Unanticipated Money Growth and the Business Cycle Reconsidered

The role of unanticipated changes in money growth for aggregate fluctuations is reexamined using the methods of quantitative equilibrium business cycle theory. A stochastic growth model with money is constructed in which production and trade take place in spatially separated markets (islands). Following Lucas (1972, 1975), individuals only observe prices in their own local market, causing them to confuse changes in the average price level with changes in market-specific relative prices. We show that this mechanism can lead to large fluctuations in real economic activity. Some aspects of the statistical properties of these fluctuations, however, differ significantly from those describing U.S. business cycles.

In Lucas (1972), an economy is described in which unanticipated increases in the money growth rate leads to increases in the level of employment and output.¹ This idea was extended in Lucas (1975) to a neoclassical growth economy with capital accumulation and modern equilibrium business cycle theory was born. The results obtained in that paper, however, were only qualitative in nature. Later, Kydland and Prescott (1982) described a methodology for obtaining quantitative results from equilibrium business cycle models, and these techniques are now standard in the theoretical literature on aggregate fluctuations. However, the model that Kydland and Prescott studied is one in which the impulses that lead to business cycles are shocks to technology rather than changes in the growth rate of money. The purpose of the current paper is to reexamine the idea of Lucas (1972, 1975) using the methods of quantitative equilibrium business cycle theory. Our goal is to use Lucas's model to study the importance of monetary shocks for fluctuations in real variables in the same sense that the real business cycle literature studies the importance of technology shocks.

The economy we study is a close relative of the cash-in-advance economy studied in Cooley and Hansen (1995). In that model, changes in the growth rate of money affect real variables only to the extent that they signal changes in the inflation tax.

The authors acknowledge helpful comments on previous versions from David Altig, Ben Bernanke, Satyajit Chatterjee, Russell Cooper, Paul Evans, Paul Gomme, Tryphon Kollintzas, Robert E. Lucas, Jr., Bruce Smith, and two anonymous referees.

¹. See Phelps (1970) for an earlier exposition of some of the ideas explored in Lucas's paper.

THOMAS F. COOLEY is a professor of economics at the University of Rochester and GARY D. HANSEN is a professor of economics at the University of California, Los Angeles.

That is, increases in the growth rate of money lead agents to expect higher inflation in the future. In response to this, agents substitute away from activities that involve the use of cash in favor of activities that do not require cash. The model studied in this paper introduces an additional monetary non-neutrality: agents confuse changes in the economy-wide price level with changes in a market-specific relative price. This is because individuals are only able to observe the market price; they cannot directly observe (or accurately infer) the economy-wide average price level. This leads perfectly rational agents to confuse money shocks with market-specific demand shocks and respond to the former as though they were the latter.

In this case, an unanticipated increase in money growth may lead agents across the economy to incorrectly infer that that they have experienced an increase in market-specific demand. Hence, they all increase production by increasing employment and investment in capital. Under the information assumptions made in this paper, agents are never able to directly observe even past values of the average price level. This opens the possibility that misperceptions persist following an unanticipated money growth shock because information revealed over many future periods is required to accurately infer that a mistake has been made. Hence, if market-specific shocks are autocorrelated and confusion on the part of agents persists, the model economy exhibits serially correlated movements in real activity that is a key feature of actual business cycles.

We conduct experiments with a version of our model calibrated to long-run properties of postwar U.S. time series and find that unanticipated changes in money growth can induce fluctuations in economic activity of the magnitude observed in U.S. business cycles. However, summary statistics describing the co-movements of variables in response to these shocks differ in significant ways with summary statistics describing U.S. aggregate fluctuations. For example, consumption and productivity are countercyclical in the model, while they are procyclical in the data. In addition, the relative volatility of some time series generated from the model is quite different than the relative volatility of the same series in U.S. data.

This is not the first attempt to study the implications of the Lucas story using the methods of quantitative equilibrium business cycle theory. Kydland and Prescott (1982), Kydland (1989), and Cooley and Hansen (1995) all describe economies that attempt to capture the central feature of the islands model using a technology shock that is observed with noise. Agents face a signal extraction problem, as they do in the Lucas model, and the noise is only informally interpreted as resulting from monetary policy. Those studies found that confusion has only a small effect on output fluctuations. In this paper we are explicit about the role of money and the role of island-specific shocks. Our findings suggest that the conclusions of those earlier papers were misleading.

In the next section, we describe the details of the model. In the second section, we discuss the calibration procedure and our findings. In particular, we compare the aggregate fluctuations exhibited by our economy with unanticipated money growth shocks with those of the same economy with technology shocks. Some brief concluding comments are provided in section 3.
1. THE MODEL ECONOMY

In this section we describe three model economies. The first is a real business cycle model with money introduced by imposing a cash-in-advance constraint. The model is similar to the one studied by Cooley and Hansen (1995) except that agents live in spatially separated markets, or islands, and newly printed money is distributed unequally across these islands. The second economy, discussed in section 1.2, is a linear quadratic approximation of the first economy. Finally, in section 1.3, we incorporate informational asymmetries of the sort described in the introduction to the linear-quadratic economy. Computational tractability is our reason for forming a linear-quadratic approximate economy before introducing informational asymmetries. We perform quantitative experiments with the latter economy in section 2.

1.1 A Cash-in-Advance Economy with Spatially Separated Markets

We study a world consisting of a large number of spatially separated markets (islands) with measure 1 households per island with identical preferences and initial endowments. Each household is composed of a shopper-worker pair, as in Lucas and Stokey (1987). These agents, who live forever, choose consumption and work effort to maximize expected discounted lifetime utility,

\[ E \sum_{t=0}^{\infty} \beta^t [\alpha \log c_{1t} + (1 - \alpha) \log c_{2t} - \gamma h_t], \quad 0 < \beta < 1 \text{ and } 0 < \alpha < 1. \quad (1) \]

Utility each period depends on consumption of a "cash good" \((c_1)\), consumption of a "credit good" \((c_2)\), and hours worked, \(h\). Households are endowed with one unit of time that can be allocated to work or leisure. The fact that hours worked enters linearly in the utility function follows from the following assumptions: labor is indivisible, utility is separable in consumption and leisure, and agents trade employment lottery (see Hansen 1985 or Rogerson 1988). The two consumption goods, which are produced using the same technology, differ in that previously accumulated cash balances are needed to purchase \(c_1\) but not \(c_2\).

A typical household begins period \(t\) with \(m_t\) units of cash and \(k_t\) units of capital carried over from the previous period. Although production using the household’s capital and labor is carried out on the home island, purchases of goods must be made elsewhere. In particular, the shopper, who carries along the household’s cash, is randomly assigned to another market to purchase \(c_{1t}', c_{2t}',\) and investment goods, \(i_t\). The shopper’s purchases of \(c_{1t}\), are subject to the cash-in-advance constraint:

\[ \tilde{P}_t c_{1t} \leq m_t, \quad (2) \]

where \(\tilde{P}_t\) is the price of output on the island visited.

Credit goods \((c_{2t}', i_t)\) can be purchased using income earned from labor and capital during the same period since payment is not made until the end of the period.
Hence, the budget constraint faced by a representative household in period \( t \) is the following:

\[
P_t(c_{1t} + c_{2t} + i_t) + m_{t+1} \leq P_t(w_t h_t + r_t k_t) + m_t.
\] (3)

Output, \( Y_t \), on the representative island is produced using a constant-returns-to-scale technology, where \( K_t \) and \( H_t \) are the island’s per capita stock of capital and hours worked, respectively:

\[
Y_t = e^{\epsilon_t} K_t^\theta H_t^{1-\theta}, \quad 0 < \theta < 1.
\] (4)

The variable \( z_t \) is a shock to technology that is common across all islands and observed at the beginning of period \( t \). It is assumed to evolve according to the law of motion,

\[
z_{t+1} = \rho_1 z_t + \epsilon_{t+1}^1, \quad 0 < \rho_1 < 1.
\] (5)

The random variable \( \epsilon^1 \) is i.i.d. normal with mean zero and standard deviation \( \sigma_1 \). Since the production function displays constant returns to scale, the number of firms does not matter. Hence, we can assume, without loss of generality, that there is one firm per island.

Capital is assumed to depreciate at the rate \( \delta \) each period and one unit of investment yields one unit of capital the following period. Hence, the island’s capital stock evolves according to

\[
K_{t+1} = (1 - \delta) K_t + I_t, \quad 0 < \delta < 1,
\] (6)

where \( I_t \) is the per capita investment on the island.

The equilibrium real wage rate and rental rate will equal the marginal product of labor and capital, respectively. Hence, we obtain the following equilibrium pricing functions:

\[
w(z_t, K_t, H_t) = (1 - \theta) e^{\epsilon_t} \left( \frac{K_t}{H_t} \right)^\theta \quad \text{and}
\]

\[
r(z_t, K_t, H_t) = \theta e^{\epsilon_t} \left( \frac{H_t}{K_t} \right)^{1-\theta}.
\] (7)

**Monetary and Fiscal Policy.** The economy-wide money supply, \( M_t \), grows at the rate \( \mu + g_t \) and new money is introduced at the beginning of period \( t \). That is,

\[
M_{t+1} = e^{\mu + g_t} M_t, \quad \text{where}
\]

\[
g_{t+1} = \rho_2 g_t + \epsilon_{t+1}^2, \quad 0 < \rho_2 < 1.
\] (9)

The random variable \( \epsilon^2 \) is i.i.d. normal with mean zero and standard deviation \( \sigma_2 \).
Seigniorage can be used by the government to finance government spending or to finance lump-sum transfers to shoppers. That is,
\[ G_t + T_t = M_{t+1} - M_t , \]
where \( G_t \) and \( T_t \) are per capita nominal government spending and lump-sum transfers, respectively. Government spending and transfers, however, differ from island to island depending on the realization of a market specific shock, \( s_t \). That is, \( G_t = \int G_t(s) d\varphi(s) \) and \( T_t = \int T_t(s) d\varphi(s) \), where \( \varphi(s) \) is the invariant distribution function of the random variable \( s \) across markets. The functions \( G_t(s) \) and \( T_t(s) \) are nominal government spending on island \( s \) and nominal lump-sum cash transfers to shoppers visiting island \( s \), respectively. In the experiments carried out in this paper, we assume that \( T_t(s) = 0 \) for all \( t \) and that
\[ G_t(s) = e^s M_{t+1} - M_t . \]
(10)
The shock \( s_t \) evolves according to the autoregressive process,
\[ s_{t+1} = \rho_3 s_t + \varepsilon_{t+1}^3 , \quad 0 < \rho_3 < 1 , \]
(11)
where \( \varepsilon^3 \) is i.i.d. normal with mean 0 and standard deviation \( \sigma_3 \). This implies that the invariant distribution of \( s \) across markets (denoted above by the function \( \varphi(s) \)) is normal with mean 0 and variance \( \sigma_3^2/(1 - \rho_3^2) \). At this point we assume that households observe \( g_t \) and \( s_t \) at the beginning of period \( t \). They do not know which market they will be assigned to for shopping until after all decisions (except the consumption decision) have been made.

This economy has been designed so that the only differences between households that persist across time are related to the island on which a household lives. Due to different realizations of the \( s \) process, households on different islands will accumulate different amounts of capital and will hold different quantities of cash balances. On a given island, each household holds the same amount of wealth in equilibrium, although individual consumption levels will differ. This follows from the fact that each household will purchase goods at a different price, \( \bar{P} \), and that all other decisions are made before observing \( \bar{P} \). Hence, the only variable that can possibly depend on \( \bar{P} \) is consumption. In addition, since the assignment of a particular household to a shopping island is independent across periods, no useful information is conveyed by the observed \( \bar{P} \) in the complete information version of our model.

When a shopper leaves his home island to shop in some randomly assigned market, he carries with him all of the household’s cash holdings, \( m_t \). From the perspective of the home market, shoppers from other islands arrive bringing their cash with

2. We have experimented with introducing money through lump-sum transfers and found that it did not affect our findings very much. In addition, as we will see later, using new money only for government spending eliminates the “inflation tax” distortion in this economy. This allows us to focus exclusively on the importance of “unanticipated money.”

3. The assumption of normally distributed shocks for the \( g_t \) and \( s_t \) processes will be exploited in section 1.3 when we introduce information asymmetries to the model.
them. Since these shoppers are randomly assigned from all over the economy, the average stock of cash on the island will equal the economy-wide per capita stock of money, \( M_t \). In addition, the government spends \( G_t(s_t) \) units of cash. Hence, at the end of the period, the per capita stock of money on the island is given by

\[
M_{t+1} = M_t + G_t(s_t) = e^{s_t}M_{t+1} = e^{s_t+g_t+s_tT+\mu}M_t.
\]

(12)

Assuming that the cash-in-advance constraint (2) is binding, implying that all of this cash is used to purchase consumption goods on the island, \( M_{t+1} \) will be the per capita stock of money on the island at the beginning of period \( t + 1 \).\(^4\) In this case, the money supply on the home island evolves according to,

\[
M_{t+1} = e^{\mu+g_t+s_t-s_{t-1}}M_t.
\]

(13)

**Defining an Equilibrium.** In this complete information version of our economy, agents observe \( s_t, g_t, \) and \( z_t \) at the beginning of period \( t \) before making any decisions. Although they do not know the precise characteristics of the island they will be assigned to for shopping, households do know the period \( t \) conditional distribution of capital and \( s \) states across the economy. We denote this distribution by the letter \( \Phi_t \). From this they are able to deduce the distribution of prices. Hence, \( \Phi_t \) is part of the household’s state vector since the distribution of capital across markets will change over time.

Before defining an equilibrium, we apply a change of variables so that the certainty version of the economy has a constant steady state. This is required by the numerical methods we use to compute an equilibrium. In particular, we define

\[
\hat{m}_t = \frac{m_t}{M_t}, \quad \hat{p}_t = \frac{P_t}{M_{t+1}}, \quad \hat{P}_t = \frac{P_t}{M_{t+1}},
\]

(14)

where a tilde above a variable indicates that it describes the randomly assigned shopping island.

Using these expressions to eliminate \( m_t, \hat{p}_t, \) and \( P_t \) from the model, the household’s dynamic programming problem, assuming that equations (2) and (3) hold with equality, is

\[
\nu(s_{t-1}, s, g, z, \hat{m}, k, K, \Phi) = \\
\max \{ \alpha \log c_1 + (1 - \alpha)\log c_2 - \gamma h + \beta E_v(s, s', g', z', \hat{m}', k', K', \Phi') \}
\]

\[\hat{m}', k', h\]

\(^4\) The assumptions made in this paper are not sufficient to guarantee that the cash-in-advance constraint is binding for all realizations of the \( g \) and \( s \) processes. However, we will be studying the behavior of an “average” agent (or island), for whom all realizations of the \( s \) process are equal to zero. For this fictitious agent, the cash-in-advance binds in all realized states.
subject to

\[ c_1 = \frac{\hat{m}e^{s-1}}{\hat{P}e^{s+\mu+g}} \]

\[ c_2 + k' + \frac{\hat{m}'}{\hat{P}} e^{s_r-\delta_r} = \frac{\hat{P}}{P} e^{s_r-\delta_r}(w(z, K, H)h + r(z, K, H)k) + (1 - \delta)k \]

\[ K' = K'(s, g, z, K, \Phi) \]

\[ H = H(s, g, z, K, \Phi) \]

\[ \hat{P} = P(s, g, z, K, \Phi) \]

\[ \hat{P} = P(\bar{s}, g, z, \bar{K}, \Phi) \]

\[ \Phi' = F(\Phi, g, z) \, . \]  

(15)

The maximization is also subject to the laws of motion for the exogenous shocks, given by equations (5), (9), and (11). In addition, the functions \( w \) and \( r \) are defined in equation (7). Note that last period’s realization of the market specific shock, \( s_{-1} \), affects the current return but does not enter the agent’s decision rules. This is because the value of \( s_{-1} \) only affects the value of cash-good consumption. Given that (2) holds with equality, \( c_1 \) is determined by decisions made in the previous period rather than the current period. In addition, \( c_2 \) is determined so that (3) holds with equality. Hence, since \( c_1 \) and \( c_2 \) are chosen residually, their realization will depend on the characteristics of the randomly assigned shopping island, \( \bar{s} \) and \( \bar{K} \), in addition to the set of state variables.

The last five constraints in (15) represent the household’s perceptions of how market variables, which are outside the control of the household, depend on the state of the market. The first of these determines the market-specific capital stock for next period, and the second determines \emph{per capita} hours worked in the market. These perceptions are necessary for agents to compute expected future wage and rental rates [see equation (7)]. The third and fourth equations represent the household’s knowledge of how prices are determined, both on the home island and on the randomly assigned shopping island. Since islands are identical except for the realized values of \( s \) and \( K \), the functional form of these two pricing functions are identical. The last equation in (15) gives the law of motion for the joint distribution of \( \bar{s} \) and \( \bar{K} \) as a function of the \emph{economy-wide} state variables, \( z \) and \( g \).

In equilibrium, these perceptions must be correct. Hence, we define a \emph{recursive competitive equilibrium} to be a set of household decision rules, \( k'(x), \hat{m}'(x), \) and \( h(x) \), where \( x = (s, g, z, \hat{m}, k, K, \Phi) \); a set of market decision rules and pricing functions, \( H(X), K'(X) \), and \( P(X) \), where \( X = (s, g, z, K, \Phi) \); and a law of motion for the distribution function \( \Phi \), \( F(\Phi, g, z) \) such that:

(i) Households optimize. Given the market specific decision rules and pricing functions, \( k'(x), \hat{m}'(x), \) and \( h(x) \) solve the household’s dynamic programming problem (15).
(ii) Individual decisions are consistent with market outcomes. Since all agents on an island are identical, this implies

\[ \hat{m}'(s, g, z, 1, K, K, \Phi) = 1 \]
\[ k'(s, g, z, 1, K, K, \Phi) = K'(s, g, z, K, \Phi) \]
\[ h(s, g, z, 1, K, K, \Phi) = H(s, g, z, K, \Phi) \]

(iii) The law of motion \( F(\Phi, g, z) \) must be consistent with the equilibrium law of motion for \( K \) and the distribution of \( \hat{s} \) across the economy, \( \varphi(s) \) [this is the invariant distribution for \( s \) obtained from (11)].

1.2 A Linear-Quadratic Approximate Economy

Since it is not possible to obtain an analytical characterization of the competitive equilibrium for the above economy, we compute the equilibrium for a linear-quadratic approximation of this model. In addition, the linearity of this equilibrium will make it relatively easy to introduce asymmetric information in the next subsection. The linear-quadratic economy is formed by computing a quadratic approximation of the nonlinear return function in (15), after substituting in the cash-in-advance and budget constraints, eliminating \( c_1 \) and \( c_2 \).\(^5\) The certainty equivalence property of linear-quadratic models implies that only the first moment properties of probability distributions matter for the solution of the model. Hence, the equilibrium decision rules and pricing functions do not depend on the value of \( \sigma_i^2 \), for \( i = 1 \) to 3. In addition, since the mean of \( \hat{s} \) is a constant, we only need to keep track of the mean of \( \hat{K} \) as it evolves over time and can ignore other moments of the distribution function \( \Phi \) in forming rational expectations of \( \hat{P} \). We denote this state variable by \( K \), just as we denoted the average stock of money by boldface \( M \) in equation (8). Rational expectations of \( \hat{P} \) when the state is defined in this way, is the same as a rational forecast of the economy-wide average price level, which we denote \( \hat{P} \).

Using this new notation, we can now define a recursive competitive equilibrium for the linear-quadratic economy. The dynamic programming problem solved by households is given by

\[
V(s_{-1}, s, g, z, \hat{m}, k, K, K) = \\
\max_{\hat{m}', k', h} \left\{ \text{Q}(s_{-1}, s, g, z, \hat{m}, k, K, \hat{P}, \hat{P}, \hat{m}', k', h, H) + \beta Ev(s, s', g', z', \hat{m}', k', K', K') \right\} \tag{16}
\]

subject to

\[
s' = \rho_3 s + \varepsilon_3' \\
g' = \rho_2 g + \varepsilon_2' \\
z' = \rho_1 z + \varepsilon_1'
\]

5. This quadratic approximation is a Taylor series approximation around the steady state of the certainty version of the model. The certainty version is obtained by setting \( \varepsilon_i \) (\( i = 1 \)– 3) and \( \hat{s} \) equal to zero, and \( \hat{K} \) equal to \( K \). See Hansen and Prescott (1995) for details.
\begin{align*}
K' &= K'(s, g, z, K, K) \\
K' &= K'(g, z, K) \\
P &= P(s, g, z, K, K) \\
\hat{P} &= P(g, z, K) \\
H &= H(s, g, z, K, K). \\
\end{align*}

In this problem, the functions \( v \) and \( Q \) are quadratic and the functions \( K', K', P, \) and \( P \) are linear.

A recursive competitive equilibrium for this linear-quadratic economy is a set of linear household decision rules, \( k'(x), m'(x), \) and \( h(x) \), where \( x = (s, g, z, m, k, K, K) \); a set of market decision rules and pricing functions, \( H(X), K'(X), \) and \( P(X) \), where \( X = (s, g, z, K, K) \); a linear law of motion for the economy-wide average capital stock, \( K'(g, z, K) \); and a function determining the economy-wide average price level, \( P(g, z, K) \), such that:

(i) Households optimize. Given the market-specific decision rules and pricing function, and the law of motion for the economy-wide average capital stock, \( k'(x), m'(x), \) and \( h(x) \) solve the household’s dynamic programming problem (16).

(ii) Individual decisions are consistent with market outcomes,

\begin{align*}
\hat{m}'(s, g, z, 1, K, K, K) &= 1 \\
k'(s, g, z, 1, K, K, K) &= K'(s, g, z, K, K) \\
h(s, g, z, 1, K, K, K) &= H(s, g, z, K, K).
\end{align*}

(iii) \( K'(g, z, K) = K'(0, g, z, K, K) \) and \( P(g, z, K) = P(0, g, z, K, K) \).

We solve for this recursive competitive equilibrium using the methods described by Hansen and Prescott (1995).

1.3 The Economy with Informational Asymmetries

In the model we have been describing, the price of output in the home market, \( P \), depends on both the aggregate money growth rate, \( g \), and the market-specific shock, \( s \). If the price increase is due to a change in \( g \), it is the result of economy-wide inflation and agents will respond to it as a change in the implicit tax rate on money holdings (the "inflation tax"). If a price increase is due to an increase in \( s \), then there has been a real increase in the demand for the output of this particular market. Hence, the firm will respond to this increase in the relative price of its output by increasing production. That is, those markets characterized by higher than average nominal government expenditures, a positive value of \( s \), will have an above average price. Hence, residents of this island expect, on average, to purchase goods at a lower price than they sell their own output. In addition, if this high level of government spending persists, residents will expect a higher than average return on investment in new capital.

We now introduce informational asymmetries to the linear-quadratic economy defined in the previous subsection. The critical feature of Lucas's (1972, 1975) model, which we now incorporate, is that agents can only observe, and hence make deci-
sions contingent on, the price of output in their own market. They cannot infer the average price level of the economy as a whole. The implication of our informational assumptions is that households are not able to observe the two shocks, \( g_t \) and \( s_t \), separately. This introduces the possibility that agents may confuse changes in these two shocks and respond to a change in the economy-wide average price level (resulting from a change in \( g_t \)) as though it were at least partly a change in the relative price of output in the home market (a change in \( s_t \)).

To be more specific, at the beginning of period \( t \), the information set a particular agent uses to form expectations of \( g_t \) and \( s_t \) is \( I_0 = \{ P_j, \tilde{P}_j, j < t \} \). Before any decisions are made, the agent observes \( P_0 \), the price of output on his own island. Hence, his information set is now \( I_1 = \{ P_j, \tilde{P}_{j-1}, j \leq t \} \). After observing this, agents form conditional expectations of \( g \) and \( s \), \( s^e_t = E(s_t|I_1) \) and \( g^e_t = E(g_t|I_1) \). Agents make decisions based on these conditional expectations rather than on direct observations of these two shocks. Hence, the market decision rules and pricing function defined in the previous subsection become \( H(s^e, g^e, z, \hat{m}, k, K, K^c) \), \( K'(s^e, g^e, z, \hat{m}, k, K, K^c) \), and \( P(s^e, g^e, z, \hat{m}, k, K, K^c) \), where \( K' = K'(g^e, z, K^c) \) describes how agents' conditional expectations of the economy-wide average stock of capital evolve.

In the remainder of this subsection we describe in greater detail how the conditional expectations \( s^e_t \) and \( g^e_t \) are computed. From equations (13) and (14), we have that \( \ln P_t = \mu + g_t + s_t - s_{t-1} + \ln M_t + \ln \tilde{P}_t \). From this, assuming that they know the value of \( M_t \), individuals can infer a linear function of \( s_t, g_t, s_{t-1}, \hat{s}_t^e, \) and \( \hat{g}_t^e \). The latter two variables represent the market average expectations of the two shocks, which enter the linear function determining \( \ln \tilde{P} \). This is because \( \tilde{P} \) is a function of agents' choices and is therefore a function of expectations and only indirectly a function of actual realized values.

Each agent living on a given island will have different information set. This follows from the fact that each one will have observed a different sequence of \( \tilde{P}_s \). However, we are interested in solving the problem of the average agent living on the average island. For this fictitious agent, \( \hat{s}_t^e = s_t^e \) and \( \hat{g}_t^e = g_t^e \) in equilibrium. Agents have perceptions about how these market average expectations are formed, which must be correct in equilibrium. In particular, they know that these will be a linear function of \( g_t, s_t, \) and \( s_{t-1} \). Denote this linear function by 

\[
\begin{bmatrix}
\hat{g}_t^e \\
\hat{s}_t^e
\end{bmatrix} = F
\begin{bmatrix}
g_t \\
\hat{s}_t \\
\hat{s}_{t-1}
\end{bmatrix},
\]

where \( F \) is a

---

6. In our model, they also observe the price on a randomly assigned shopping island, but we assume this is observed only after all decisions have been made. This information is, however, incorporated into their information set available at the beginning of the subsequent period.

7. There are a large number of households on each island and each one observes a different value of \( \tilde{P} \). We assume that households are not able to pool this information. If they could, they would be able to infer the economy-wide average price level and hence the value of \( g_t \).

8. In practice, to make it easier to compute conditional expectations, we will assume that households observe slightly more than this. They will observe the money supply on the shopping island which they can compare with the money supply on their own island. This will be explained when we describe how we compute agent's conditional expectations.

9. We assume that the economy starts off with all islands being identical. Hence, \( K^e_0 = K_0 \) for all islands.
2 \times 3 matrix to be defined below. Substituting this into the linear function inferred from observing lnP, we obtain a linear function of g_t, s_t, and s_{t-1}, which we denote

\[ B(g_t, s_t, s_{t-1}) = B_1 \begin{bmatrix} g_t \\ s_t \\ s_{t-1} \end{bmatrix}, \] where \( B_1 \) is a 1 by 3 matrix. This function \( B \) represents the incremental information agents receive at the beginning of a period when the information set changes from \( I_0 = \{ P_j, \tilde{P}_j, j < t \} \) to \( I_1 = \{ P_j, \tilde{P}_{j-1}, j \leq t \} \).

After shopping, households are able to observe \( \tilde{P}_t \) and \( \ln M_{t+1} - \ln \tilde{M}_{t+1} = s_t - \tilde{s}_t \). That is, agents now observe \( B_2 \begin{bmatrix} g_t \\ s_t \\ s_{t-1} \end{bmatrix} = B_2 \begin{bmatrix} \varepsilon_t \\ \varepsilon_{t+1} \end{bmatrix} + \varepsilon_t^4, \) where \( \varepsilon_t^4 = -\tilde{s}_t \) and the matrix \( B_2 \) is equal to \( \begin{bmatrix} 0 & 1 & 0 \end{bmatrix} \). The variable \( \varepsilon_t^4 \) is, from the household’s point of view an i.i.d. random variable distributed \( N(0, \sigma_2^2/(1 - \rho_3^2)) \). We assume that agents see this rather than simply \( \tilde{P}_t \), so that we can abstract from the part of \( \tilde{P}_t \), namely \( \tilde{P}_t \), that depends on the conditional expectations of agents on the shopping island. This has the advantage of simplifying the procedure used to compute the conditional expectations of agents on the home island.

Let \( e_{0t} = E[x_t|I_{0t}] \) and \( V_{0t} \) be the corresponding conditional covariance matrix, where \( x_t = (g_t, s_t, s_{t-1})^T \). Similarly, let \( e_{1t} = E[x_t|I_{1t}] \) and \( e_{2t} = E[x_t|I_{2t}] \), where \( I_{2t} = \{ P_j, \tilde{P}_j, j \leq t \} = I_{0,t+1} \). In addition, \( V_{1t} \) and \( V_{2t} \) are the corresponding conditional covariance matrices. From equations (9) and (11), we can express the law of motion for \( x \) as \( x_{t+1} = Ax_t + E \begin{bmatrix} \varepsilon_{t+1}^2 \\ \varepsilon_{t+1}^3 \end{bmatrix} \), where \( A = \begin{bmatrix} \rho_2 & 0 & 0 \\ 0 & \rho_3 & 0 \\ 0 & 0 & 1 \end{bmatrix} \) and \( E = \begin{bmatrix} 1 & 0 \\ 0 & 1 \\ 0 & 0 \end{bmatrix} \).

Given that the \( \varepsilon \)s are normally distributed, the covariance matrices \( V_{0t}, V_{1t}, \) and \( V_{2t} \) are constant (over time) matrices that can be obtained from solving the following equations: \( ^{10} \)

\[
V_1 = (I - (B_1 V_0)^T (B_1 V_0 B_1^T)^{-1} B_1) V_0 \\
V_2 = \left( I - (B_2 V_1)^T \left( B_2 V_1 B_2^T + \frac{\sigma_3^2}{1 - \rho_3^2} \right)^{-1} B_2 \right) V_1 \\
V_0 = A V_2 A^T + E \Sigma E^T,
\]

where \( \Sigma = \begin{bmatrix} \sigma_2^2 & 0 \\ 0 & \sigma_3^2 \end{bmatrix} \). Applying conditional probability formulas for the multivariate normal distribution, we obtain the following expressions:

\[
e_{1t} = (B_1 V_0)^T (B_1 V_0 B_1^T)^{-1} B_1 x_t + (I - (B_1 V_0)^T (B_1 V_0 B_1^T)^{-1} B_1) e_{0t}
\]

\( ^{10} \) For a derivation of these formulas, as well as those in equation (17), see Mood, Graybill, and Boes (1974).
\[ e_{2t} = (B_2V_1)^T(B_2V_1B_2^T)^{-1}B_2x_t + \left( I - (B_2V_1)^T\left( B_2V_1B_2^T + \frac{\sigma_3^2}{1 - \rho_3^2}\right)^{-1}B_2 \right)e_{1t} \]

\[ e_{0,t+1} = A e_{2t}. \]  

(17)

Finally, we employ the following procedure in order to solve for the equilibrium value of the matrix \( \mathbf{F} \), that is, the value of \( \mathbf{F} \) such that \( \hat{s}_t = s_t^c \) and \( g_t^c = g_t^r \). First, set \( \mathbf{F} \) equal to an arbitrary \( 2 \times 3 \) matrix and solve for \( \mathbf{V}_0 \) as described above. Then, using equation (17), we set \( \mathbf{F} = (B_1V_0)^T(B_1V_0B_1)^{-1}B_1 \) and repeat until successive iterations have converged.

The state variables, \( g_t^c \) and \( s_t^c \), are equal to the first two elements of \( e_{1t} \). In our quantitative experiments, we use these variables in place of \( g_t \) and \( s_t \) in the linear pricing function and decision rules shown in Table 2.

2. QUANTITATIVE RESULTS

We do three things in this section. First, we describe the calibration of the model. Second, we consider the impulse response of the endogenous variables of the model to a one-standard deviation shock to the money growth rate. For comparison, we also consider the response of the same set of variables to a technology shock. Finally, we present results from three simulation experiments designed to assess the importance of money growth shocks for business cycles. In particular, these experiments enable us to compare the business cycle properties of our model economy with the same properties of postwar U.S. data.

2.1 Calibration

Given that the model studied here is very similar to the cash-in-advance economy presented in Cooley and Hansen (1995), we follow the calibration procedure employed in that paper whenever appropriate. In particular, we chose \( \beta, \gamma, \theta, \) and \( \delta \) so that the steady-state capital-output ratio, investment-output ratio, labor income share, and time spent participating in the labor market are equal to the average of these values computed from U.S. data.\(^{11}\) Similarly, we employ the same value for \( \alpha \) as in our previous paper. In particular, we chose \( \alpha \) based on information from a survey of consumer transactions administered by the Federal Reserve Board in 1984 and 1986, which lead us to choose \( \alpha = .84 \). According to this survey, 84 percent of consumer transactions are made with cash, if we define cash to be currency, checks, and money orders.

The parameters of the money supply process \([\mu, \rho_2, \text{and } \sigma] \) in equation (9) were assigned values based on estimates from a first-order autoregression of the growth rate of M1 (again, see our previous paper for details). The autoregressive parameter of the technology shock process \( \rho_1 \) was chosen to match the stochastic properties of the Solow residual. In our experiments, we consider alternative values for the standard deviation, \( \sigma_1 \).

\(^{11}\) See Cooley and Prescott (1995) for details.
We do not attempt to calibrate, at least in the usual sense, the parameters of the idiosyncratic shock process, $s$. Given that we do not have much information from actual economies that can be used to calibrate this stochastic process, we chose to calibrate in a way that gives the economy with money growth shocks the best chance of accounting for the business cycle facts. In particular, the autoregressive parameter of this process [$\rho_3$ in equation (11)] was chosen so as to make the response of the model to aggregate money growth shocks as persistent as possible. By setting $\rho_3$ close to 1, agents are driven to produce more and accumulate capital in response to a positive value of $e_3$ since they expect the good times to persist for a long time. This lead us to choose $\rho_3 = .99$.$^{12}$ As with $\sigma_1$, we experiment with alternative values for $\sigma_3$. The exact values assigned to each of the parameters are given in Table 1. The log-linear market decision rules and pricing function obtained for the calibrated version of our economy are shown in Table 2.

2.2 Impulse Response Functions

In computing the impulse response functions shown in Figures 1–4, we set the standard deviation of innovations to the technology shock process, $\sigma_1$, equal to 0.00685. This value was chosen so that the variance of output in simulations of the model with only technology shocks equals the variance of output in U.S. time series. Similarly, the standard deviation of innovations to the idiosyncratic ($s$) process was chosen so that the variance of output in the model with only money growth shocks equals the variance of output in the data. This led us to set $\sigma_2 = 0.0048$.

In Figure 1 we show the response of $s^t$ to a one-standard-deviation shock to aggregate money growth. This shows that it takes agents a large number of periods to learn that the true value of $s$ is zero. The half-life of the misperceived increase in $s$ is about seven or eight quarters when $\rho_3 = .99$. Hence, the fact that agents never directly observe $g$ and $s$ leads to a fair amount of persistence in this model. For comparison, we also show the response of $s^t$ for $\rho_3$ equal to .95 and .9 to illustrate the sensitivity of the persistence of misperceptions to autocorrelation in the $s$ process.

We plot the response of real variables to a one-standard-deviation shock to the money growth rate in Figure 2. Since the possibility that fluctuations are caused by technology shocks has played such an important role in the recent literature on business cycles, we compare these impulse responses with those of a one-standard-deviation shock to technology. The most striking difference between the two sets of

---

12. We chose not to allow $s$ to follow a random walk since this would imply that the standard deviation of $\dot{s}$ would be infinite. This would mean that agents would learn nothing from observing the price on their assigned shopping island.
response functions is that the response to a technology shock lasts longer. However, the shape of these responses are quite similar, with the notable exception of the consumption response. In response to a technology shock, both consumption and investment rise. In response to a money shock, consumption falls.

The countercyclical response of consumption is due to various facts. First, given the functional form we use for preferences, our assumption that seigniorage is used entirely for government purchases means that an anticipated increase in money growth leads to a one for one decrease in cash good consumption. No other real variables are affected. An unanticipated shock will also have this fiscal consequence in addition to the effect resulting from misperceptions on the part of private agents. To illustrate how much the increase in government consumption accounts for the fall in private consumption shown in Figure 2, we also plot the percentage change in private plus government consumption. This also falls significantly, so the assumption linking fiscal and monetary policy in this model cannot fully account for the

![Perceived Value of s](image)

**Fig. 1.** Perceived Island-Specific Shock in Response to a Money Growth Shock
Fig. 2. Response of Real Variables to Various Shocks
fact that consumption falls in response to an unanticipated increase in money growth. In fact, the increase in government spending can account for a relatively small fraction of the decline in private consumption. In addition, the fiscal component of the consumption response disappears completely after fifteen periods while the private consumption response persists much longer.

A second factor contributing to the shape of the consumption response follows from the way households respond to the change in the equilibrium wage rate resulting from an unanticipated money shock. The household's first-order condition governing the choice of \( h_r \), which is chosen before \( \bar{P}_r \) is observed, can be written as

\[
c_{2t}^{planned} = \frac{1 - \alpha}{\gamma} w_t E \left[ \frac{P_t}{\bar{P}_t} \mid I_{1t} \right].
\]

Of course, actual \( c_2 \) is chosen after \( \bar{P}_r \) is observed. In the absence of a technology shock, a perceived increase in \( s \) causes equilibrium hours worked to increase and hence the real wage, \( w \), to fall. Holding the last term of the above equation constant, this will lead to a planned decrease in \( c_2 \). Similarly, using the first-order condition for choosing \( m_{r+1} \), it can be shown that the increase in the wage rate will lead to a planned decrease in \( c_{1, t+1} \) as well. However, a money growth shock leading to a perceived increase in \( s \) will also cause the expected value of \( P_t / \bar{P}_t \) to increase.
Hence, depending on the size of this increase, households may actually plan to increase their consumption purchases. On average, however, households will not be able to afford this increase since their inference about $P_t/\hat{P}_t$ is incorrect. Average levels of $c_1$ and $c_2$ must fall after a money growth shock. Thus, consumption falls after an unanticipated money growth shock for three reasons: additional resources are used for government purchases, the wage rate falls, and consumption serves as the only "shock absorber" enabling households to satisfy their budget and cash-in-advance constraints once $\hat{P}_t$ has been revealed.

In Figure 3 we show the responses of money-related variables to both an anticipated and unanticipated money growth shock, as well as a technology shock. The rate of inflation and the price level increase in response to both types of money growth shocks. They both fall in response to a technology shock. The initial response of inflation (or the price level) to a misperceived money growth shock is almost twice as large as the response to a perfectly observed money growth shock. Intuitively this follows from the fact that the demand for real money balances falls in response to an unanticipated shock and remains unchanged in response to an anticipated shock. That is, misperceptions lead households to overestimate the spending power next period of a given quantity of real balances chosen today. Hence, they underestimate the amount of real balances needed today in order to purchase a desired quantity of cash goods next period.

The nominal interest rate shown in the third panel of Figure 3 is the average of the island-specific nominal interest rates across the economy. The interest rate response is the same for both types of money growth shocks and it does not respond at all to a technology shock. This is because the equilibrium nominal interest rate in a particular market, given the functional form for preferences we have employed, depends only on the growth rate of the money supply in that market. This is something that agents in both versions our economy can infer accurately.

### 2.3 Investigating the Business Cycle Properties of the Model Economies

Table 3 presents the business cycle properties of the postwar U.S. economy. Tables 4–6 display the results of three experiments where the standard deviations of the technology and idiosyncratic shocks are tailored to explore their potential for explaining features of the business cycle. In the first experiment only technology shocks drive fluctuations in output, while in the second monetary shocks are the only source of fluctuations. In each of these experiments, we choose the standard deviation of the respective shocks so that the variance of output from simulations of the model equals the variance computed from U.S. data. As explained above, this implies setting $\sigma_1 = .00685$ and $\sigma_2 = 0.0048$. In the third experiment we include

---

13. Business cycle properties are computed by logging the data (except for series already expressed in percent terms) and applying the Hodrick-Prescott filter. We report the ratio of the standard deviation of variables to the standard deviation of output as well as cross-correlations with output and the contemporaneous correlation with the money growth rate. Each experiment involved computing 100 simulations of 250 periods each. The statistics reported are averages of statistics computed from the last 150 periods of each simulation.

**NOTE:** Data has been logged (except for inflation, interest rate, and the money growth rate) and detrended using the Hodrick-Prescott filter.
both technology shocks and monetary growth shocks. In particular, we exploit the findings of Kydland and Prescott (1991) and Aiyagari (1994) and choose the standard deviation of shocks so that technology shocks account for about 70 percent of the fluctuations in output. We then calibrate so that the remainder is due to monetary shocks. This led us to set $\sigma_1 = .00575$ and $\sigma_2 = 0.00345$ in this experiment.

The results in Table 4 confirm that the islands economy, when driven solely by technology shocks, behaves very much like a standard real business cycle model: it displays business cycle properties that are remarkably similar to the cyclical properties of the U.S. economy. In particular, it matches the real features of the U.S. economy well in most dimensions: consumption is less volatile than output, investment is three and a half times as volatile as output, and hours fluctuations are somewhat smaller than those of output. In addition, consumption, investment, hours, and productivity are procyclical. Although technology shocks cause fluctuations in some money-related variables, we do not come close to accounting for the size of these fluctuations without introducing monetary shocks.

Table 5 presents results for the islands economy driven only by monetary shocks. There are several features of these results that are striking. First it is noteworthy that the islands economy, driven by monetary shocks alone, is capable of producing output fluctuations of the magnitude observed in U.S. business cycles. Monetary shocks of that magnitude, however, produce fluctuations in consumption, investment, and hours that are all more volatile than those observed in U.S. data. These shocks also lead to a price level that is twice as volatile as that in U.S. data and an inflation rate that is three times as volatile. Nominal interest rates, however, are still less volatile in this economy than they are in the data. In general, in comparison with the economy driven by technology shocks, this economy exhibits business cycle properties that have less in common with those of the data.

Some of the money-related features of the islands economy mimic features of the U.S. economy better than the standard cash-in-advance model (see Cooley and Hansen 1995). In the islands economy, inflation, nominal interest rates, and velocity are all procyclical. The price level, however, is also procyclical in contrast to the data.

The most striking failures of this version of the islands economy is the finding that consumption and productivity are countercyclical. As explained above, the consumption correlation is primarily a consequence of the way this particular islands economy is structured in that consumption alone has the role of "shock absorber." When agents are fooled by a monetary shock they end up, on average, having to reduce their consumption.

Table 6 presents results for the economy driven by both monetary and technology shocks. As in the previous experiment, the relative volatility of real variables with respect to output are too large. The real business cycle properties are, however, closer to those observed in the data than are the results in Table 5. In addition, as in Table 5, there is a positive contemporaneous correlation between output and inflation, interest rates, and velocity. However, the major failings of this as a model of the business cycle remain. Consumption and productivity are countercyclical and

See note for Table 4.
the price level is procyclical, although not as strongly as in the economy driven only by monetary shocks.

3. CONCLUDING COMMENTS

Previous attempts, such as Kydland (1989) and Cooley and Hansen (1995), to study the quantitative implications of the Lucas (1972) "islands" economy have reached a pessimistic assessment of the ability of this type of monetary non-neutrality to produce significant output fluctuations. Our findings suggest a very different conclusion. When the important elements of the islands economy are incorporated, unanticipated monetary shocks can have powerful real effects. The statistical properties of the fluctuations resulting from these shocks share some aspects in common with the real and nominal features of U.S. business cycles. However, there are many differences as well; our version of the islands model does not account for the business cycle features of U.S. data nearly as well as a standard real business cycle model. Hence, although money shocks may have significant quantitative effects on real activity for the reasons articulated by Lucas (1972), our findings indicate that the induced fluctuations are quite different from those experienced in the postwar U.S. economy.

We interpret our findings as suggesting that the Lucas islands model may have been abandoned prematurely. We admit, however, that this paper does not address many of the criticisms of this approach that have been raised over the years (see, for example, Barro 1989). For example, the plausibility of the informational assumptions made by Lucas has often been questioned. Future work should attempt to quantify the value of the information that, by assumption, is being denied to private agents in the model. Further work is required before a definitive conclusion can be made as to whether this monetary non-neutrality is an important contributor to aggregate fluctuations in actual economies.
