \frac{2 \psi (1 - \overline{\theta})}{\omega \overline{\theta} (1 - \pi)} \right]
\]

(41)

The conditions for \( R_k > \overline{\theta} X_k \) and \( R_j + R_k \geq \overline{\theta} X_j + \theta \epsilon X_k \) are respectively:

\[
\frac{(1 + i_A)^2 - 1}{1 - \pi} < \frac{2 \pi (\theta_h - \theta \epsilon) \delta_0}{\psi}
\]

(42)

\[
\frac{(1 + i_A)^2 - 1}{1 - \pi} \leq \frac{2 \psi (1 - \overline{\theta}) + \omega \overline{\theta}^2 (1 - \pi) (\theta_h - \theta \epsilon) \delta_0}{\psi (1 - \overline{\theta}) + \omega \overline{\theta}^2 (1 - \pi)}
\]

(43)

Now, for the interbank rate to increase when moving from \( \alpha = 0 \) to \( \alpha = \overline{\theta} \), we need (40) to exceed (31). Equivalently, we need:

\[
\frac{(1 + i_A)^2 - 1}{1 - \pi} > \frac{\overline{\theta} (1 - \delta_0)}{\psi} \left[ 1 + \frac{2 \psi (1 - \overline{\theta})}{\omega \overline{\theta}^2 (1 - \pi)} \right]
\]

(44)

We must now collect all the conditions involved in the \( \alpha = 0 \) and \( \alpha = \overline{\theta} \) equilibria and make sure they are mutually consistent. There are two lowerbounds on \( i_A \), namely (33) and (44). Condition (44) is clearly stricter so it is the relevant lowerbound. There are also four upperbounds on \( i_A \), namely (36), (41), (42), and (43). For the lowerbound in (44) to not violate any of these upperbounds, we need:

\[
\frac{\psi (1 - \overline{\theta})}{\omega (1 - \pi)} < \overline{\theta}^2 \min \left\{ \frac{\pi (\theta_h - \theta \epsilon) \delta_0}{\overline{\theta} (1 - \delta_0)} - \frac{1}{2} \left( \frac{\theta_h - \theta \epsilon}{\overline{\theta} (1 - \delta_0)} - 1 \right) \right\}
\]

This inequality is only possible if the right-hand side is positive. Therefore, we need:
\[ \theta_{\ell} < \left[ 1 - \frac{1 - \delta_0}{\min \{\delta_0 + \pi (1 - \delta_0), \pi (1 + \delta_0)\}} \right] \theta_h \quad (45) \]

Once again, the right-hand side must be positive so we need:

\[ \pi > \max \left\{ \frac{1 - 2\delta_0}{1 - \delta_0}, \frac{1 - \delta_0}{1 + \delta_0} \right\} \quad (46) \]

Notice that (45) and (46) are just refinements of (37) and (38). We can now conclude that the model with fixed funding shares generates the desired results under the following conditions: \( \pi \) sufficiently high, \( \theta_{\ell} \) and \( \frac{\psi}{\omega} \) sufficiently low, and \( i_A \) within an intermediate range. □

**Endogenous Funding Share**  Return to equations (27), (28), and (29). Impose \( \alpha = \bar{\theta} \) and \( \delta_1 = \omega \) with \( \phi = \phi^* \) as per (32). Combine to get:

\[ i^h_L = \frac{(1 + i_A)^2 - 1}{1 - \pi} - \frac{2\phi}{1 - \pi} + \frac{\omega \bar{\theta}^2}{2(1 - \bar{\theta} + \phi^* \omega)} \left[ \frac{(1 + i_A)^2 - 1}{2(1 - \pi)} - \frac{\omega \bar{\theta}^2(1 - \delta_0)}{2\psi [2(1 - \bar{\theta}) + \phi^* \omega]} \right] \]

\[ \xi_k = \frac{\bar{\theta}(1 - \pi)}{2} \left[ \frac{\bar{\theta}(1 - \delta_0)}{\psi} + \left( \frac{\phi^* \omega}{1 - \bar{\theta}} - 1 \right) \frac{(1 + i_A)^2 - 1}{1 - \pi} - \frac{\phi^* \omega \cdot h}{1 - \bar{\theta} i^h_L} \right] \]

We now need to go through the steps in Remark 1 to establish the equilibrium for \( \alpha = \bar{\theta} \) and endogenous funding shares. The expressions here are more complicated so we proceed by finding one value of \( i_A \) that satisfies all the steps in Remark 1. A continuity argument will then allow us to conclude that all the steps are satisfied for a non-empty range of \( i_A \).

Consider \( i_A \) such that:

\[ \frac{(1 + i_A)^2 - 1}{1 - \pi} = \frac{\bar{\theta}}{\psi} \quad (49) \]

Substituting into (32) then pins down \( \phi^* \) as:

\[ \phi^* = \frac{\bar{\theta}}{\psi} \frac{(1 - \pi)}{\delta_0} + \frac{\bar{\theta}}{2} \quad (50) \]

From the proof of Proposition 4, we already have (33) and (36) as restrictions on \( i_A \). We also have (37) as an upperbound on \( \theta_{\ell} \) and (38) as a lowerbound on \( \pi \). It is easy to see that \( i_A \) as defined in (49) satisfies (33). For (49) to also satisfy (36), we need:
\[ 0_\ell < \left[ 1 - \frac{2 - \delta_0}{2\delta_0 + \pi (2 - \delta_0)} \right] 0_h \] (51)

\[ \pi > \frac{2 - 3\delta_0}{2 - \delta_0} \] (52)

Conditions (51) and (52) are stricter than (37) and (38). We can thus drop (37) and (38).

The first step is to verify \( \mu_j > 0 \). Use (14) and (47) to write \( \mu_j > 0 \) as:

\[ \frac{(1 + i_A)^2 - 1}{1 - \pi} \left[ 1 - \frac{\phi^*}{2(1 - \bar{\theta}) + \bar{\phi}^* \omega} \right] > \frac{\bar{\theta} (1 - \delta_0)}{\psi} \]

This is true by condition (33).

The second step is to verify \( \xi_k > 0 \). Substituting (47) into (48), we see that we need:

\[ \frac{(1 + i_A)^2 - 1}{1 - \pi} \left[ 1 - \frac{\phi^*}{2(1 - \bar{\theta}) + \bar{\phi}^* \omega} \right] < \frac{\bar{\theta} (1 - \delta_0)}{\psi} \] (53)

Using \( i_A \) as per (49) and \( \phi^* \) as per (50):

\[ \frac{\psi (1 - \bar{\theta})}{\omega (1 - \pi)} < \frac{\bar{\theta} (1 - \delta_0)}{2\delta_0^2} \left[ 1 - \theta_h - \bar{\theta} \delta_0 \left( \frac{\delta_0 - \frac{1}{2}}{2} \right) \right] \] (54)

If \( Z_1 > 0 \), then (54) requires \( \frac{\psi}{\omega} \) sufficiently low. Note that \( Z_1 > 0 \) can be made true for any \( \delta_0 \in (0, 1) \) by assuming \( \bar{\theta} < 2 (1 - \theta_h) \) or, equivalently, \( \theta_\ell < \frac{2 - (3 - \pi) \theta_h}{\pi} \). This is another positive ceiling on \( \theta_\ell \) provided \( \pi > 3 - \frac{2}{\bar{\theta}_h} \).

The third step is to verify \( R_k > \bar{\theta} X_k \). Use \( \alpha = \bar{\theta} \) and \( \delta_1 = \omega \) to rewrite (25) and (26) as:

\[ X_k = \delta_0 + \omega \left( \xi_k - \xi_j \right) \] (55)

\[ R_k = \delta_0 \theta_h + \omega \theta_h \xi_k - \omega \left( \theta_h - \bar{\theta} \right) \xi_j - \psi \bar{i}_L^h \] (56)

Therefore, \( R_k > \bar{\theta} X_k \) requires:

\[ \bar{i}_L^h < \frac{\delta_0 (\theta_h - \bar{\theta})}{\psi} + \frac{\omega (\theta_h - \bar{\theta})}{\psi} (\xi_k - \xi_j) + \frac{\omega \bar{\theta}}{\psi} \xi_j \]
Use (48) to replace \( \xi_k \) and (27) with \( \alpha = \bar{\theta} \) to replace \( \xi_j \):

\[
\begin{align*}
\left[ 1 + \frac{\omega \bar{\theta} (1 - \pi)}{2 \psi (1 - \bar{\theta})} \left[ \bar{\theta} - 2 \left( 1 - \bar{\theta} \right) \left( \theta_h - \bar{\theta} \right) \right] \right] i_L^h \\
\leq \frac{\theta_h - \bar{\theta}}{\psi} \left[ \delta_0 + \frac{\omega \bar{\theta}^2 (1 - \pi) (1 - \delta_0)}{2 \psi \left[ 2 \left( 1 - \bar{\theta} \right) + \phi^* \omega \right]} \right] - \frac{\omega \bar{\theta} \left[ (1 + i_A)^2 - 1 \right]}{2 \psi} \left[ \frac{3 \left( \theta_h - \bar{\theta} \right)}{2 \left( 1 - \bar{\theta} \right) + \phi^* \omega - \bar{\theta}} \right] - \frac{1}{1 - \bar{\theta}} \left[ 2 \left( 1 - \bar{\theta} \right) + \phi^* \omega - \bar{\theta} \right]
\end{align*}
\]

Now use (47) to replace \( i_L^h \) and rearrange to isolate \( i_A \):

\[
\begin{align*}
\left[ \frac{(1 + i_A)^2 - 1}{1 - \pi} \right] \left[ 2 \theta_h - \frac{3 \bar{\theta}}{2} + \frac{2 \psi (1 - \bar{\theta})}{\omega \bar{\theta} (1 - \pi)} \frac{\omega \bar{\theta}^2 (1 - \pi)}{4 \psi (1 - \bar{\theta})} \left( 3 \theta_h - 4 \bar{\theta} \right) + \frac{\phi^*}{\bar{\theta}} \left[ \frac{\omega \bar{\theta}^2}{1 - \bar{\theta}} + \frac{\psi}{1 - \pi} \right] \right] \\
< \left[ \frac{2 \delta_0 (1 - \bar{\theta})}{1 - \pi} \frac{2 \left( 1 - \bar{\theta} \right) + \phi^* \omega - \bar{\theta}}{\omega \bar{\theta} (1 - \pi)} + \frac{\bar{\theta}^2 (1 - \delta_0)}{2 \psi} \right] \left[ 1 + \frac{\bar{\theta}^2 \omega (1 - \pi)}{2 \psi (1 - \bar{\theta})} \right] \\
+ \left( \theta_h - \bar{\theta} \right) \frac{\bar{\theta}}{\psi} \left[ \frac{\omega \phi^* \delta_0}{2 (1 - \bar{\theta})} + (1 - \delta_0) \left[ 1 + \frac{3 \bar{\theta}^2 \omega (1 - \pi)}{4 \psi (1 - \bar{\theta})} \right] \right]
\end{align*}
\]

We can simplify a bit further by using (32) to replace all instances of \( \phi^* \delta_0 \) then grouping like terms:

\[
\begin{align*}
\left[ \frac{(1 + i_A)^2 - 1}{1 - \pi} \right] \left[ \frac{\theta_h - \bar{\theta}}{2} + \frac{2 \psi (1 - \bar{\theta})}{\omega \bar{\theta} (1 - \pi)} - \frac{\omega \bar{\theta}^3 (1 - \pi)}{4 \psi (1 - \bar{\theta})} + \frac{\phi^*}{\bar{\theta}} \left[ \frac{\omega \bar{\theta}^2}{1 - \bar{\theta}} + \frac{\psi}{1 - \pi} \right] \right] \\
< \left[ \frac{4 \delta_0 (1 - \bar{\theta})}{\omega \bar{\theta} (1 - \pi)} \left( \theta_h - \bar{\theta} \right) \left( 1 - \theta_h \right) \left[ \frac{2 \psi}{\omega (1 - \bar{\theta})} \right] \right] \left[ 1 + \frac{\bar{\theta}^2 \omega (1 - \pi)}{2 \psi (1 - \bar{\theta})} \right] \\
- \left( \theta_h - \bar{\theta} \right) \left( 1 - \theta_h \right) \left[ \frac{2 \psi}{\omega (1 - \bar{\theta})} \right] \left[ 1 + \frac{\bar{\theta}^2 \omega (1 - \pi)}{2 \psi (1 - \bar{\theta})} \right]
\end{align*}
\]

Substitute \( i_A \) as per (49) and \( \phi^* \) as per (50) then rearrange:

\[
\begin{align*}
\frac{\psi (1 - \bar{\theta})}{\omega (1 - \pi)} \left[ \theta_h - \frac{\bar{\theta} (1 + \delta_0)}{2} + \frac{\theta_h - \bar{\theta}}{\delta_0} + \frac{2 \psi (1 - \bar{\theta})}{\bar{\theta} \omega (1 - \pi)} \left[ 1 - \frac{2 \delta_0 (\theta_h - \bar{\theta})}{\bar{\theta}} \right] \right] \\
< \frac{\bar{\theta}}{\delta_0} \left[ \frac{\bar{\theta}^2 \delta_0^2}{4} + \frac{\delta_0}{2} \left[ 3 (\theta_h - \bar{\theta}) (1 - \theta_h) - \bar{\theta}^2 \right] - \bar{\theta} (1 - \theta_h) \right]
\end{align*}
\]

Condition (57) will be true for \( \frac{\psi}{\omega} \) sufficiently low if \( Z_2 > 0 \). Use \( \bar{\theta} = \pi \theta_k + (1 - \pi) \theta_h \) to rewrite \( Z_2 > 0 \) as:
\[
\pi^2 (\theta_h - \theta_e)^2 - 2 \left[ \theta_h + \frac{(2 + 3\delta_0)(1 - \theta_h)}{\delta_0 (2 - \delta_0)} \right] \pi (\theta_h - \theta_e) + \theta_h \left[ \theta_h + \frac{4(1 - \theta_h)}{\delta_0 (2 - \delta_0)} \right] < 0
\]

Based on the roots of this quadratic, we can conclude that \(Z_2 > 0\) requires:

\[
\pi (\theta_h - \theta_e) > \theta_h + \frac{(2 + 3\delta_0)(1 - \theta_h)}{\delta_0 (2 - \delta_0)} - \sqrt{\frac{1 - \theta_h}{2 - \delta_0} \left( 6\theta_h + \frac{(2 + 3\delta_0)^2(1 - \theta_h)}{\delta_0^2 (2 - \delta_0)} \right)} \quad (58)
\]

Condition (58) is satisfied by \(\theta_e = 0\) and \(\pi = 1\). The left-hand side is decreasing in \(\theta_e\) and increasing in \(\pi\) so it follows that \(Z_2 > 0\) requires \(\theta_e\) sufficiently low and \(\pi\) sufficiently high.

The fourth step is to verify \(W_j \leq X_j\). Use \(W_j = \omega \xi_j\) and (24) with \(\delta_1 = \omega\) to rewrite \(W_j \leq X_j\) as:

\[
\xi_k \leq \frac{1 - \delta_0}{\omega}
\]

Now use (48) with \(i_k^h\) as per (47) to replace \(\xi_k\). Substitute \(i_A\) as per (49) and \(\phi^*\) as per (50). Rearrange to isolate all terms with \(\psi(1-\overline{\theta})\omega(1-\pi)\) on one side. The condition for \(W_j \leq X_j\) becomes:

\[
\frac{\psi (1 - \overline{\theta})}{\omega (1 - \pi)} \left[ \frac{\overline{\theta}^2}{2} + (1 - \delta_0) \left[ \theta^2 + \frac{\overline{\theta}(1 - \theta_h)}{\delta_0} + \frac{2\psi (1 - \overline{\theta})}{\omega (1 - \pi)} \right] \right]
\geq \frac{\overline{\theta}^3}{4} \left[ (1 - \theta_h) \left( 3 - \frac{2}{\delta_0} \right) - \overline{\theta} \left( 1 - \frac{\delta_0}{2} \right) \right]
\]

call this \(Z_3\)

A sufficient condition for \(Z_3 < 0\), and hence \(W_j \leq X_j\), is \(\delta_0 \leq \frac{2}{3}\).

The fifth step is to verify \(W_k \leq X_k\). Use \(W_k = \omega \xi_k\) and (55) to rewrite \(W_k \leq X_k\) as:

\[
\xi_j \leq \frac{\delta_0}{\omega}
\]

Now use (27) with \(\alpha = \overline{\theta}\) and \(i_k^h\) as per (47) to replace \(\xi_j\). Substitute \(i_A\) as per (49) and \(\phi^*\) as per (50). Rearrange to isolate all terms with \(\psi(1-\overline{\theta})\omega(1-\pi)\) on one side. The condition for \(W_k \leq X_k\) becomes:
\[
\frac{\psi (1 - \bar{\theta})}{\omega (1 - \pi)} \left[ 1 - 3 \delta_0 - \frac{2 \delta_0}{\bar{\theta}} \left[ \frac{1 - \theta_h}{\delta_0} + \frac{2 \psi (1 - \bar{\theta})}{\bar{\theta} \omega (1 - \pi)} \right] \right] \\
\leq \frac{\bar{\theta}}{2} \left( 1 - \theta_h \right) \left( 3 - \frac{1}{\delta_0} \right) - \bar{\theta} \left( \frac{1}{2} - \delta_0 \right)
\]

call this \( Z_4 \)

Condition (60) will be true for \( \frac{\psi}{\omega} \) sufficiently low if \( Z_4 > 0 \). Use the definition of \( \bar{\theta} \) to rewrite \( Z_4 > 0 \) as:

\[
\pi (\theta_h - \theta_\ell) \delta_0 (1 - 2 \delta_0) > \theta_h \delta_0 (1 - 2 \delta_0) - 2 (1 - \theta_h)(3 \delta_0 - 1)
\]

If \( \delta_0 \geq \frac{1}{2} \), then (61) is always true. If \( \delta_0 < \frac{1}{2} \), then (61) reduces to:

\[
\theta_\ell < \frac{1}{\pi} \left[ \frac{2 (1 - \theta_h)(3 \delta_0 - 1)}{\delta_0 (1 - 2 \delta_0)} - \theta_h (1 - \pi) \right]
\]

This is a positive ceiling on \( \theta_\ell \) provided \( \pi > 1 - \frac{2(1-\theta_h)(3\delta_0-1)}{\theta_h \delta_0 (1 - 2 \delta_0)} \) with \( \delta_0 > \frac{1}{3} \). Therefore, (61) is guaranteed by \( \theta_\ell \) sufficiently low, \( \pi \) sufficiently high, and \( \delta_0 > \frac{1}{3} \).

The sixth step is to verify feasibility of \( i_\ell^h = 0 \). This requires \( R_j + R_k \geq \bar{\theta} X_j + \theta_\ell X_k \). Use (23) with \( \alpha = \bar{\theta} \) to replace \( R_j \). The desired inequality becomes:

\[
R_k \geq \theta_\ell X_k + \omega \bar{\theta} \xi_j
\]

Substituting \( X_k \) and \( R_k \) as per equations (55) and (56):

\[
i_\ell^h \leq \frac{\theta_h - \theta_\ell}{\psi} \left[ \delta_0 + \omega (\xi_k - \xi_j) \right]
\]

Use (48) to replace \( \xi_k \). Also use (27) with \( \alpha = \bar{\theta} \) to replace \( \xi_j \). Rearrange to isolate \( i_\ell^h \) then use (47) to replace \( i_\ell^h \). Substitute \( i_A \) as per (49) and \( \phi^* \) as per (50). Rearrange to isolate all terms with \( \frac{\psi (1 - \pi)}{\omega (1 - \pi)} \) on one side. The feasibility condition for \( i_\ell^h = 0 \) becomes:

\[
\frac{\psi (1 - \bar{\theta})}{\omega (1 - \pi)} \left[ \frac{3(5-\delta_0)}{4} - (\theta_h - \theta_\ell) \left[ \frac{1-\theta_h}{\bar{\theta}} + \frac{2 \delta_0 - 1}{\bar{\theta} \omega (1 - \pi)} \right] \right] \leq \frac{3 \bar{\theta}}{4} \left[ (1 - \theta_h) \left[ \theta_h - \theta_\ell - \frac{\bar{\theta}}{\delta_0} \right] - \frac{\bar{\theta}^2}{2} \right]
\]

call this \( Z_5 \)

Condition (62) will be true for \( \frac{\psi}{\omega} \) sufficiently low if \( Z_5 > 0 \). Use the definition of \( \bar{\theta} \) to rewrite \( Z_5 > 0 \) as:
\[
\pi^2 (\theta_h - \theta_{\ell})^2 - 2 \left[ \pi \theta_h + \frac{(\pi + \delta_0)(1 - \theta_h)}{\delta_0} \right] (\theta_h - \theta_{\ell}) + \theta_h \left[ \theta_h + \frac{2(1 - \theta_h)}{\delta_0} \right] < 0
\]

Based on the roots of this quadratic, we can conclude that \( Z_5 > 0 \) requires:

\[
\theta_{\ell} < \frac{1}{\pi^2} \left[ \sqrt{2\pi \theta_h (1 - \theta_h) + \frac{(\pi + \delta_0)^2 (1 - \theta_h)^2}{\delta_0^2} - \frac{(\pi + \delta_0)(1 - \theta_h)}{\delta_0} - \theta_h \pi (1 - \pi) \right]
\]

This is a positive upperbound on \( \theta_{\ell} \) provided \( \frac{\theta_h (1 - \pi)^2}{2(1 - \theta_h)} + \frac{1 - \pi}{\delta_0} < 1 \). Therefore, \( Z_5 > 0 \) requires \( \theta_{\ell} \) sufficiently low and \( \pi \) sufficiently high.

It now remains to check that the interbank rate increases when moving from \( \alpha = 0 \) to \( \alpha = \bar{\alpha} \). This requires (47) to exceed (31) or, equivalently:

\[
\frac{(1 + i_A)^2 - 1}{1 - \pi} > (1 - \delta_0) \left[ \frac{\bar{\theta}}{\psi} + \frac{4(1 - \bar{\theta})}{\omega \bar{\theta} (1 - \pi)} \frac{2(1 - \bar{\theta})}{2(1 - \bar{\theta}) + 3\phi^* \omega} \right]
\]

Using \( i_A \) as per (49) and \( \phi^* \) as per (50):

\[
\frac{\psi}{\omega (1 - \pi)} \left[ \frac{1 - \theta_h}{\delta_0} + \frac{\bar{\theta} (1 - 2\delta_0)}{2(1 - \delta_0)} + \frac{2 \psi (1 - \bar{\theta})}{\omega \bar{\theta} (1 - \pi)} \right] < \frac{3\bar{\theta}^2}{4(1 - \delta_0)} \left[ 1 - \theta_h + \frac{\bar{\theta} \delta_0}{2} \right] \tag{63}
\]

The right-hand side is positive so (63) will be true for \( \frac{\psi}{\omega} \) sufficiently low.

Putting everything together, we have shown that the model with endogenous funding shares generates the desired results under the following conditions: \( \pi \) sufficiently high, \( \theta_{\ell} \) and \( \frac{\psi}{\omega} \) sufficiently low, \( \delta_0 \in \left( \frac{1}{5}, \frac{2}{3} \right) \), and \( i_A \) as per (49). The results then extend to a non-empty range of \( i_A \) by continuity. □

**Comparison** We now compare the interbank rate increases in the fixed share and endogenous share models. Notice from the proof of Proposition 4 that the interbank rate at \( \alpha = 0 \) is the same in both models. Therefore, we just need to show that the interbank rate in the endogenous share model exceeds the interbank rate in the fixed share model at \( \alpha = \bar{\alpha} \). In other words, we need to show that (47) exceeds (40) for a given set of parameters. This reduces to:
\[
\frac{(1+i_A)^2 - 1}{1-\pi} \left[ 1 - \frac{\phi^*}{2(1-\bar{\theta}) + \frac{\bar{\theta}^2(1-\pi)}{\psi}} \right] < \frac{\bar{\theta}(1-\delta_0)}{\psi}
\]

which is exactly (53), where (53) was the condition for \( \xi_k > 0 \) at \( \alpha = \bar{\theta} \) in the endogenous share model. To complete the proof, we must now show that there are indeed parameters that satisfy the conditions in both models. For \( \alpha = 0 \), we imposed conditions (33) and (36) along with \( \pi \) sufficiently high and \( \theta_\ell \) sufficiently low. These conditions applied to both models. For \( \alpha = \bar{\theta} \) in the fixed share model, we also imposed conditions (41), (42), (43), and (44) along with \( \frac{\psi}{\omega} \) sufficiently low. For \( \alpha = \bar{\theta} \) in the endogenous share model, we added \( \delta_0 \in \left(\frac{1}{3}, \frac{3}{2}\right) \) and \( i_A \) in the neighborhood of (49). In (51) and (52), we showed that \( \pi \) sufficiently high and \( \theta_\ell \) sufficiently low make (49) satisfy condition (36). We have also shown that condition (44) is stricter than condition (33). Therefore, we just need to show that (49) satisfies conditions (41), (42), (43), and (44). Substituting \( i_A \) as per (49) into these conditions produces the following inequalities which we must check:

\[
\frac{\psi(1-\bar{\theta})}{\omega(1-\pi)} > \frac{\bar{\theta}^2(2\delta_0 - 1)}{4(1-\delta_0)} \tag{64}
\]

\[
\theta_\ell < \left[ 1 - \frac{1}{\pi(1+2\delta_0)} \right] \theta_h \tag{65}
\]

\[
\frac{\psi(1-\bar{\theta})}{\omega(1-\pi)} \left[ 1 - \frac{2(\theta_h - \theta_\ell)\delta_0}{\bar{\theta}} \right] < \bar{\theta}^2 \left[ \frac{(\theta_h - \theta_\ell)\delta_0}{\bar{\theta}} - 1 \right] \tag{66}
\]

\[
\frac{\psi(1-\bar{\theta})}{\omega(1-\pi)} < \frac{\bar{\theta}^2\delta_0}{2(1-\delta_0)} \tag{67}
\]

A sufficient condition for (64) is \( \delta_0 \leq \frac{1}{2} \) which is still consistent with \( \delta_0 \in \left(\frac{1}{3}, \frac{2}{3}\right) \). Condition (65) is just another positive upperbound on \( \theta_\ell \) provided \( \pi > \frac{1}{1+2\delta_0} \). In other words, (65) is satisfied by \( \theta_\ell \) sufficiently low and \( \pi \) sufficiently high. Condition (66) will be true for \( \frac{\psi}{\omega} \) sufficiently low if \( (\theta_h - \theta_\ell)\delta_0 > \bar{\theta} \) or, equivalently, \( \theta_\ell < \left[ 1 - \frac{1}{\delta_0 + \pi} \right] \theta_h \) with \( \pi > 1 - \delta_0 \) which again means \( \theta_\ell \) sufficiently low and \( \pi \) sufficiently high. Finally, condition (67) is clearly satisfied by \( \frac{\psi}{\omega} \) sufficiently low. □

**Proof of Proposition 6**

Evaluate (27) at \( \alpha = \bar{\theta} \) then subtract (48) to get:
\[ \xi_j - \xi_k \overset{\text{sign}}{=} \left[ \frac{(1 + i_A)^2 - 1}{1 - \pi} - \frac{\bar{\theta} (1 - \delta_0)}{\psi} \right] + 2 \left[ \frac{(1 + i_A)^2 - 1}{1 - \pi} - i_L^h \right] \]

The expression in the first set of square brackets is positive by condition (33). The expression in the second set of square brackets is proportional to \( \mu_j \). The proof of Proposition 5 established \( \mu_j > 0 \). Therefore, \( \xi_j > \xi_k \) at \( \alpha = \bar{\theta} \).

Now consider total credit:

\[ TC \equiv 1 - R_j - R_k \]

Use market clearing as per (12) to replace \( R_j + R_k \):

\[ TC = 1 - \bar{\theta} X_j - \theta_h X_k + \psi i_L^h \]

Use (24) and (25) to replace \( X_j \) and \( X_k \):

\[ TC = 1 - \bar{\theta} - (\theta_h - \bar{\theta}) \delta_0 + \delta_1 (\theta_h - \bar{\theta}) (\xi_j - \xi_k) + \psi i_L^h \]

Proposition 5 showed \( i_L^h|_{\alpha=\bar{\theta}} > i_L^h|_{\alpha=0} \). We also know \( \xi_j = \xi_k = 0 \) at \( \alpha = 0 \) and \( \xi_j > \xi_k \) at \( \alpha = \bar{\theta} \). Therefore, we can conclude \( TC|_{\alpha=\bar{\theta}} > TC|_{\alpha=0} \).

Finally, we want to show that the loan-to-deposit ratios of big and small banks converge. The equilibrium has \( \tau_j = 1 \), meaning that small banks move all DLPs (and the associated investments) off-balance-sheet. The loan-to-deposit ratio of the representative small bank is then \( \lambda_j \equiv 1 - \frac{R_j}{X_j - W_j} \). The equilibrium also has \( \tau_k = 0 \), meaning that the big bank records everything on-balance-sheet. Its loan-to-deposit ratio is then \( \lambda_k \equiv 1 - \frac{R_k}{X_k} \). Proposition 4 established \( R_k > 0 = R_j \) at \( \alpha = 0 \) so it follows that \( \lambda_k|_{\alpha=0} < 1 = \lambda_j|_{\alpha=0} \). To show convergence, we just need to show \( \lambda_k|_{\alpha=\bar{\theta}} > \lambda_k|_{\alpha=0} \) since \( \lambda_j|_{\alpha=\bar{\theta}} < \lambda_j|_{\alpha=0} \) follows immediately from equation (23). Use \( X_j + X_k = 1 \) along with the definition of \( \lambda_k \) to rewrite (12) as:

\[ \psi i_L^h = \bar{\theta} + [\theta_h - \bar{\theta} - (1 - \lambda_k)] X_k - R_j \]

We know \( i_L^h|_{\alpha=\bar{\theta}} > i_L^h|_{\alpha=0} \) so it must be the case that:

\[ [\theta_h - \bar{\theta} - (1 - \lambda_k|_{\alpha=\bar{\theta}})] X_k|_{\alpha=\bar{\theta}} - R_j|_{\alpha=\bar{\theta}} > [\theta_h - \bar{\theta} - (1 - \lambda_k|_{\alpha=0})] X_k|_{\alpha=0} \]

Proposition 4 also established \( \xi_j = \xi_k = 0 \) at \( \alpha = 0 \). Substituting into equation (25) then implies \( X_k = \delta_0 \) at \( \alpha = 0 \) so:
\[
\lambda_k|_{\alpha=\tilde{\theta}} \frac{X_k|_{\alpha=\tilde{\theta}}}{\delta_0} - \lambda_k|_{\alpha=0} > \frac{R_j|_{\alpha=\tilde{\theta}}}{\delta_0} - [1 - \pi (\theta_h - \theta_i)] \left[ 1 - \frac{X_k|_{\alpha=\tilde{\theta}}}{\delta_0} \right]
\]

call this \(Z_6\)

We have shown \(\xi_j > \xi_k\) at \(\alpha = \tilde{\theta}\) so equation (25) also implies \(\frac{X_k|_{\alpha=\tilde{\theta}}}{\delta_0} \leq 1\) for any \(\delta_1 \geq 0\).

Therefore, \(Z_6 \geq 0\) will be sufficient for \(\lambda_k|_{\alpha=\tilde{\theta}} > \lambda_k|_{\alpha=0}\). If \(\delta_1 = 0\), then \(Z_6 \propto R_j|_{\alpha=\tilde{\theta}} \geq 0\).

If \(\delta_1 = \omega\), then we can rewrite \(Z_6 \geq 0\) as:

\[
1 - \delta_0 - \omega \xi_k \geq \frac{1 - \pi (\theta_h - \theta_i)}{\theta} \omega (\xi_j - \xi_k)
\]

(68)

where \(\xi_j\) is given by (27) with \(\alpha = \tilde{\theta}\) and \(\xi_k\) is given by (48). Use these expressions to substitute out \(\xi_j\) and \(\xi_k\) then use equation (47) to substitute out \(i^h_L\). Evaluate \(i_A\) at (49) and \(\phi^*\) at (50) to rewrite (68) as:

\[
\frac{4\psi (1 - \tilde{\theta}) (1 - \delta_0)}{\omega \tilde{\theta} (1 - \pi)} + \tilde{\theta} (2 - 3\delta_0) + (1 - \theta_h) \left( \frac{2}{\delta_0} - 3 - \delta_0 \right)
\]

call this \(\Delta(\delta_0)\)

\[
\geq - \frac{\tilde{\theta}^2}{4} \frac{\omega (1 - \pi)}{\psi (1 - \tilde{\theta})} \left[ 2 \tilde{\theta} (1 - 2\delta_0) + (1 - \theta_h) \left( \frac{4}{\delta_0} - 6 - 3\delta_0 \right) \right]
\]

call this \(\tilde{\Delta}(\delta_0)\)

A sufficient condition for this is \(\min \left\{ \Delta(\delta_0), \tilde{\Delta}(\delta_0) \right\} \geq 0\). Notice \(\Delta'(\cdot) < 0\) and \(\tilde{\Delta}'(\cdot) < 0\).

Also notice \(\min \left\{ \Delta \left( \frac{1}{2} \right), \tilde{\Delta} \left( \frac{1}{2} \right) \right\} > 0\) and \(\min \left\{ \Delta \left( \frac{2}{3} \right), \tilde{\Delta} \left( \frac{2}{3} \right) \right\} < 0\). Therefore, there is a threshold \(\delta_0 \in \left( \frac{1}{2}, \frac{2}{3} \right)\) such that \(\delta_0 \leq \delta_0\) guarantees \(Z_6 \geq 0\). ■
Appendix B – Deposit and DLP Demands

Here we sketch a simple household maximization problem which generates the demands in equations (1) and (2). There is a continuum of ex ante identical households indexed by \( i \in [0, 1] \). Each household is endowed with \( X \) units of funding. Let \( D_{ij} \) and \( W_{ij} \) denote the deposits and DLPs purchased by household \( i \) from bank \( j \), where:

\[
\sum_j (D_{ij} + W_{ij}) \leq X
\]  

(69)

Assume that buying \( W_{ij} \) entails a transaction cost of \( \frac{1}{2\omega_0}W_{ij}^2 \), where \( \omega_0 > 0 \). As per the main text, the interest rate on the DLP is zero if withdrawn early and \( \xi_j \) otherwise. The interest rate on deposits is always zero and the average probability of early withdrawal is \( \bar{\xi} \). The household requires subsistence consumption of \( X \) in each state, above which it is risk neutral. If the household were to bypass the banking system and invest in long-term projects directly, it would fall below subsistence in the state where it needs to liquidate early since long-term projects cannot be liquidated early. Therefore, the household does not invest directly. Instead, it chooses \( D_{ij} \) and \( W_{ij} \) for each \( j \) to maximize:

\[
\sum_j \left( D_{ij} + [1 + (1 - \bar{\xi}) \xi_j] W_{ij} - \frac{W_{ij}^2}{2\omega_0} \right)
\]

subject to (69) holding with equality. The first order condition with respect to \( W_{ij} \) is:

\[
W_{ij} = (1 - \bar{\xi}) \omega_0 \xi_j
\]  

(70)

Substituting (70) into (69) when the latter holds with equality gives the household’s total deposit demand, \( D_i \equiv \sum_j D_{ij} \). The household is indifferent about the allocation of \( D_i \) across banks so we assume that it simply allocates \( D_i \) uniformly. For \( J \) banks, this yields:

\[
D_{ij} = \frac{X}{J} - \frac{(1 - \bar{\xi}) \omega_0}{J} \xi_j - \frac{(J - 1) (1 - \bar{\xi}) \omega_0}{J} \frac{1}{J - 1} \sum_{x \neq j} \xi_x
\]  

(71)

---

12 We interpret transactions costs broadly. They have been used in many literatures to parsimoniously model imperfect substitutability between goods.

13 Here is how to recover the two-point distribution of idiosyncratic bank shocks in Section 2 from the household withdrawals. Each household has probability \( \theta_{t} \) of being hit by an idiosyncratic consumption shock at \( t = 1 \) and having to withdraw all of its funding early. This results in each bank losing fraction \( \theta_{t} \) of its deposits and DLPs at \( t = 1 \). Then \( \theta_{h} - \theta_{t} \) of the remaining \( 1 - \theta_{t} \) households observe a sunspot and withdraw all of their funding from \( 1 - \pi \) banks at \( t = 1 \). The \( \theta_{h} - \theta_{t} \) households and \( 1 - \pi \) banks involved in the sunspot are chosen at random. Note \( \bar{\xi} \equiv \pi \theta_{t} + (1 - \pi) \theta_{h} \).
With a unit mass of ex ante identical households, $W_j = W_{ij}$ and $D_j = D_{ij}$. As $J$ approaches a unit mass of equally-weighted banks, (70) and (71) belong to the family of functions specified by (1) and (2).
Appendix C – Benchmark with Aggregate Shock

Consider the benchmark model (only price-taking banks) in Section 2 but with an aggregate interbank shock. In particular, the interbank rate is $i^e_L$ with probability $\pi$ and $i^h_L$ with probability $1 - \pi$. The expected interbank rate is $i^e_L \equiv \pi i^e_L + (1 - \pi) i^h_L$. We will specify how $i^e_L$ and $i^h_L$ are determined shortly. In the meantime, banks take both as given.

The objective function of the representative bank simplifies to:

$$\Upsilon_j = (1 + i_A)^2 (X_j - R_j) + (1 + i^e_L) R_j - \left[ X_j + i^e_L \bar{\theta} X_j + (1 - \bar{\theta}) \xi_j W_j \right] - \frac{\phi}{2} X_j^2$$

This is identical to the benchmark model except with the expected interbank rate $i^e_L$ instead of the deterministic $i_L$. Therefore, the first order conditions are still given by equations (7) to (9) but with $i^e_L$ in place of $i_L$.

The goal is to show that $i^e_L$ is always highest at $\alpha = 0$. The proof follows Proposition 3 but, to proceed, we must replace the deterministic market clearing condition (equation (4)) with conditions for each realization of the aggregate shock. We model the shock as a shock to the aggregate demand for liquidity at $t = 1$. In particular, aggregate liquidity demand is $\bar{\theta} X - \varepsilon$ with probability $\pi$ and $\bar{\theta} X$ with probability $1 - \pi$, where $\varepsilon > 0$. The interbank rates are then $i^e_L$ and $i^h_L$ respectively. To avoid liquidity shortages, we need these rates to satisfy:

$$R_j + \psi i^e_L \geq \bar{\theta} X - \varepsilon \quad (72)$$

$$R_j + \psi i^h_L \geq \bar{\theta} X \quad (73)$$

The equilibrium $i^h_L$ solves (73) with equality. If $i^h_L \leq \frac{\varepsilon}{\psi}$, then we can set $i^e_L = 0$. Otherwise, the equilibrium $i^e_L$ solves (72) with equality.

Let $i^e_{L0}$ denote the expected interbank rate at $\alpha = 0$ and let $i^e_{L1}(\rho)$ denote the expected interbank rate at some $\alpha > 0$. Using (72) and (73), we can write:

$$i^e_{L1}(\rho) = \frac{\bar{\theta} X}{\psi} - \frac{R_{j1}(\rho)}{\psi} - \frac{\pi}{\psi} \min \left\{ \bar{\theta} X - R_{j1}(\rho), \varepsilon \right\} \quad (74)$$

where $R_{j1}(\rho)$ is reserve holdings at the $\alpha > 0$ being considered. The proof of $i^e_{L1}(\rho) \leq i^e_{L0}$ proceeds by contradiction. In particular, suppose $i^e_{L1}(\rho) > i^e_{L0}$. Then (7) implies $\mu_j > 0$ at $\alpha = 0$. Complementary slackness then implies $R_j = 0$ at $\alpha = 0$ so we can write: 53
\[ i_L^e = \frac{\theta X}{\psi} - \pi \min \{ \theta X, \varepsilon \} \]  \hspace{1cm} (75)

Subtract (75) from (74) to get:

\[ i_{L1}^e (\rho) = i_{L0}^e - \frac{R_{j1}(\rho)}{\psi} + \frac{\pi}{\psi} \left[ \min \{ \theta X, \varepsilon \} - \min \{ \theta X - R_{j1}(\rho), \varepsilon \} \right] \]

There are three cases. If \( \varepsilon \leq \theta X - R_{j1}(\rho) \), then:

\[ i_{L1}^e (\rho) = i_{L0}^e - \frac{R_{j1}(\rho)}{\psi} \]

If \( \theta X - R_{j1}(\rho) < \varepsilon < \theta X \), then:

\[ i_{L1}^e (\rho) = i_{L0}^e - \frac{1 - \pi}{\psi} R_{j1}(\rho) - \frac{\pi}{\psi} (\theta X - \varepsilon) \]

If \( \theta X \leq \varepsilon \), then:

\[ i_{L1}^e (\rho) = i_{L0}^e - \frac{1 - \pi}{\psi} R_{j1}(\rho) \]

In each case, \( i_{L1}^e (\rho) > i_{L0}^e \) would require \( R_{j1}(\rho) < 0 \) which is impossible. \( \blacksquare \)
Appendix D – The June 20 Event

Here we study in more detail the dramatic spike in interbank interest rates that occurred in China on June 20, 2013. The weighted average interbank repo rate hit an unprecedented 11.6% on this date. For comparison, the average across all other trading days in June 2013 was 6.4%, the average in the prior month (May) was 3.0%, and the average in the following month (July) was 3.6%.

A common narrative in China is that interbank conditions tightened on June 20 because the government wanted to discipline the market, either deliberately or by not responding to some market pressures. An analysis of individual transactions will show whether or not this narrative is correct. Our identification strategy makes use of the fact that China’s three policy banks participate in the interbank repo market. The policy banks are agents of the government so the price and quantity of the liquidity that they provide is easily controlled by the government. In contrast, China’s big commercial banks have become much more independent since the market-oriented reforms discussed in Section 4.1. If China’s interbank repo market tightened at the hands of the government, there should be at least some evidence of restrictive behavior by policy banks relative to other banks on June 20.

The transaction-level data show that this was not the case. The policy banks provided a lot of liquidity to the interbank market at fairly low interest rates, to the point that they became the largest net lenders on June 20. The Big Four, on the other hand, were extremely restrictive, amassing RMB 50 billion of net borrowing by the end of the trading day.

Figure D.1: Repo Lending (RMB Billions)

![Figure D.1: Repo Lending (RMB Billions)](image)

Figure D.1 illustrates the sharp difference between the Big Four and the policy banks in terms of both quantity and price of liquidity provision on June 20. Notice the sizeable increase in policy bank loans and the more moderate nature of policy bank interest rates.
Figure D.1 also reveals that much of the increase in policy bank lending on June 20 was absorbed by the Big Four, a fact also visible from the flow of funds depicted in Figure D.2.

Figure D.2: Interbank Network on June 20, Net Flows

Were big banks borrowing because they really needed liquidity? Two pieces of evidence suggest no. First, the Big Four’s ratio of gross lending to gross borrowing was 0.7 on June 20, with 71% of the loans directed towards small banks. If the Big Four were in dire need of liquidity, we would expect to see very little outflow. Second, the repo market activities of big banks on June 20 involved a maturity mismatch. Overnight trades accounted for 96% of big bank borrowing but only 83% of big bank lending to small banks. Roughly 80% of policy bank lending to small banks was also at the overnight maturity. If big banks really needed liquidity on June 20, we would expect the maturity of their lending to be closer to the maturity of their borrowing. Instead, it was closer to the maturity offered by policy banks to borrower groups that policy banks and big banks had in common.

Figure D.3: Interbank Market Spreads
The left panel of Figure D.3 shows that big banks also commanded an abnormally high interest rate spread on June 20. In particular, their weighted average lending rate was 266 basis points above their weighted average borrowing rate. This is high relative to other banks: JSCBs and city banks commanded spreads of 113 and 46 basis points respectively. It is also high relative to other days in the sample: on any other day in June 2013, the spread commanded by big banks was between -40 and 58 basis points. Pricing among big banks was also much more uniform than pricing among small banks, both on June 20 and throughout our sample. To this point, we calculate the coefficient of variation (CV) of overnight lending rates offered by banks in different groups and find that the CV among big banks was 61% of the CV among JSCBs and 21% of the CV among city banks on June 20. Averaging over all trading days in June 2013 yields similar figures, namely 62% and 29% respectively.14

The right panel of Figure D.3 shows that JSCBs paid a lot more for non-policy bank loans on June 20 than they did for policy bank loans.15 There were no major differences in the haircuts imposed by policy banks versus other lenders. It then stands to reason that JSCBs would have liked a higher share of policy bank lending. Instead, they received 20% of what policy banks lent on June 20, down from an average of 28% over the rest of the month. The situation was similar for city and rural banks: they faced large price differentials between policy and non-policy bank loans yet their share of policy bank lending on June 20 was 22%, well below an average of 47% over the rest of the month.

Taken together, the evidence presented in this appendix has identified a concrete example of price-setting by the Big Four. Specifically, the Big Four can and do change prices on China’s interbank market, even controlling for government policy. China’s policy banks provided a sizeable amount of liquidity on June 20 but interbank rates did not fall because the funds were absorbed by the Big Four and re-intermediated at much higher interest rates.

14 We exclude lending rates charged to policy banks given the proximity of policy banks to the government. 15 For completeness, the overnight and 7 day maturities shown in the right panel of Figure D.3 were 94% of JSCB borrowing on June 20. They were also 100% of JSCB borrowing from policy banks on this date.
Appendix E – Supplement to Table 1

This appendix explains how we calculated the elasticities in Table 1 of the main text.

Consider the $N$ nodes in Figure 1. Let $\varepsilon_i^+$ denote the money that node $i$ brings into the interbank market and let $\varepsilon_i^-$ denote the money that node $i$ takes out of the interbank market. Also let $y_{i,s}$ denote the money that node $i$ lends to node $s$ on the interbank market. The adding-up constraint for each node $i$ is therefore:

$$\sum_s y_{i,s} + \varepsilon_i^- = \sum_s y_{s,i} + \varepsilon_i^+$$  \hspace{1cm} (76)

It will be convenient to rewrite in matrix notation. Define $y_i \equiv \sum_s y_{i,s} + \varepsilon_i^-$ and $m_{i,s} \equiv \frac{y_{i,s}}{y_i}$. Also define an $N \times N$ matrix $M = (m_{i,s})$ and $N \times 1$ vectors $Y = (y_i)$ and $E^+ = (\varepsilon_i^+)$. The system of (76) for all $i$ is just:

$$Y = M'Y + E^+$$

which can be rearranged to write:

$$Y = [I - M']^{-1} E^+$$  \hspace{1cm} (77)

where $I$ is an $N \times N$ identity matrix. Suppose the matrix $M$ and the vector $E^+$ are fixed. Then, for each node $i$, we can use (77) to calculate the elasticity of total lending by the interbank market, $\sum_s y_s$, to the money that $i$ brings into the interbank market, $\varepsilon_i^+$.

To proceed, we need the matrix $M$. The $(i, s)^{th}$ element of $M$ is $m_{i,s} \equiv \frac{y_{i,s}}{y_i}$, where $y_i \equiv \sum_s y_{i,s} + \varepsilon_i^-$. For $y_{i,s}$, we use the average daily lending from node $i$ to node $s$ in June 2013, excluding June 20 and 21. The policy banks and the Big Four are net lenders so we assume $\varepsilon_i^- = 0$ for each of them then use (76) to get their respective $\varepsilon_i^+$’s. For each of the other nodes, we assume that the money it brings into the interbank market ($\varepsilon_i^+$) as a fraction of what the Big Four brings equals the ratio of its deposits to the Big Four’s deposits in 2013. We can then use (76) to get $\varepsilon_i^-$ for each of these other nodes.
Appendix F – Estimation Procedure

Let $m = 1, ..., 6$ index the empirical moments to be matched. The six moments are the six correlations in Table 3.

1. Bootstrap: Let $N$ denote the total number of random samples generated by bootstrap. We set $N = 500$. Denote by $g_{m,n}$ the $m^{th}$ moment in the $n^{th}$ sample. We will target $\frac{1}{N} \sum_n^N g_{m,n}$, the $m^{th}$ moment averaged across $N$ samples.

2. Denote by $\Omega$ the vector of parameters to be estimated. Given $\Omega$, we can simulate the model to generate the moments $g_m(\Omega)$. Denote by $\varepsilon_{m,n} = g_m(\Omega) - g_{m,n}$ the residual for moment $m$ in sample $n$. Define the weighting matrix $(M \times M)$ as:

$$\mathcal{W} = \frac{1}{N} \sum_n^N \varepsilon_{m,n} \varepsilon_{m,n}^T$$

3. Minimizing the weighted sum of the distance between the empirical and simulated moments:

$$\hat{\Omega} = \arg \min_{\Omega} h(\Omega)' \mathcal{W}^{-1} h(\Omega)$$

where $h(\Omega)$ is a vector with $M$ elements and $h_m(\Omega) = g_m(\Omega) - \frac{1}{N} \sum_n^N g_{m,n}$.

4. We use two-step Simulated Method of Moments. We set $\mathcal{W}$ to the identity matrix in the first step and use the variance-covariance matrix of the residuals from the first-step as the weighting matrix for the second-step estimation.

5. Repeat the above exercise 100 times to calculate the standard errors of the estimated parameters.
