End-User License Agreement

This is a contract between you and Econometric Software, Inc. The *software product* refers to the computer software and documentation as well as any upgrades, modified versions, copies or supplements supplied by Econometric Software. By installing, downloading, accessing or otherwise using the software product, you agree to be bound by the terms and conditions of this Agreement.

Subject to the terms and conditions of this Agreement, Econometric Software, Inc. grants you a non-assignable, non-transferable license, without the right to sublicense, to use the licensed software and documentation in object-code form only, solely for your internal business, research, or educational purposes.

Copyright, Trademark, and Intellectual Property

This software product is copyrighted by, and all rights are reserved by Econometric Software, Inc. No part of this software product, either the software or the documentation, may be reproduced, distributed, downloaded, stored in a retrieval system, transmitted in any form or by any means, sold or transferred without prior written permission of Econometric Software. You may not, or permit any person, to: (i) modify, adapt, translate, or change the software product; (ii) reverse engineer, decompile, disassemble, or otherwise attempt to discover the source code of the software product; (iii) sublicense, resell, rent, lease, distribute, commercialize, or otherwise transfer rights or usage to the software product; (iv) remove, modify, or obscure any copyright, registered trademark, or other proprietary notices; (v) embed the software product in any third-party applications; or (vi) make the software product, either the software or the documentation, available on any website.

LIMDEP® and *NLOGIT*® are registered trademarks of Econometric Software, Inc. The software product is licensed, not sold. Your possession, installation and use of the software product does not transfer to you any title and intellectual property rights, nor does this license grant you any rights in connection with software product registered trademarks.

Use of the Software Product

You have only the non-exclusive right to use this software product. A single user license is registered to one specific individual as the sole authorized user, and is not for multiple users on one machine or for installation on a network, in a computer laboratory or on a public access computer. For a single user license only, the registered user may install the software on a primary stand alone computer and one home or portable secondary computer for his or her exclusive use. However, the software may not be used on the primary computer by another person while the secondary computer is in use. For a multi-user site license, the specific terms of the site license agreement apply for scope of use and installation.

Limited Warranty

Econometric Software warrants that the software product will perform substantially in accordance with the documentation for a period of ninety (90) days from the date of the original purchase. To make a warranty claim, you must notify Econometric Software in writing within ninety (90) days from the date of the original purchase and return the defective software to Econometric Software. If the software does not perform substantially in accordance with the documentation, the entire liability and your exclusive remedy shall be limited to, at Econometric Software's option, the replacement of the software product or refund of the license fee paid to Econometric Software for the software product. Proof of purchase from an authorized source is required. This limited warranty is void if failure of the software product has resulted from accident, abuse, or misapplication. Some states and jurisdictions do not allow limitations on the duration of an implied warranty, so the above limitation may not apply to you. To the extent permissible, any implied warranties on the software product are limited to ninety (90) days.

Econometric Software does not warrant the performance or results you may obtain by using the software product. To the maximum extent permitted by applicable law, Econometric Software disclaims all other warranties and conditions, either expressed or implied, including, but not limited to, implied warranties of merchantability, fitness for a particular purpose, title, and non-infringement with respect to the software product. This limited warranty gives you specific legal rights. You may have others, which vary from state to state and jurisdiction to jurisdiction.

Limitation of Liability

Under no circumstances will Econometric Software be liable to you or any other person for any indirect, special, incidental, or consequential damages whatsoever (including, without limitation, damages for loss of business profits, business interruption, computer failure or malfunction, loss of business information, or any other pecuniary loss) arising out of the use or inability to use the software product, even if Econometric Software has been advised of the possibility of such damages. In any case, Econometric Software's entire liability under any provision of this agreement shall not exceed the amount paid to Econometric Software for the software product. Some states or jurisdictions do not allow the exclusion or limitation of liability for incidental or consequential damages, so the above limitation may not apply to you.

Table of Contents

E1: Econometric Model Estimation

E1.1 Introduction

The primary function carried out by *LIMDEP* is the estimation of econometric models. The first part of the documentation, the *Reference Guide* describes how to use *LIMDEP* to read a data set, establish the current sample, compute transformations of variables, and carry out other functions that get your data ready to use for estimation purposes. Several important tools, such as the matrix algebra program, scientific calculator and program editor are described there as well. This second part, the *Econometric Modeling Guide*, will describe specific modeling frameworks and instructions to be used for fitting these models. A large part of this documentation is devoted to descriptions of the models, themselves, including mathematical background. However, the presentation is (of necessity) not complete, and users are urged to supplement this documentation with the necessary background material for the models they are using.

The organization of this manual is by estimation framework, not by model command. We have found that users prefer that the program documentation be oriented toward the types of functions they want to perform, not to an alphabetical listing of commands. As such, you will find the arrangement of topics in this manual rather similar to the arrangement of topics in treatises in econometrics, such as Greene (2011). We begin with descriptive statistics in Chapters E2-E4, various linear regression models in Chapters E5-E8, and so on. To some degree, the complexity of the models deepens as this manual proceeds.

E1.2 Econometric Models

This manual is devoted primarily to the methods by which you can use *LIMDEP* to fit equations to data, to test hypotheses about the relationships implied by that estimation process, and to use the models for simulation and computation of useful partial effects. For purposes of documenting the program, we use the term 'model estimation' broadly, to encompass all those functions that involve manipulation of data to produce statistics to summarize the information the data contain. Thus, this manual begins with several chapters about computing descriptive statistics, which one might not normally consider model building. However, as data summaries, for program purposes, we consider these part of the model building functions in *LIMDEP*.

The definition of a 'model' in *LIMDEP* consists of the modeling framework, the statement of the variables in the model, and what role the variables will play in that model. The remainder of this chapter will describe in general terms how to use this format to construct model estimation commands in *LIMDEP*.

E1.3 Model Commands

LIMDEP's model commands all use the same format. The essential parts are as follows:

Model name ; model variables specification
; essential specifications for some models
; optional specifications $

The '**Model name**' designates the modeling framework. In most cases, this defines a broad class of models, such as **POISSON**, which indicates that the command is for one of the twenty or so different models for count data, most of which are extensions of the basic Poisson regression model.

The 'model variables specification' generally defines the dependent and independent variables in a model. In almost all cases, the model will include one or more dependent variables, denoted a Lhs, or 'left hand side' variable in *LIMDEP*'s command structure. Independent variables usually appear on the Rhs, or 'right hand side,' of a model specification. To continue our example, a Poisson model might be specified using

POISSON ; Lhs = patents ; Rhs = one,r_and_d $

which specifies one of the most well known applications of this model in economics. (The variable '*one*' is the constant term. We'll return to this below.) Some 'model' commands will have only one of these two specifications, such as

DSTAT ; Rhs = patents $

which requests descriptive statistics for the variable *patents*. As can be seen here, we use the term 'model command' broadly to indicate analysis of a set of data, whether for description or parameter estimation. Other model commands might have only a Lhs variable, such as

SURVIVAL ; Lhs = failtime $

which requests a nonparametric (life table) analysis of a variable named *failtime*. There are also many other types of variable specifications, such as

; Inst = a set of variable names

which will be used to specify the set of instrumental variables in the **2SLS** or **LIML** command.

Most models can be specified with nothing more than the model name and the identification of the essential variables. But, some models require additional specifications in order to be identified. For example, the specific model you want may be a particular case of a broad class of models and in order to specify it, you must provide the 'essential' specifications. For example, the basic command for survival modeling (with covariates to provide the 'model') would be

SURVIVAL ; Lhs = failtime ; Rhs = one,usehours $

This form of the command is for Cox's proportional hazard model. In order to fit a parametric model, such as the Weibull model, you would use

SURVIVAL ; Lhs = failtime ; Rhs = one,usehours
; Model = Weibull $

Note the last specification. This is the only way to specify a Weibull model, so for this model, this specification is essential. The Weibull model is requested as a type of survival model by this command. Obviously, not all models have mandatory specifications – the examples above do not. But, many do. The documentation in the chapters to follow will identify these.

Finally, all model frameworks have options which either extend the model itself or control how the model is estimated or how the estimation results are displayed. For example, the following fits a linear regression model and requests a robust estimator of the covariance matrix of the estimates:

REGRESS ; Lhs = profit ; Rhs = one,sales
; Heteroscedasticity consistent $

The latter specification does not change the model specification, it requests an additional computation, the White heteroscedasticity consistent estimator. For another example,

REGRESS ; Lhs = profit ; Rhs = one,sales
; Plot residuals $

fits a linear model and then plots the residuals. If the latter specification is omitted, the residuals will not be plotted.

In writing commands, there is a shortcut you may use either to shorten your commands or, in other cases, to include documentation in your commands. The form is as follows: Certain specifications are simply 'switches' in commands. Thus, in the two examples immediately above, the optional specifications merely request certain computations – the switch is 'off' until the specification turns it on. In specifications such as these, only the first three or more characters are sufficient to make the switch unique. Thus, the two examples above could be

REGRESS ; Lhs = profit ; Rhs = one,sales ; Het $
REGRESS ; Lhs = profit ; Rhs = one,sales ; Plot $

This applies to all 'switch – type' specifications, whether essential or optional.

Other specifications provide information as part of the sentence. In such a case, the provision will always be in the form

; Specification = information

For example,

; Wts = weighting variable name

will be used to specify a weighting variable for estimation. When a specification provides information after an equals sign, then the string must be in exactly the form shown for that command – you may not include superfluous text in this case. *LIMDEP* will always be looking for the equals sign in a specific place, and will issue a diagnostic when it does not find it. Thus, for the example shown,

; Wts variable = weighting variable

will produce an error message.

Model commands for *LIMDEP*'s models may become very long and complicated mixtures of many specifications. The language is fairly terse so as to be concise, but bear in mind that it is being used to specify several hundred different variations on over 50 broad model categories.

E1.4 The Command Builders

Nearly all of the documentation to follow, and most discussions, will assume that commands are being issued from a text editor (editing window), such as shown in the example below. The command is issued, that is, actually carried out, by highlighting it in the editing window and submitting it with the GO button. (See Chapter R2 for further discussion.)

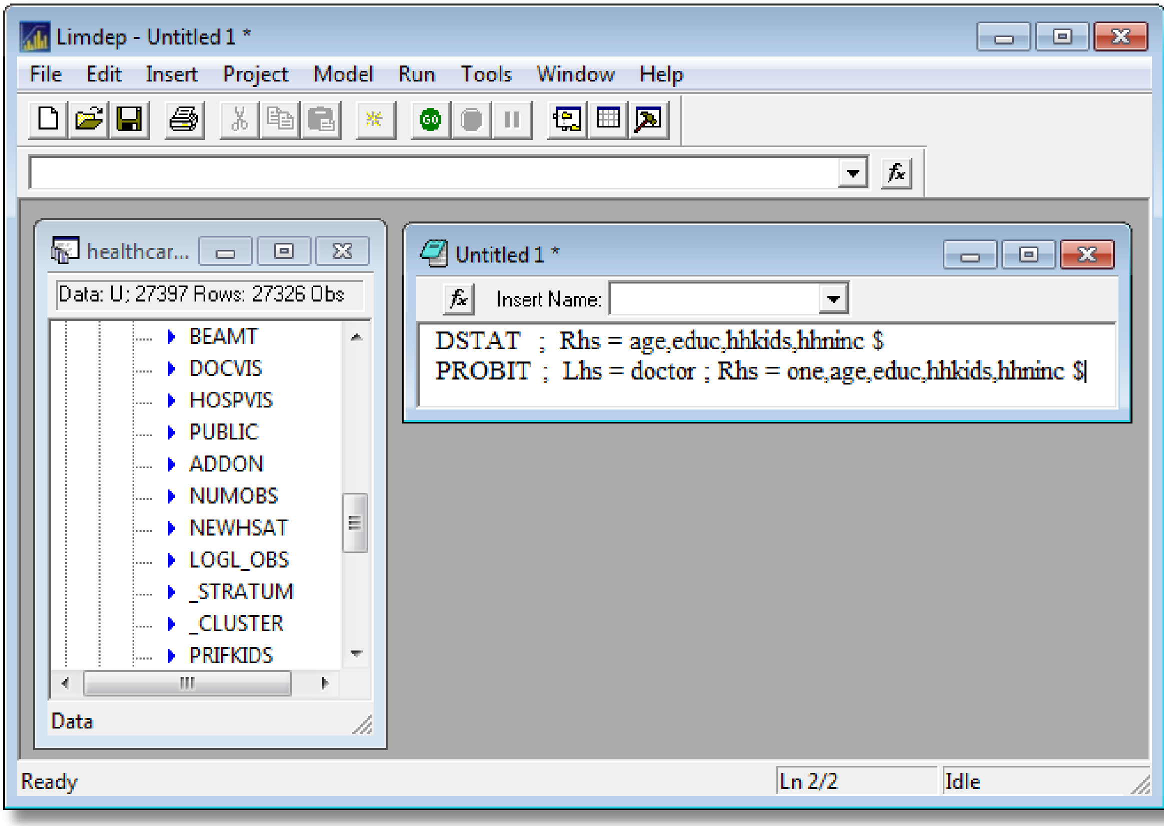

Figure E1.1 Desktop with Project and Editing Windows

An alternative method of submitting commands is to use the interactive dialog boxes, which, for reasons that will be evident shortly, we call the command builders. Command builders for model commands are produced by selecting Model in the main menu above the toolbar. This brings down the menu shown in Figure E1.2 which offers a number of groups of model frameworks. You may then select one of the groupings of models shown, to open a subsidiary menu of specific models. An example for the binary choice models is shown in Figure E1.2. You may then click a model name to open the command builder dialog box for that specific command. An example for the **PROBIT** command is shown in Figure E1.3.

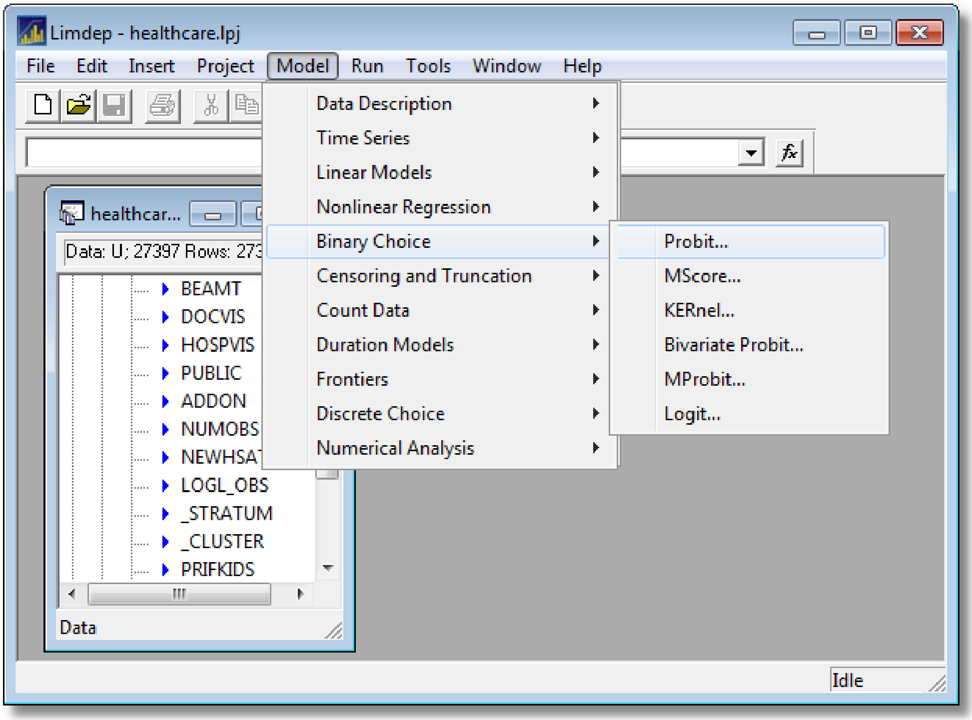

Figure E1.2 Model Choice from the Model Menu

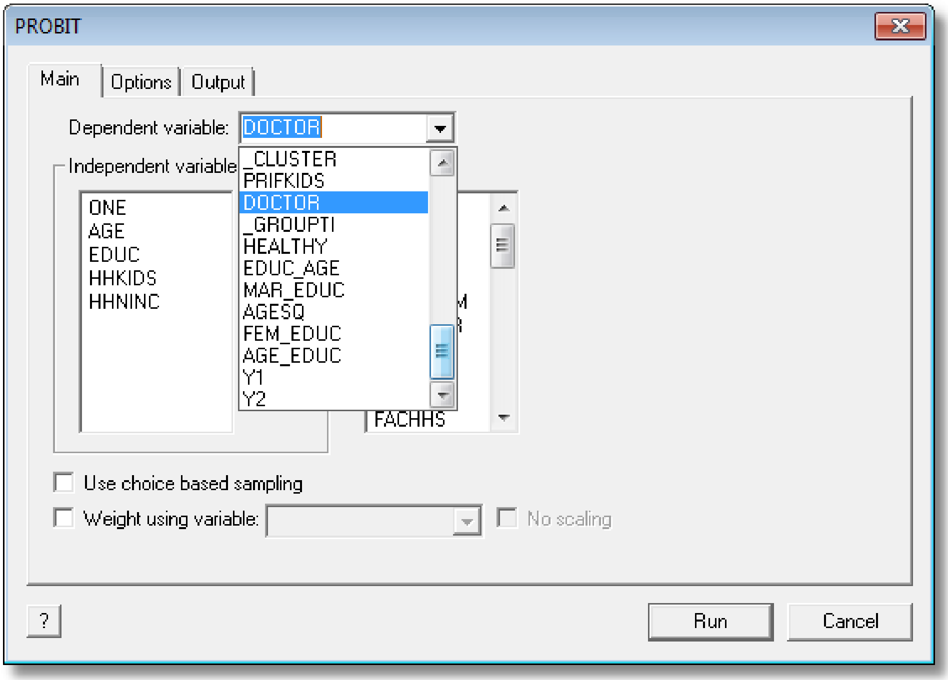

Figure E1.3 Main Page for Command Builder (PROBIT)

NOTE: The '?' button at the lower left of the command builder dialog box is a link to a context sensitive Help file that contains a large amount of information about the command.

The Main tab (or page) in the command builder dialog box requests the variables part of the commands. Note in Figure E1.3, we have selected the Lhs and Rhs variables that will appear in the probit model to be estimated. A few of the optional features will usually appear here as well, including, for example, a weighting variable. Other optional specifications are provided on the other pages of the command builder window. As can be seen in Figure E1.3, the probit model command builder has two additional pages. *Note, you must provide the essential variable parts of a command before you may enter the* Options *page. The command builder will insist on this.*

Once you have selected the model specification in the command builder window, click the Run to submit the command to *LIMDEP* for processing. This produces two results: First, the command is carried out, and the results appear in the output window, as would result in general when a model command is issued. Second, as its name implies, the command builder 'builds' the model command, and places a copy of it in the output window with the results. (See Figure E1.4.)

The first line of text above the output is the command generated by this selection in the window. You can copy these commands from the output window and paste them into the editing window, as we have done in our example in Figure E1.5. You might find this useful if you wish to modify the model and reuse the command. The editor will usually be more convenient. Note, as well, that the command interpreter will ignore the leading '-->' so there is no absolute need to edit these characters out of the editing window.

Figure E1.4 Output Window

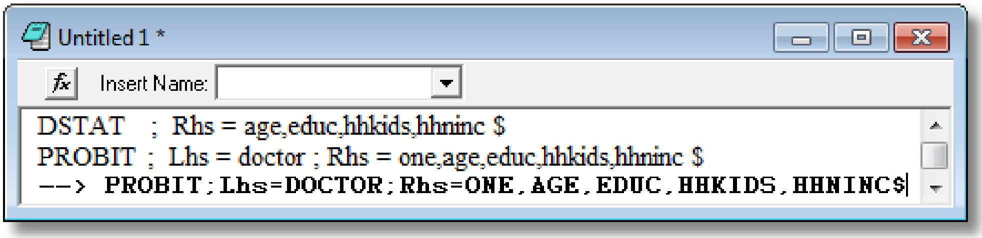

Figure E1.5 Detail from Editing Window

NOTE: The command builders are not complete. Some options and model forms must be specified with commands formed in the text editor. The command builders are intended generally for development of the more basic forms of the models and for relatively uncomplicated models. Not all optional features in all models are present in the command builder. Moreover, many of the model frameworks are not contained in the command builder menu. We anticipate that the command builders will be used by those who are becoming accustomed to using *LIMDEP*. After a relatively short introductory period, you will probably find the text editor more convenient than the command builders.

E1.5 Model Groups

The various model commands and modeling frameworks supported by *LIMDEP* and *NLOGIT* are discussed in the chapters to follow. The following are the model names for the different classes of estimators. Do note, some, such as **HISTOGRAM** and **BURR** are quite narrow, single purpose instructions, while others, such as **POISSON**, call for large classes of models that may (as in this case) contain a large number of different variants.

Data Setup and Model Preparation

NAMELIST	defines lists of variables for model commands (and matrices).
REVIEW	reviews model commands and create tables.
SORT	sorts variables.
SETPANEL	establishes parameters for panel data analysis.
IMPUTE	estimates imputation model for multiple imputation procedures.

Descriptive Statistics

CLASSIFY	discriminant analysis – classification into latent groups.
DSTAT	descriptive statistics.
TABLES	descriptive statistics for stratified data.

Cross Section

CROSSTAB	cross tabulations for discrete data.
HISTOGRAM	histograms for discrete and continuous data.
KERNEL	kernel density estimation of the density for a variable.

Time Series

IDENTIFY	descriptive statistics (ACF, PACF) for time series data.
SPECTRAL	spectral analysis of a time series.

Plotting

FPLOT	function plot for user specified function.
MPLOT	scatter plot of matrices.
PLOT	scatter or time plots of variables against each other.
SPLOT	simultaneous scatter plots for several variables.

Linear Regressions and Variants

Single Equation

FRONTIER	stochastic frontier models.
HREG	heteroscedastic linear regression based on Harvey's exponential model.
QREG	quantile regression.
REGRESS	linear regression models (also **OLSQ** and **CRMODEL**).
TSCS	time series/cross section, covariance structure models.
2SLS	two stage (instrumental variable) estimation of linear models.
LIML	limited information maximum likelihood estimation.
LOWESS	locally weighted nonparametric regression.

Multiple Linear Equation Models

SURE	linear seemingly unrelated regression models.
3SLS	three stage (IV, GLS) estimator for systems of linear equations.

Sample Selection Models

MATCH	propensity score matching to analyze treatment effects.
SELECT	sample selection models with linear and tobit models.
INCIDENTAL	incidental truncation (selection) model.
SWITCH	switching regression models.

Nonlinear Regression, Optimization, Manipulation of Nonlinear Functions

ARMAX	Box-Jenkins ARMA and dynamic linear equations.
BOXCOX	regression based on the Box-Cox transformation of variables.
NLSQ	nonlinear least squares for nonlinear regression models.
NLSURE	nonlinear systems of equations, SURE or GMM estimation.

Analysis of Nonlinear Functions

FINTEGRATE	function integration for user specified nonlinear function.
GMME	GMM estimation of model parameters.
MAXIMIZE	maximization of user specified functions.
MINIMIZE	user defined minimization command.
WALD	standard errors and Wald tests for user specified nonlinear functions.
SOLVE	finds roots of nonlinear functions.
FUNCTION	computes and displays function values.

Single Equation Models for Binary, Ordered and Multiple Discrete Choices

ARCTANGENT	arctangent model for binary choice.
BINARY CHOICE	simulation program for all binary choice estimators.
BIVARIATE	bivariate probit models, partial observability models.
BURR	Burr model for binary choice.
CLOGIT	multinomial logit model for discrete choice among multiple alternatives (*LIMDEP only – not used in NLOGIT*).
COMPLOG	complementary log log model for binary choice.
FRACRESP	fractional response model for panel data.
GOMPERTZ	Gompertz model for binary choice.
LOGIT	binary and multinomial choice models based on the logistic distribution.
MLOGIT	multinomial logit model.
MPROBIT	multivariate probit model.
MSCORE	maximum score semiparametric estimation for binary dependent variable.
NPREG	nonparametric regression models.
ORDERED	ordered probability models for ordered discrete choice.
PROBIT	several forms of binary choice models.
SEMIPAR	Klein and Spady semiparametric estimator for binary choice.

Models for Count Data

GAMMA	gamma model for count data.
NEGBIN	negative binomial regression model.
POISSON	models for count data.

Models for Censored Variables

BTOBIT	bivariate tobit models.
GROUPED	regression models for categorical censored data.
MIMIC	multiple indicators and multiple causes for a latent variable.
NTOBIT	nested tobit models.
TOBIT	censored regression models.

Models for Variables with Limited Range of Variation

LOGLINEAR	loglinear models, beta, gamma, Weibull, exponential, geometric, inverse Gaussian, arctangent, binomial.
LOGNORMAL	lognormal regression model.
TRUNCATE	truncated regression models.

Models for Survival Times and Hazard Functions

SURVIVAL	survival (hazard function) models.

Post Estimation Commands for Estimated Models

PARTIAL EFFECTS	analyzes average partial effects.
DECOMPOSE	Oaxaca-Blinder decompositions.
SIMULATE	simulation of outcome variables with estimated models.

E1.6 General Model Specifications

The preceding section listed the model commands that are used for estimation and data analysis. The various specifications that accompany the command are used to specify the basic model and to add certain optional features or model variations. Some of these are extremely general. For example, nearly every model command will contain a **; Lhs = variable(s)** specification to identify the dependent variable(s). In contrast, **; Cost** is used only by the frontier model command to request a cost (as opposed to a production) stochastic frontier model. Altogether, there are several hundred different specifications that attend the various model commands. The following list gives some of the most frequently used model specifications, in decreasing level of generality. Specialized codes, such as **; Cost** and **; DEA** for the frontier models are omitted here, and are detailed in the particular chapters for the specific models.

E1.6.1 Variable Specifications in Model Commands

These essential parts of model commands are described in Chapter R8.

; Lhs = names	specifies model dependent variable(s).
; Rhs = names	specifies model independent variable(s).
; Rh1 = names	provides first list of variables in two equation model.
; Rh2 = names	provides second list of variables in two equation model.
; Inst = names	provides list of instrumental variables.
; Wts = name	specifies a weighting variable; the optional parameter, [**,Noscale**] prevents scaling to sum to sample size.
; Hfn = names	provides a list of variables for variance in heteroscedasticity model.
; Hf1 = names,	**; Hf2 = names**, **; Hfu = names**, **; Hfe = names**, **; Hfr = names** are all used to provide lists of variables that appear in variance (heteroscedastic) functions.
; Eqn = names	is used in the SURE/3SLS, multivariate probit models to provide the lists of variables that appear in the set of equations. The '**n**' will be the number of the equation, as in **; Eq1 = list of variables**.

NOTE: The variable *one* is a program created variable that always equals 1.0. Use *one* to indicate a constant term in a model.

E1.6.2 Controlling Output from Model Commands

These optional features are described in the Chapter R9.

; Par	requests the program to keep ancillary parameters such as a correlation coefficient in the main results vector *b*.
; Partial Effects	requests display of marginal effects (same as **; Marginal Effects**).
; OLS	requests display of least squares starting values when (and if) they are computed.

; Clevel = value requests use of value for confidence level in confidence intervals in model results tables.
; Table = name requests the estimator to save model results to be combined later in output tables.
; Covariance Matrix requests display of the estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Matrix includes matrix forms as embedded objects in the output window.
; Quietly requests that model output not be displayed for this command.

E1.6.3 Robust Asymptotic Covariance Matrices

The clustering computation for robust covariance matrices is described in Sections R10.2 and E17.5. Choice based sampling is described at several points; a somewhat detailed discussion appears in Section E39.4. Robust estimation also appears in the discussion of several models. General discussion appears in Section E17.5.

; Choice requests the choice based sampling (sandwich with weighting) estimated matrix.
; Cluster = spec requests computation of the cluster form of corrected covariance estimator.
; Stratum = spec is used with **; Cluster** to specify a stratified, two level form of data clustering.
; Robust requests a 'sandwich' estimator or robust covariance matrix for TSCS and several discrete choice models.

E1.6.4 Optimization Controls for Nonlinear Optimization

These optional features are described in detail in Chapter R26.

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets the convergence value for convergence on the gradient.
; Tlf [= value] sets the convergence value for function convergence.
; Tlb[= value] sets the convergence value for convergence on change in parameters.
; Tln = value sets the convergence tolerance for nonlinear least squares.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Lpt = n sets the number of points to use for Laguerre quadrature.
; Hpt = n sets the number of points to use for Hermite quadrature.
; Set keeps current setting of optimization parameters as permanent.

E1.6.5 Predictions and Residuals

Fitted values (predictions) and residuals are described in Section R12.2.

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps the fitted values as a new (or replacement) variable in data set.
; Res = name	keeps the residuals as a new (or replacement) variable.
; Prob = name	saves the probabilities as a new (or replacement) variable for discrete choice models such as probit or logit.
; Fill	requests that missing values or values outside the estimating sample be replaced by fitted values based on the estimated model.

E1.6.6 Hypothesis Tests and Restrictions

These features are described in Chapter R13.

; CML: spec	defines a constrained maximum likelihood estimator.
; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; Rst = list	specifies equality and fixed value restrictions.

E1.6.7 Setup for Panel Data Models

LIMDEP contains an extremely large menu of panel data estimators. The set of controls listed below are used primarily with the nonlinear estimators for panel data. The data arrangement is described in Chapter R5 and in Section E15.2. Models may also have a two way structure, in which there is a time specific effect. Time effects are described in Sections E17.3 and E30.4. The controls listed below are discussed in numerous chapters and summarized with the estimators in Chapter E30.

Data Specification for Panel Data

SETPANEL	is the general command used to set up a panel.
; Pds = spec	is the general specification for panel data, either a fixed number of periods or a variable number given by the named variable.
; Time = spec	specifies the time dimension for two way fixed effects models.
; Periods = t	specifies a length of time (number of periods) for panel estimators.
; Str = name	specifies a stratification variable for **DSTAT, REGRESS, SURVIVAL**.

Panel Data Specifications in Nonlinear Modeling Frameworks

; FEM	specifies a fixed effects model.
; Fixed	when used, requests fixed effects. This is used by only two models, **LOGIT** and **REGRESS**. **; FEM** is used more generally. In **LOGIT**, **; Fixed** and **; FEM** request different estimators. Elsewhere, **; Fixed** and **; FEM** will be synonyms.
; Random	is the general request for random effects models.
; RPM	indicates a random parameters model used throughout *LIMDEP*. (Note, **; RPL** is a random parameters counterpart – random parameters logit model – that is used only in *NLOGIT*)
; LCM	requests a latent class model. It appears with **; Pts = number of classes**.
; Halton	is used with **; RPM** and **; RPL** to request Halton sequences.
; Cor	is used with **; RPM** and **; RPL** to request correlated random parameters.

E2: Descriptive Statistics for Cross Section and Panel Data

E2.1 Introduction

This chapter describes methods of obtaining univariate descriptive statistics for one or more variables in your data set. Procedures are given for cross sections and for panel data.

E2.2 Univariate Summary Statistics

The primary command for descriptive statistics is

DSTAT ; Rhs = list of variables $

This produces a table which lists for each variable, x_k, $k = 1,...,K$, the basic statistics:

Sample mean $= \bar{x}_k = \frac{1}{n}\sum_{i=1}^{N_k} x_{ik}$,

Standard deviation $= s_k = \sqrt{\frac{1}{N_k - 1}\sum_{i=1}^{N_k}\left(x_{ik} - \bar{x}_k\right)^2}$,

Maximum value,

Minimum value,

Number of valid (nonmissing) cases.

Standard deviations are computed in two steps, computing the means first, then the sums of squared deviations (rather than in the less accurate one step using the mean square minus the square of the mean).

E2.2.1 Weights

Weights may be used in computing all of the sums above by specifying

; Wts = name of weighting variable

Weights are always scaled so they sum to the current sample size. Thus, for example, the weighted mean would be

$$\bar{x}_k = \frac{1}{N_k}\sum_{i=1}^{N_k} w_{ik} x_{ik}$$

where $$w_{ik} = \frac{N_k z_{ik}}{\sum_{i=1}^{N_k} z_{ik}}$$

and z_i = the weighting variable.

E2.2.2 Missing Observations in Descriptive Statistics

In all cases, weighted or otherwise, sums are based on the valid observations. **DSTAT** automatically selects out the missing data. Most other models (save for those in *NLOGIT* 5 and most of the panel data estimators) do not routinely do so unless you have the **SKIP** switch set. (See Section R7.5.5.) Each variable may have a different number of valid cases, so the table of results gives the number for each one.

NOTE: The covariance and correlation matrices are based on the subset of observations for which there were no missing data for any variables. Each row in the table of results will list the number of valid cases used for that particular variable. Unfortunately, if different observations are missing for the various variables used in a covariance or correlation matrix, the union of the observations for which all variables are present can contain very few observations. For better or worse, this union is the set of observations used in computing the matrices.

If your data contain missing values, the scaling described in the previous section is automatically adjusted for each variable. Moments are scaled by the number of valid observations or sum of weights for that variable.

E2.2.3 Display of Descriptive Statistics

The standard display of results for descriptive statistics is shown in the example below for the Longley data (Longley.dat) displayed in Figure E2.1 as they are ready to be read into *LIMDEP*. The Longley data as well as the other sample data sets are located in the Data Sets book of the Help file and also in the C:\LIMDEP10\Data Files folder created with program installation.

Figure E2.1 Longley Data to Be Read from Text Editor

The command is

DSTAT ; Rhs = year,gnpdefl,gnp,armdforc,total,agr,nonagr $

Descriptive Statistics

Variable	Mean	Std.Dev.	Minimum	Maximum	Cases	Missing
YEAR	1954.50	4.76095	1947	1962	16	0
GNPDEFL	101.681	10.79155	83	116.900	16	0
GNP	387698.	99394.9	234289	554894	16	0
ARMDFORC	2606.69	695.920	1456	3594	16	0
TOTAL	65317.0	3511.97	60171	70551	16	0
AGR	6636.75	930.816	5190	8256	16	0
NONAGR	42819.6	2846.30	37922	46652	16	0

If weights have been specified with **; Sts = variable**, the title line of the table will declare the name of the weighting variable, for example ‘Descriptive Statistics (Weighted by POPULATN).’

E2.2.4 Command Builder Dialog Box

Select Model:Data Description/Descriptive Statistics to invoke the dialog boxes for this program. The Main page is shown in Figure E2.2. The various optional specifications available for the **DSTAT** command are provided on the Options page, as shown in Figure E2.3.

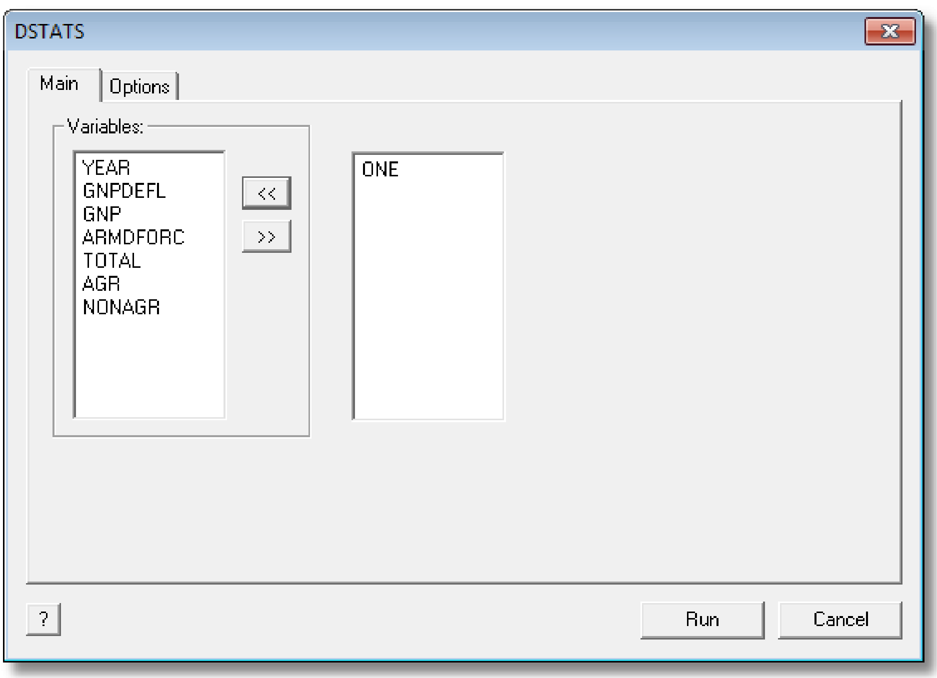

Figure E2.2 Command Builder Main Page for DSTAT

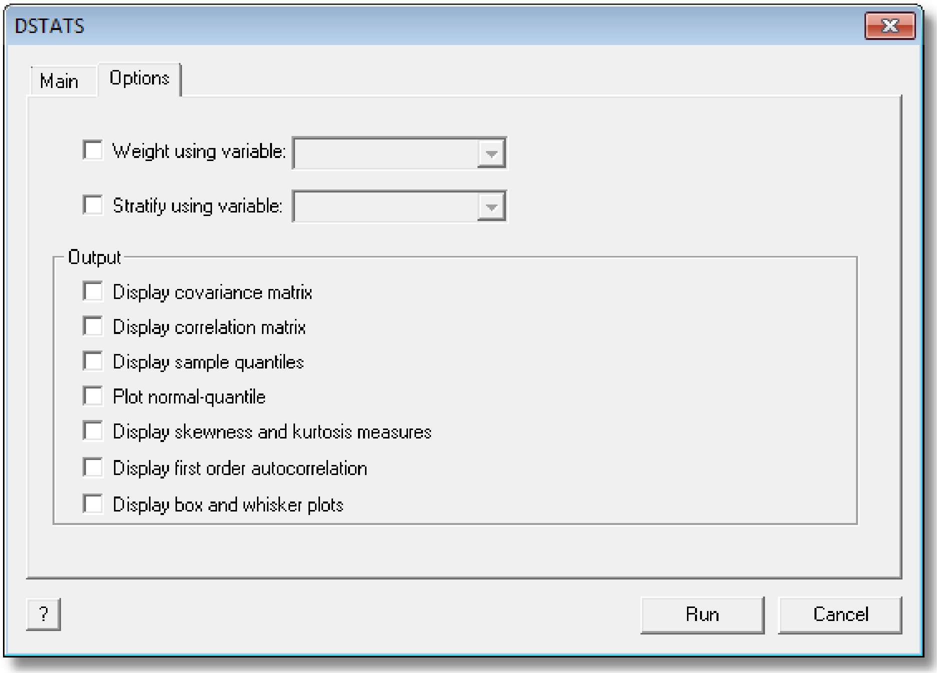

Figure E2.3 Command Builder Options Page for DSTAT

E2.3 Standard Error of the Mean

The sample mean reported in the standard table is purely descriptive. When the sample mean is viewed as an estimator of a population mean, it is customary to report the 'standard error,' as well. The estimate of the standard error of the mean is estimated with

$$s_{\bar{x}}(k) = \frac{s_x(k)}{\sqrt{N_k}}$$

where $s_x(k)$ is the standard deviation for x_k and N_k is the sample size. Request a display of the standard error of the mean with each variable by adding

; Sem

to the **DSTAT** command. This will also produce a listing of a confidence interval,

$$CI(k) = \bar{x}_k \pm z^*_{1-\alpha/2} s_{\bar{x}}(k)\ ,$$

where $z^*_{1-\alpha/2}$ is the critical value from the standard normal distribution. We do not assume that data are drawn from a normal population, so the normal rather than the t distribution is used for the confidence interval. If you wish to produce confidence intervals based on the t distribution with $N_k - 1$ degrees of freedom, rather than the normal, use

; Sem (t).

(Note that if the sample size exceeds 50, the *t* and normal distributions will be indistinguishable.) By default, the estimator produces a 95% confidence interval. You can change this with

; Clevel = value.

(See Section R9.1.1.) Partial results from the earlier example appear below.

```
Descriptive Statistics
--------+--------------------------------------------------------------------
Variable|     Mean       Std.Dev.     Minimum      Maximum        Cases Missing
--------+--------------------------------------------------------------------
    YEAR|  1954.50      4.76095         1947         1962            16       0
        | SE(mean) =    1.19024   95% CI = [  1952.16718,1956.83282  ]
 GNPDEFL|  101.681     10.79155           83      116.900            16       0
        | SE(mean) =    2.69789   95% CI = [    96.39349,106.96901   ]

        | SE(mean) =  711.57410   95% CI = [ 41424.90289,44214.22211 ]
--------+--------------------------------------------------------------------
```

E2.4 Clustered Data

When the sample mean is used as an estimator and the data are clustered as in a panel or sometimes in a stratified data set, then the standard error of the mean computed in the previous section will generally underestimate the true standard error of the estimator. The ‘cluster’ estimator is often used to produce a more robust estimator of the standard error. The alternative formulation used in this case is (after a bit of algebra)

$$s_{\bar{x}}^{c}(k) = \sqrt{\frac{1}{N_k}\sum_{c=1}^{C}\left(\sum_{i=1}^{N_c}\left(x_{ik,c} - \bar{x}_k\right)\right)^2}$$

where C is the total number of clusters indexed $c = 1,...,C$, N_c is the number of observations in cluster c. (There are no corrections for degrees of freedom). This calculation does not change the basic statistics; it modifies the computation of the standard error of the mean. This computation is requested by adding

; Cluster = specification

to the **DSTAT** command. (See Section R10.1 for details.) If the data set is such that the full population sizes are known and not (assumed to be) infinite, then one may specify a ‘finite population correction’ with

; FPC = the fixed number of clusters in the population from which the sample is drawn.

When you specify a finite population correction, you provide the known value for the total number of clusters in the population. The reported standard error of the mean is computed as the square root of

$$Corrected\ Variance[\overline{x}] = \left(1 - \frac{C}{C^*}\right)\left(\frac{C}{C-1}\right) s_{\overline{x}}^{c}(k)$$

The finite population correction is (1 – C/C^*). The population number of clusters is assumed to be infinite if you do not specify **; FPC =** ***C*** ***** for a particular value of C^*.

The example below is based on the German health care data used in numerous applications throughout the documentation. The data are from Riphahn, Wambach, and Million (2003). The raw data were downloaded from the journal's data archive website, http://qed.econ.queensu.ca/jae/2003-v18.4/riphahn-wambach-million, and are provided in the sample data file German-healthcare.dat. (The data files can be found in the resource folder created with installation: C:\LIMDEP10\Data Files.) The results show a comparison of the corrected and uncorrected estimates based on the health care panel data, which has 7,293 clusters ranging in size from one to seven.

DSTAT ; Rhs = hhninc ; Sem $

```
Descriptive Statistics
--------+-------------------------------------------------------------------
Variable|     Mean       Std.Dev.     Minimum      Maximum        Cases Missing
--------+-------------------------------------------------------------------
  HHNINC|    .35208       .17691            0      3.06710        27326       0
        | SE(mean) =     .00107   95% CI = [      .34999,.35418      ]
--------+-------------------------------------------------------------------
```

DSTAT ; Rhs = hhninc ; Sem ; Cluster = id $

```

```

E2.5 Skewness and Kurtosis

The third and fourth moments for the variables may be obtained with

DSTAT ; Rhs = list of variables
; All $

This requests the skewness and kurtosis measures,

$$\text{Sample skewness} \quad = m_3 = \frac{\sum_{i=1}^{N_k}(x_{ik} - \overline{x}_k)^3 / (N_k - 1)}{s_k^3},$$

$$\text{Sample kurtosis} \quad = m_4 = \frac{\sum_{i=1}^{N_k}(x_{ik} - \overline{x}_k)^4 / (N_k - 1)}{s_k^4}.$$

(This option may be combined with **; Sem** described in the preceding section.) Note that the higher moments are normalized by the standard deviations. This produces the comparison to the values for the normal distribution of zero and three, respectively. For the earlier example, we have

DSTAT ; Rhs = year,gnpdefl,gnp,armdforc,total,agr,nonagr
; All $

```

```

E2.6 Display Format

Three different formats are provided for display of descriptive statistics.

E2.6.1 Fixed Width Format

The default output display shown in the earlier examples is in a floating point format with integers displayed for the minimum and maximum if the variable is an integer. If your data contain extremely large or small values, you may prefer to change the display to scientific notation. Add

; Fixed

to the command to request a fixed with decimal format. For example,

DSTAT ; Rhs = year,gnpdefl,gnp,armdforc,total,agr,nonagr
; Fixed $

produces the following:

```
Descriptive Statistics
--------+--------------------------------------------------------------------
Variable|     Mean        Std.Dev.     Minimum      Maximum        Cases Missing
--------+--------------------------------------------------------------------
    YEAR|  .195450D+04  .476095D+01     1947         1962           16       0
 GNPDEFL|  .101681D+03  .107916D+02       83      .116900D+03       16       0
     GNP|  .387698D+06  .993949D+05   234289       554894           16       0
ARMDFORC|  .260669D+04  .695920D+03     1456         3594           16       0

Figure E2.5 Embedded Descriptive Statistics Matrix

E2.7 Stratified Data

DSTAT allows a stratification variable to be used to provide descriptive statistics for subgroups in the sample. A second command, **TABLES**, described in the next section, is provided to allow a convenient format for the results.

One full set of results is produced for each value of the stratification variable. Use

```
DSTAT       ; Rhs = list of variables
            ; Str = the stratification variable ... $
```

The variable must take values 1,2,... Up to 50 strata may be defined by the variable, which is assumed to be discrete. If a continuous variable is given instead, too many strata (each with one observation) will result, and an error will follow.

To specify ranges of a continuous variable, use

```
CREATE      ; Copy = the stratification variable $
RECODE      ; ... to create the discrete variable ... $
DSTAT       ; ... ; Str = the recoded variable $
```

The health care data provides an example. The following produces descriptive statistics for several variables for men, women, and the full sample.

```
CREATE      ; gender = female + 1 $
DSTAT       ; Rhs = age,educ,hhninc,married
            ; Str  = gender $
```

```

```

E2.8 Tables for Stratified Samples

The command for descriptive statistics for stratified data arranged in separate tables is

TABLES ; Rhs = list of variables
; Str = stratification $

This procedure is used to compute means and standard deviations for a stratified sample. As shown below, it differs from the **DSTAT** command described above in the format of the tables that it produces. You can use this procedure for stratified data in the same manner as described in the previous section. The command can specify any of three types of sample partitioning:

TABLES ; Rhs = up to 10 variables
; Pds = specification for groups in a panel data set
or **; Str = specification for strata as defined above $**

One of the two setups for a partitioned sample is used. The **; Pds** or **; Str** sets up the sample specification as if it were a panel data set (which it could, but need not be). The results will include for the full sample, then for each stratum or group in the sample, means, standard deviations, and sample sizes for each variable specified. The data set may contain up to 10,000 strata and up to 10 variables for this processor.

The data used in the preceding example are an unbalanced panel observed for seven years. To illustrate the **TABLES** command, we will produce a table for the seven years using the default format of the command.

TABLES ; Rhs = hhninc ; Str = year $

```
---------+------------------------------------------------------------
         | Means and Standard Deviations for Clustered  or Stratified Data
         | Variable  =  HHNINC       Weights for observations are 1.000000
         | Full Sample =   27326 data rows. Valid rows =    27326
         | Rows skipped (bad stratum or weight)       =        0
         | Sum of weights for all valid observations   =    27326.000
 Overall | Mean       Std Dev.   Sum of Weights   Sample  Missing    Total

---------+------------------------------------------------------------
```

The default names are *stratum*00 to *stratum*99 then *strat*0100 to *strat*9999. If you have a relatively small number of strata, you may wish to provide names for them in the results. You may provide names for the strata with the specification

; Labels = labels for strata.

If you provide fewer labels than there are strata, the names you provide are used for the first group of strata, and the default names are used for the remainder. For the preceding example, we could use

```
TABLES      ; Rhs = hhninc ; Str = year
            ; Labels = 1984,1985,1986,1987,1998,1991,1994 $
```

```

E2.8.1 Groups in the Sample

The general form of model commands allows you to partition the sample during the processing. See Section R8.7.3. To use that feature here to produce separate analyses for male and female headed households, we could use.

```
TABLES      ; For[female = 0,1] ; Rhs = age
            ; Str = year
            ; Labels = 1984,1985,1986,1987,1988,1991,1994 $
```

The results are as follows:

```
+------------------------------------------------------+
| Setting up an iteration over the values of FEMALE    |
| The model command will be executed for   2 values    |
| of this variable.  In the current sample of   27326 |
| observations, the following counts were found:       |
| Subsample   Observations    Subsample  Observations |
| FEMALE   =   0      14243    FEMALE  =   1     13083 |
+------------------------------------------------------+
| Actual subsamples may be smaller if missing values   |
| are being bypassed.  Subsamples with 0 observations |
| will be bypassed.                                    |
+------------------------------------------------------+
```

```

E2.8.2 Weights

The moments may be weighted with

; Wts = any kind of weights

Weights are handled the same as described earlier, but are now scaled appropriately for each stratum as well as by variable, again to account properly for missing observations.

E2.9 Sample Quantiles

You may obtain more detailed statistics about variables by requesting the sample quantiles. This feature produces sample order statistics and the deciles and quartiles of the sample of values for each variable. The keyword in the command is

; Quantiles

NOTE: The quantiles feature in **DSTAT** is limited to samples of 200,000 observations.

For an example based on our earlier results:

DSTAT ; Rhs = age,hhninc
; Quantiles $

```

E2.9.1 Box and Whisker Plots

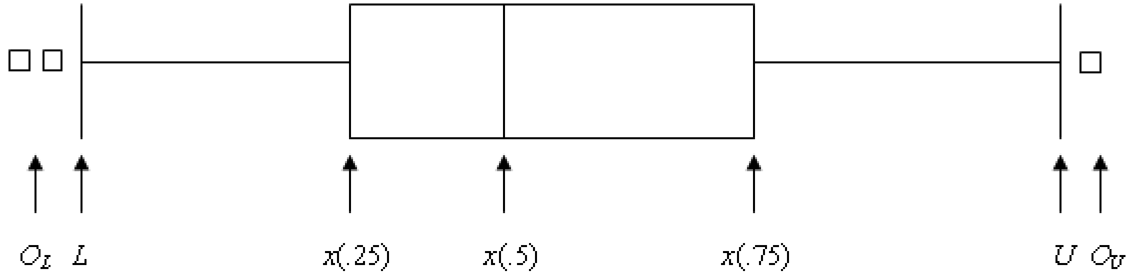
The box and whisker plot is a device used crudely to describe the location, range and skewness of a variable. *LIMDEP* will place up to five such plots in a figure. The function is requested simply by adding

; Box Plots

to the **DSTAT** command.

NOTE: Box and whisker plots can produce less than helpful, even absurd results when variables with very different scales are forced into the same figure. Figure E2.7 below suggests how the problem arises. Users are cautioned about this problem. There is no practical fix, other than to be sure that variables that are placed in the same figure have similar locations and scales.

Box and whisker plots are constructed (vertically in *LIMDEP*'s plots) for the variable x as follows:



$x(.5)$	=	the median of the sample values,
$x(.25)$	=	the 25^{th} sample percentile of the sample values,
$x(.75)$	=	the 75^{th} sample percentile of the sample values,
$x(.75) - x(.25)$	=	the interquartile range of x = the *IQR*,
L	=	the smallest sample value larger than $x(.25)$ - 1.5×*IQR*,
U	=	the largest sample value smaller than $x(.75)$ + 1.5×*IQR*,
O_L	=	sample values less than L marked as 'outliers,'
O_U	=	sample values greater than U marked as 'outliers.'

In the example below, box and whisker plots are produced for *age* and *educ* in the health care sample using

DSTAT ; Rhs = age,educ ; Box plots $

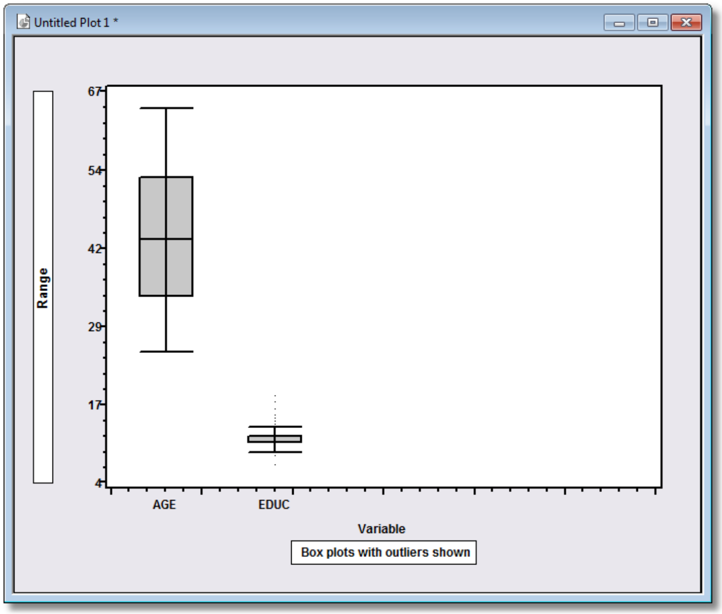


Figure E2.7 Box and Whisker Plots

E2.9.2 Related Procedures for Quantiles

There are four **CALC** functions provided for computing specific quantiles for a variable: Min(*variable*), Max(*variable*), Med(*variable*), and Qnt(*quantile*,*variable*). For example,

```
CALC        ; List
            ; Med(x) ; Qnt(0.50, x) $
```

will display the median of the sample of values on variable x (twice).

Two regression features based on quantiles are also available. The median regression is estimated by least absolute deviations (LAD). The LAD estimator is requested with

```
REGRESS     ; Lhs = dependent variable
            ; Rhs = independent variables
            ; Alg = LAD $
```

A more general program for quantile regressions is available with the **QREG** command,

```
QREG        ; Lhs = dependent variable
            ; Rhs = independent variables
            ; Qnt = the specific quantile $
```

The LAD results are reproduced with **; Qnt = .5**, but any other quantile may be specified instead. The LAD or median and quantile regressions are detailed in Section E9.3.

E2.10 Analysis of Variance and Panel Data

LIMDEP contains a wide variety of routines for analysis of panel data. Most of these are estimation programs for models that involve fixed or random effects specifications. Listed below is a set of functions and routines that can be used to produce descriptive statistics for a panel. In all cases, it is assumed that you have a stratification variable that takes values 1, 2, ..., G, where G is the number of groups of observations. The number of observations in each group is T_g. This is never required to be the same across groups. (See Section R5.3 for discussion of group indicators for panel data.)

E2.10.1 Analysis of Variance

One way analysis of variance is computed by regression of the variable to be analyzed on a complete set of group dummy variables. The command is

```
REGRESS     ; Lhs = the variable
            ; Rhs = one
            ; Str = the stratification variable
            ; Panel   $
```

If the number of observations is the same in every group, then you may dispense with the stratification variable and use

```
            ; Pds = the fixed number of observations
```

There are no other optional specifications for this command. The results produced are shown in the example below, where we analyze the income in the health care data set.

REGRESS ; Lhs = hhninc ; Rhs = one
; Pds = _groutppi
; Panel $ (We could use **; Str = id**.)

```

The preceding analysis of variance can also be obtained with

SETPANEL ; … to set up the panel $
DSTAT ; Rhs = the variable ; Panel $

E2.10.2 Matrix Functions for Describing Panel Data

These functions are used to compute statistics for columns of data which are stratified. For example, the variable *income* might contain time series of 10 yearly observations on average family income in each of the 50 states. The number of observations would then be 500. In order to use these commands, you must provide a stratification variable. Stratification variables are described at length in Section R5.3.

Each of the functions listed below creates a matrix with number of rows equal to the largest value found for your stratification indicator. For our example above, that would be 50 since there are 50 states and our indicator would (presumably) take values 1,...,50. However, these functions do not require that all values be present in the indicator. For example, suppose our statewide data did not include states 14, 21-29, and 36. Our indicator would take 39 distinct values, but the highest value would be 50. The matrices created here would have 50 rows, but 11 rows in each one would contain zeros (not -999s). For purposes of this discussion, we will call this maximum *G*, emphasizing that *G* is only the exact number of groups if your indicator takes all of the values 1,...,*G*.

NOTE: These functions automatically bypass missing data. If any variable shows -999, the observation is omitted from any sum. If the stratification indicator is missing, the entire group is bypassed.

The results are limited to the maximum size of a matrix, 50,000 cells. The commands produce different numbers of columns, so the number of groups which can be accommodated by these commands will differ somewhat. Thus, **MATRIX ; gs = Grps(i) $** could create a 4,500×5 matrix. This function creates a single column of length *G*.

Gsiz(*indicator*) = G×1 matrix of group sizes.

These functions require a namelist or a list of *K* variables. The matrices they create each have one column for each variable and *G* rows, one for each group.

Gxbr(*list, indicator*) = G×K matrix of group means,
Gsdv(*list, indicator*) = G×K matrix of group standard deviations,
Gmax(*list, indicator*) = G×K matrix of group maxima,
Gmin(*list, indicator*) = G×K matrix of group minima,
Gsum (*list, weight, indicator*) = G×K matrix of sums, weighted by the weight variable.

You must use a namelist in the Gsum(*list, weight, indicator*) function. You may follow the namelist with the names of some variables which are also to be summed, but not to be multiplied by the weighting variable. The following function requires a single variable and the indicator, and produces a five column matrix:

Grps(*variable, indicator*) = G×5 matrix,
Column 1 = group sizes,
Column 2 = group means,
Column 3 = group standard deviations,
Column 4 = group maxima,
Column 5 = group minima.

The Gxbr function can be used to compress a panel data set into a data set of group means that you can analyze with other statistical commands. You would do so as follows:

Step 1. Define the list of variables.

NAMELIST ; old = list of variables to be compacted $

Step 2. Give the replacement list. This step is not needed if the original data can be overwritten.

NAMELIST ; new = namelist for variables to be created $

Step 3. Set up the stratification indicator if it is not already in the data set.

CREATE ; i = whatever is appropriate $

Step 4. Get the matrix of means.

MATRIX ; means = Gxbr(old, i) $

Step 5. Move group means into the data area, and pick up the number of rows.

```
CALC      ; g = Row(means) $
CREATE    ; new =  means $
SAMPLE    ; 1 - g $
```

If necessary, you might want to drop observations with empty cells. You cannot do this by selecting on zero values for the group means, since 0.0 is a valid value for this variable. But, you can do this by computing the group sizes with the Gsiz function. For a small number of groups, you can look at the matrix directly to find the empty cells. For a large number of cells, you can use the following after you have set up the sample as shown above:

```
MATRIX    ; gsize  =  Gsiz(indicator) $
CREATE    ; newg =  gsize $
REJECT    ; newg =  0 $
```

Another common operation is to create a variable which repeats the group means of that variable for each observation in a group. You can easily to this with **MATRIX**, with

```
MATRIX    ; grpmeans= Gxbr(variable, i) $
CREATE    ; means = grpmeans(i) $
```

There is also a **CREATE** command that does the same thing,

```
CREATE    ; means = Group Mean(variable, Str = i ) $
```

E2.11 Discriminant Analysis

The command for carrying out a linear discriminant analysis is

```
CLASSIFY  ; Lhs = class stratification variable = 0 for out of sample
          ; Rhs = covariates $
```

This procedure carries out a 'discriminant analysis' for a set of observations on variables $x_1,...,x_K$. The sample is divided into G+1 groups of observations identified with known classification 1,...,G or classification unknown, the 'G+1 group.' The objective is to use the data with known classification to develop a rule which is then used to make a best guess as to the appropriate classification of the unclassified (class G+1) observations. Analysis is carried out as follows: For the data in the G groups, we have prior assignment probabilities

$$\Pi^0 = (\pi_1,..., \pi_G)^0$$

These represent the *prior* classification probabilities for each observation in the sample (i.e., given no information about the covariates is used). Under most circumstances, π_g will equal 1/G, indicating no specific prior information, though we allow for others if the user has specific values to provide. If the group sizes are unequal and not randomly so, then the group proportions, N_g/N, may be a preferable prior. Each observation also has an assignment to its specific group, y_{ig} which equals either 'g' or 0 if the assignment is unknown (and will be estimated here).

For the data in the *G* groups, we first compute mean vectors and covariance matrices,

$$\overline{\mathbf{x}}_g = \frac{1}{N_g}\sum_{i=1}^{N_g}\mathbf{x}_{ig}$$

$$\mathbf{S}_g = \frac{1}{N_g}\sum_{i=1}^{N_g}(\mathbf{x}_{ig} - \overline{\mathbf{x}}_g)(x_{ig} - \overline{\mathbf{x}}_g)'$$

For each observation *i* in group *g*, $\mathbf{x}_{ig}$, the 'distance measure' (Mahalanobis distance) from the center of each group *m* is

$$d_{ig|m} = (\mathbf{x}_{ig} - \overline{\mathbf{x}}_m)'\mathbf{S}_m^{-1}(\mathbf{x}_{ig} - \overline{\mathbf{x}}_m)\,.$$

The predicted assignment for all observations, including those without prior known classification, is the one with the smallest distance;

$$\hat{y}_{ig|m} = m \text{ such that } d_{ig|m} < d_{ig|j} \text{ for } m \neq j.$$

(Note that for observations with known classification, the rule can predict incorrectly.)

When unequal prior probabilities are provided, a refinement of the prediction rule uses the ex post (posterior) probabilities:

$$\hat{\pi}_{ig|m} = K\frac{exp(\text{-}.5(d_{ig|m} + |\mathbf{S}_g|))}{\pi_m^0}$$

(The leading scalar *K* is used to make the probabilities sum to one.) Then, the predicted classification is the one with the maximum posterior probability. Note that since the computations require the inverses of the group specific covariance matrices, the entire procedure breaks down if this cannot be computed for any group.

This calculation is requested with the command

CLASSIFY ; Lhs = class stratification variable = 0 for out of sample
; Rhs = covariates

with optional specifications:

; Wts = weighting variable, used as replications
; Keep = variable to use for classification result
; List = switch to request observation specific listing
; Labels = list of labels for groups to use in displays

The default calculation allows the covariance matrix to differ among the groups. Use

; Pooled

to specify that the distance measures should based on the single full sample covariance matrix, **S**, rather than $\mathbf{S}_g$ for the specific groups. You can also control the way the distance measure is computed, with

; Var = identity

to ignore the covariance matrix, and use, simply, the distance of $\mathbf{x}_{ig|m}$ from the mean in group m. In this case,

$$d_{ig|m} = (\mathbf{x}_{ig} - \overline{\mathbf{x}}_m)'(\mathbf{x}_{ig} - \overline{\mathbf{x}}_m) = \sum_{k=1}^{K} (x_{ig,k} - \overline{x}_{m,k})^2 .$$

You may, instead, just scale the variables without rotating them – in this instance, you would use only the diagonal elements of the covariance matrix. Use

; Var = diagonal

to employ

$$d_{ig|m} = (\mathbf{x}_{ig} - \overline{\mathbf{x}}_m)'[diag(\mathbf{S}_m)]^{-1}(\mathbf{x}_{ig} - \overline{\mathbf{x}}_m) = \sum_{k=1}^{K} \frac{(x_{ig,k} - \overline{x}_{m,k})^2}{S_{m,kk}^2} .$$

Finally, the priors are formulated as follows: If no prior probabilities are specified, then

$\pi_g^0 = 1/G$ (this is the default).

If you specify simply

; Priors

then $\pi_g^0 = N_g / \Sigma_g N_g$.

Finally, you may specify your own group of priors with

; Prior = a list of G values that must sum to one.

In the example below, there are four groups of 20 observations. We specified that the firms in the last group were unidentified. There are three variables analyzed, *i,f,c*. The command is

CLASSIFY ; Lhs = j ; Rhs = i,f,c ; List $

In the listing (which is abbreviated), a ‘*’ indicates a correctly predicted group identifier. Otherwise, ‘=P’ and ‘=A’ indicates the predicted and actual group, respectively. The prior and posterior probabilities are listed as well.

```

E2.12 Accuracy and the NIST Benchmarks

The National Institute of Standards and Technology (NIST) has compiled a set of accuracy benchmarks for statistical software, the *Statistical Reference Datasets* (StRD at http://www.itl.nist.gov/div898/strd/), which can be used for testing the accuracy of programs such as *LIMDEP*. There are (as of this writing) five sets of problems: univariate summary statistics, analysis of variance, linear regression, nonlinear regression and Markov Chain Monte Carlo estimation. The problems are designed to test different aspects of computation and present varying levels of difficulty. We will be presenting some of the test problems in this manual, primarily to verify the program accuracy, but also to demonstrate the variety of problems that they present. McCullough (1999) presents a detailed analysis of the datasets with several programs, including *LIMDEP*, and suggests a routine method of measuring accuracy. For the first three suites, as will be seen below, *LIMDEP* matches the NIST standard for all visible digits, so accuracy is not a consideration. Some of McCullough's analysis will be presented with the nonlinear least squares suite, where there is much more variation.

E2.12.1 NIST Benchmarks for Univariate Statistics

In the examples below, the source level NIST problem statement is presented with the *LIMDEP* solution to the problem. In some cases, only a few of the data observations are listed with the problem, so as to suggest their appearance. Many of the NIST datasets are included with the *LIMDEP* program, and can be found in the NIST Benchmarks book of the Help file and also in the C:\LIMDEP10\Command Files folder created with program installation. The full NIST datasets can be downloaded from the NIST website. The following shows two of the datasets from the univariate summary statistics suite. The first, the Maryland lottery problem is rated 'lower level of difficulty.' One of the problem sets in this suite, NumAcc4 (Numerical Accuracy #4) is rated 'Higher Level of Difficulty.' (This is the top of three levels in the suites.) This problem involves 1,001 observations (actually 500 occurrences each of 1.00000001 and 1.00000003, and one of 1.00000002. The certified values and *LIMDEP*'s results for this data set are shown below.

```
Dataset Name:  Maryland Pick-3 Lottery
Description:   This is an observed/"real world" data set
               consisting of 218 Maryland Pick-3 Lottery values
               from September 3, 1989 to April 14, 1990 (32 weeks).
               One 3-digit random number (from 000 to 999)
               is drawn per day, 7 days per week for most
               weeks, but fewer days per week for some weeks.
               We use these data here to test accuracy
               in summary statistics calculations.
Stat Category: Univariate: Summary Statistics

E3: Histograms and Kernel Density Estimators

E3.1 Introduction

This chapter describes methods of describing the empirical distribution of a variable. The tools provided are:

- Normal quantile plots to compare the empirical CDF to the normal distribution,
- Histograms for continuous data to describe the distribution,
- Histograms for discrete data to provide frequency counts and characterize the distribution,
- Kernel density estimators,
- Tests for normality based on moments (Bowman-Shenton) and on the CDF (Kolmogorov-Smirnov).

E3.2 Normal-Quantile Plots

A normal-quantile, or N-Q plot compares the within sample cumulative distribution of a variable to what would have been expected if the data were drawn from a normal population. The calculations are as follows:

1. Data on $x_1,...,x_n$ are sorted in ascending order into $x_{(i)}$.
2. For $i = 1,...,n$, compute $c_i = (i - .5)/n$, $t_i = \Phi^{-1}(c_i)$, $z_i = s_k t_i + \bar{x}_k$.

Thus, z_i is the counterpart to $x_{(i)}$ from the normal distribution with the same mean and standard deviation as the sample of *x*s. We then plot *x* and *z* against *z*. This produces a scatter plot plus a straight line (*z* vs. *z*). The larger the deviation of the scatter from the line, the greater the departure from normality. To obtain this additional output, add

; Plot

to the **DSTAT** command. An example based on the income variable in the health care data used earlier is shown in Figure E3.1. Income is highly skewed, so the large departure from normality in the left figure is to be expected. Taking logs of income or wealth variables usually renders them normally distributed, or at least approximately so.

DSTAT ; Rhs = hhninc, Log(hhninc) ; Plot $

The figure on the right suggests that the lower tail of the log of *hhninc* does not approximate normality very well.

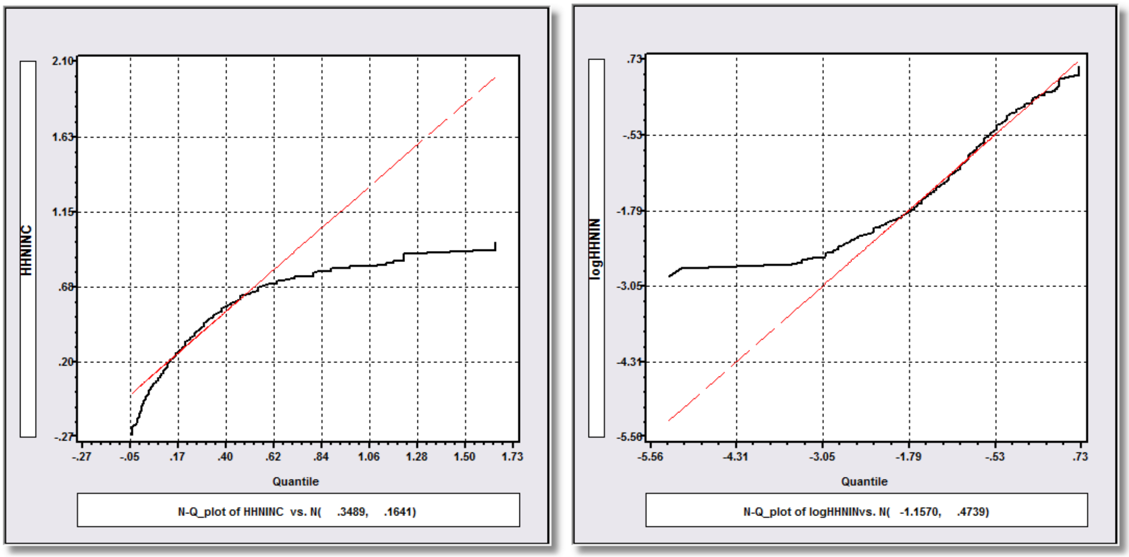

Figure E3.1 Normal-Quantile Plots

Figure E3.2 shows the appearance of an N-Q plot for a variable that is precisely normally distributed.

```
CREATE    ; z = Rnn(0,1) $
DSTAT     ; Rhs = z ; Plot $
```

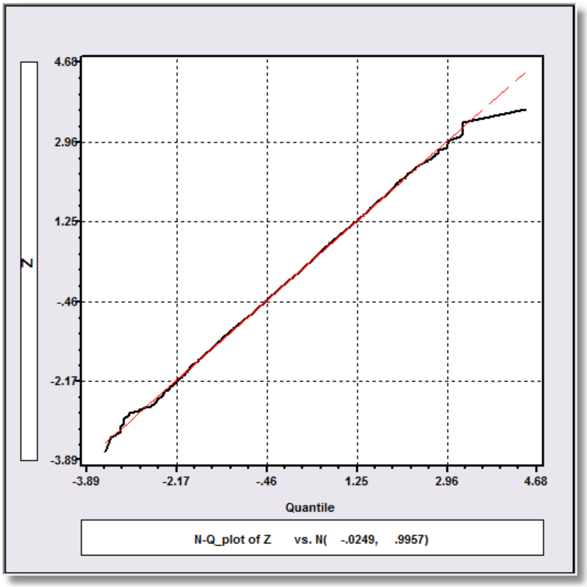

Figure E3.2 N-Q Plot for Normally Distributed Variable

E3.3 HISTOGRAM Command

The basic command for computing and plotting a histogram for a variable is

HISTOGRAM ; Rhs = the variable $

A title for the figure may be provided by using

; Title = ...< the desired title, up to 60 characters> ...

To use the command builder for the **HISTOGRAM** command, select Data Description from the Model menu, then select Histogram. The Main page of the **HISTOGRAM** command builder is shown in Figure E3.3.

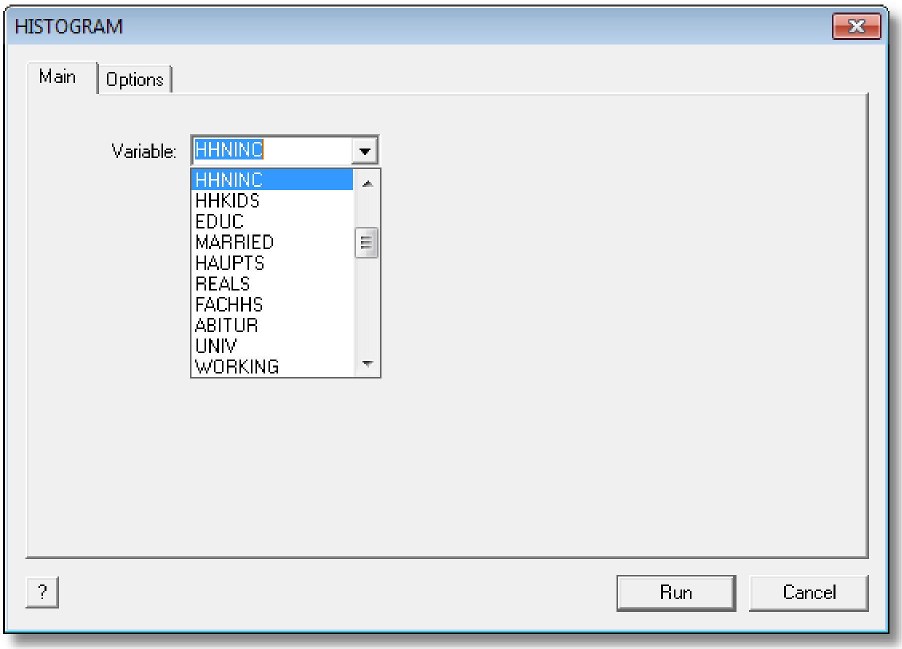

Figure E3.3 Main Page of Command Builder for HISTOGRAM

The Options page of the command builder for **HISTOGRAM** is shown in Figure E3.4.

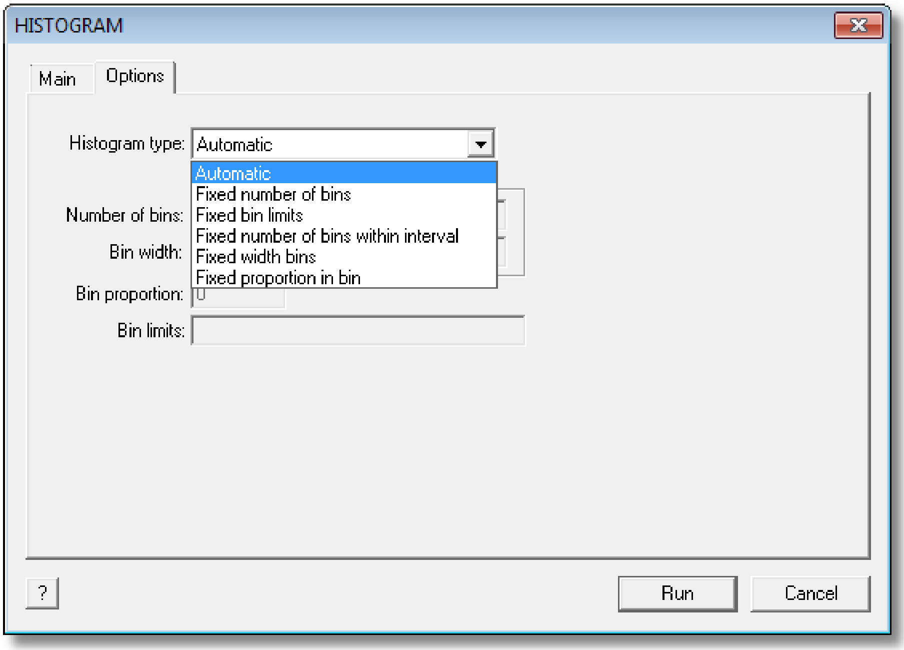

Figure E3.4 Options Page of Command Builder for HISTOGRAM

LIMDEP computes histograms for continuous and discrete (count) data. In the default figure for continuous data, the values are assigned to 40 equal width intervals over the range of the variable. (The number of and widths of the bins in the figure may be changed.) The histogram for continuous data provides a descriptive device to illustrate the distribution of the variable. (The kernel density estimator described in Section E3.6 may be better suited for this purpose.) The default figure for discrete data is a frequency count. Data are assumed to be coded 0,1,...,499. Values less than zero or greater than 499 are treated as out of range. A count of invalid observations is given with the output of the command. The histogram can be accompanied by a table listing the relative and cumulated frequencies.

To illustrate the use of this feature, we use the health care data set. (See Section E2.4.) The data, which will be used in several applications below, are an unbalanced panel of observations on health care utilization by 7,293 individuals. The group sizes in the panel number as follows: T_i: 1=1525, 2=1079, 3=825, 4=926, 5=1051, 6=1000, 7=887. There are altogether 27,326 observations. Some of the variables in the file are

hhninc	=	household nominal monthly net income in German marks / 10000.
hhkids	=	children under age 16 in the household = 1, otherwise = 0,
educ	=	years of schooling
married	=	marital status
female	=	1 for female, 0 for male
docvis	=	number of visits to the doctor
doctor	=	number of doctor visits > 0
hospvis	=	number of visits to the hospital

E3.4 Histograms for Continuous Data

A histogram for the continuous variable *hhninc* would appear as shown in Figure E3.5:

HISTOGRAM ; Rhs = hhninc $

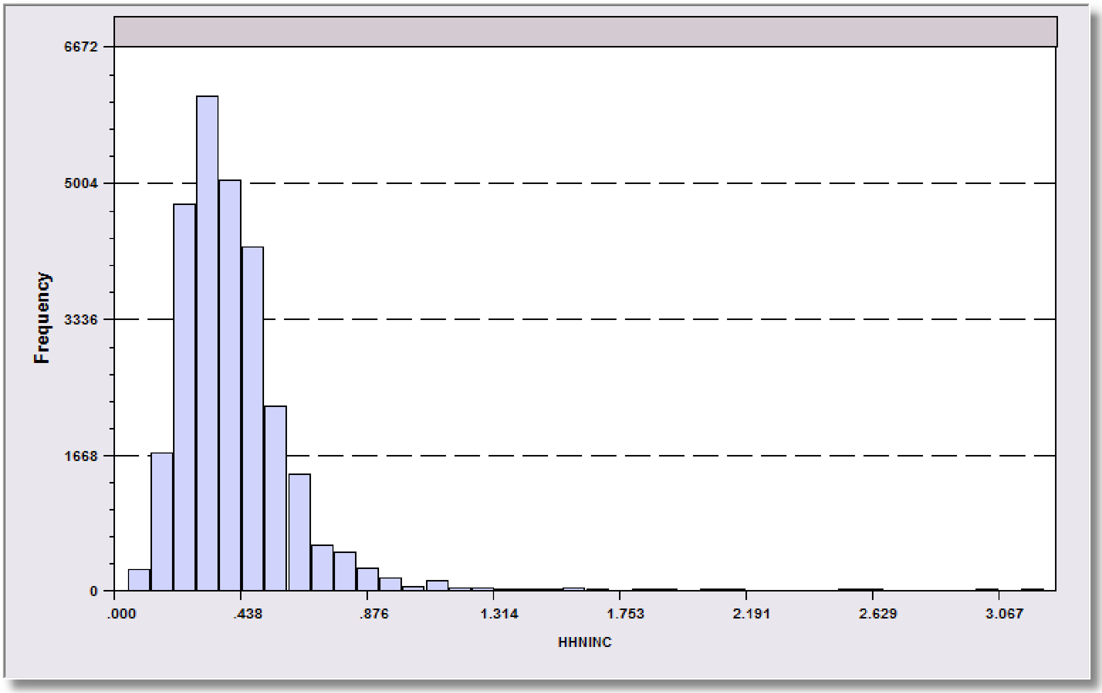

Figure E3.5 Histogram for a Continuous Variable

The displayed output from this command consists only of the figure containing the histogram. You can request a listing of the bin boundaries and frequency counts by adding

; List

to the **HISTOGRAM** command. The listing below would be produced for this histogram.

```
Histogram for HHNINC    NOBS =   27326, Too low:     0, Too high:     0
Bin is defined as Lower <= X < Upper.
Bin  Lower limit   Upper limit       Frequency     Cumulative Frequency
========================================================================
  0        .000          .767        252 ( .0092)         252( .0092)
  1        .767         1.534       1683 ( .0616)        1935( .0708)
  2       1.534         2.300       4725 ( .1729)        6660( .2437)
  3       2.300         3.067       6062 ( .2218)       12722( .4656)
  4       3.067         3.834       5023 ( .1838)       17745( .6494)
  5       3.834         4.601       4208 ( .1540)       21953( .8034)
  6       4.601         5.367       2253 ( .0824)       24206( .8858)
  7       5.367         6.134       1414 ( .0517)       25620( .9376)
  8       6.134         6.901        554 ( .0203)       26174( .9578)
  9       6.901         7.668        454 ( .0166)       26628( .9745)
 10       7.668         8.435        264 ( .0097)       26892( .9841)
 11       8.435         9.201        154 ( .0056)       27046( .9898)
 12       9.201         9.968         37 ( .0014)       27083( .9911)
 13       9.968        10.735        110 ( .0040)       27193( .9951)
 14      10.735        11.502         26 ( .0010)       27219( .9961)
 15      11.502        12.268         34 ( .0012)       27253( .9973)
 16      12.268        13.035         15 ( .0005)       27268( .9979)
 17      13.035        13.802          5 ( .0002)       27273( .9981)
 18      13.802        14.569          9 ( .0003)       27282( .9984)
 19      14.569        15.336         21 ( .0008)       27303( .9992)
 20      15.336        16.102          2 ( .0001)       27305( .9992)
 21      16.102        16.869          0 ( .0000)       27305( .9992)
 22      16.869        17.636          1 ( .0000)       27306( .9993)
 23      17.636        18.403          2 ( .0001)       27308( .9993)
 24      18.403        19.169          0 ( .0000)       27308( .9993)
 25      19.169        19.936          2 ( .0001)       27310( .9994)
 26      19.936        20.703          8 ( .0003)       27318( .9997)
 27      20.703        21.470          0 ( .0000)       27318( .9997)
 28      21.470        22.236          0 ( .0000)       27318( .9997)
 29      22.236        23.003          0 ( .0000)       27318( .9997)
 30      23.003        23.770          0 ( .0000)       27318( .9997)
 31      23.770        24.537          2 ( .0001)       27320( .9998)
 32      24.537        25.304          1 ( .0000)       27321( .9998)
 33      25.304        26.070          0 ( .0000)       27321( .9998)
 34      26.070        26.837          0 ( .0000)       27321( .9998)
 35      26.837        27.604          0 ( .0000)       27321( .9998)
 36      27.604        28.371          0 ( .0000)       27321( .9998)

 38      29.137        29.904          0 ( .0000)       27322( .9999)
 39      29.904        30.671          4 ( .0001)       27326(1.0000)
```

E3.4.1 Fixed Number of Bins

You can select the number of bars to plot with

; Int = k

This can produce less than satisfactory results, however. For the example above, we add

; Int = 10

to obtain the following:

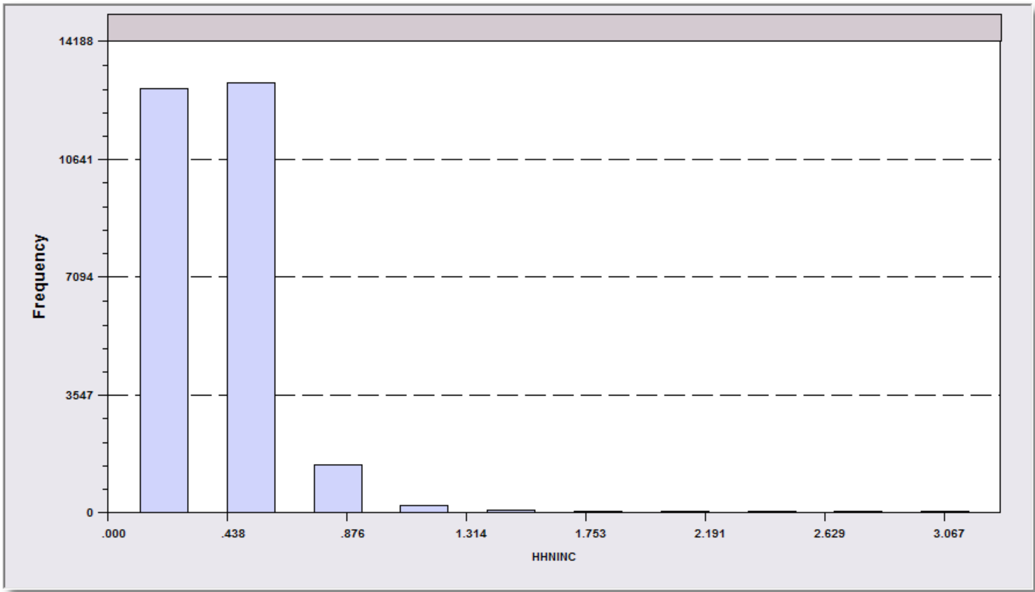

Figure E3.6 Histogram with Fixed Number of Bins

The problem is that the skewness of the income distribution has placed many observations out in the right tail. In order to accommodate them, *LIMDEP* has created several bins that have few observations in them. Fixing the number of bins may also cause some observations of a discrete variable to be out of range if you have values that exceed *K*-1. (The values for *K* intervals are 0,1,...,*K*-1.) For continuous variables, this specification requests that the range of the variable be divided into *K* equal length parts. Obtaining a satisfactory representation of the distribution may take some experimentation. For the preceding application, using 100 bins instead of 10 produces the results in Figure E3.7, which seems reasonable.

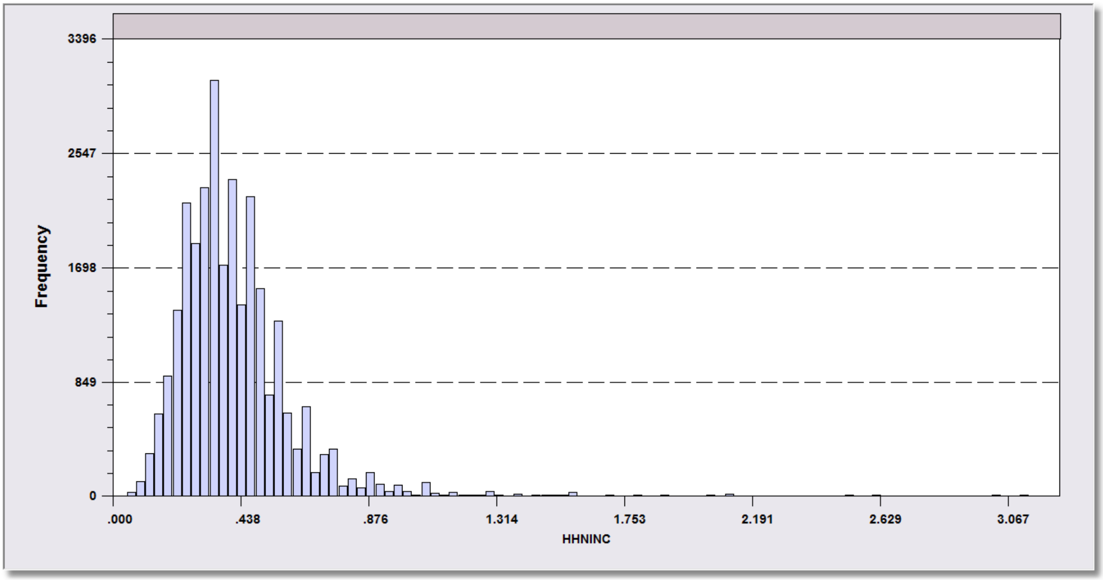

Figure E3.7 Histogram for Household Income

E3.4.2 Trimming Data for Histograms

The figure is still being substantially influenced by the long thin tail of the distribution. By trimming the extreme observations, the figure can sometimes be improved. Figure E3.8 shows the result. We have also added a title to the figure

HISTOGRAM ; If [hhninc <= 1.6] ; Rhs = hhninc
; Int = 50
; Title = Household Income (Trimmed: Less than 1.6) $

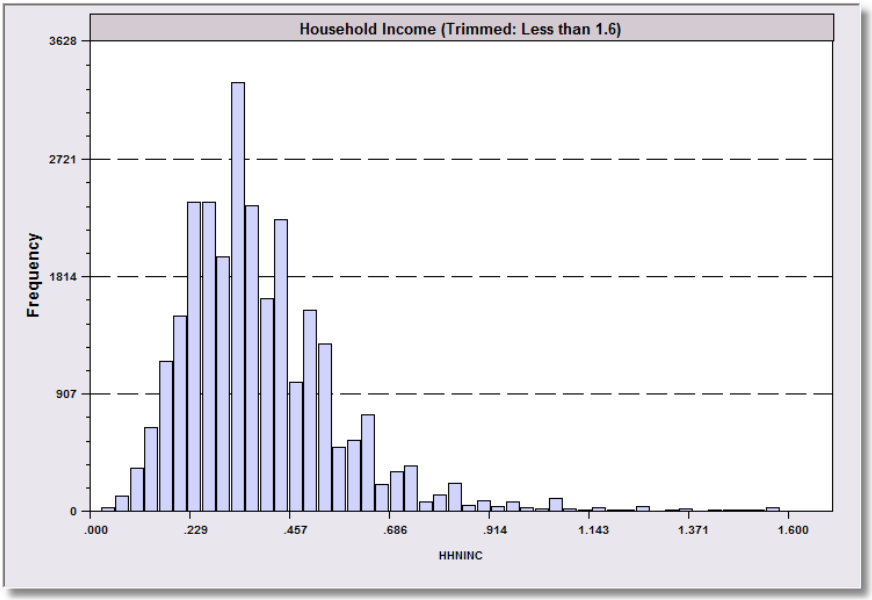

Figure E3.8 Histogram for Trimmed Data

E3.4.3 Fixed Bin Limits

There are other ways to examine continuous data. One way is to use **RECODE** to change your continuous variable into a discrete one. Alternatively, you may provide a set of interval limits and request a count of the observations in the intervals you define. The command would be

HISTOGRAM ; Rhs = variable ; Limits = l0,l1,...,lk $

where the limits you give are the left boundaries of the intervals. Thus, the number of limits you provide gives the number of intervals. Intervals are defined as 'greater than or equal to lower' and 'less than upper.' With this specification, the rightmost upper limit is +∞. For example, still using our income data,

HISTOGRAM ; Rhs = educ ; Limits = 8,10,12,14,16,18 $

defines six bins for the histogram, with the rightmost containing all values greater than or equal to 18. The result appears in Figure E3.9.

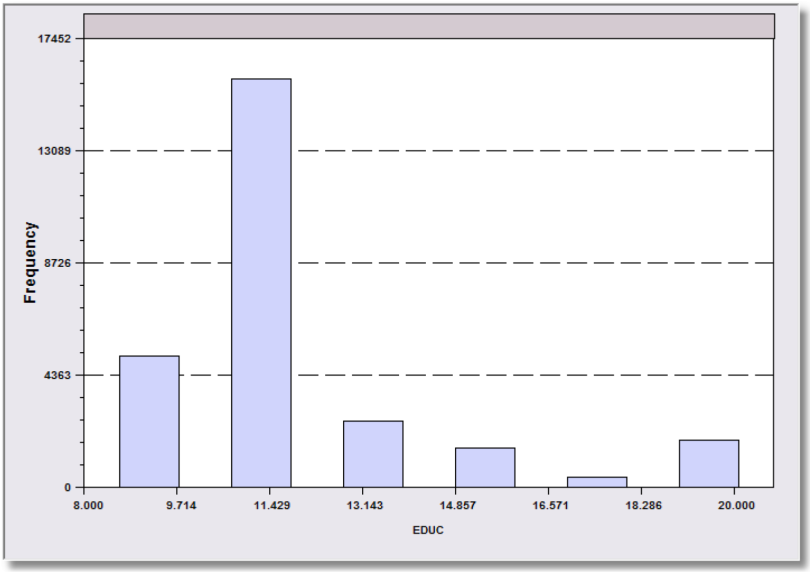

Figure E3.9 Histogram with Fixed Bin Limits

If you wish to avoid having data discarded, provide a very large negative value (-1.D10) for the lowest limit – the highest interval is assumed to be open. Otherwise, observations lower than the lowest value in the list are treated as out of range.

E3.4.4 Fixed Number of Bins in a Range

To request *K* equal length intervals in the range *lower* to *upper*, use

HISTOGRAM ; Rhs = variable ; Int = k ; Limits = lower,upper $

We'll use this device to remove some of the long tail of the income distribution.

HISTOGRAM ; Rhs = hhninc ; Int = 20 ; Limits = 0, 1.2 $

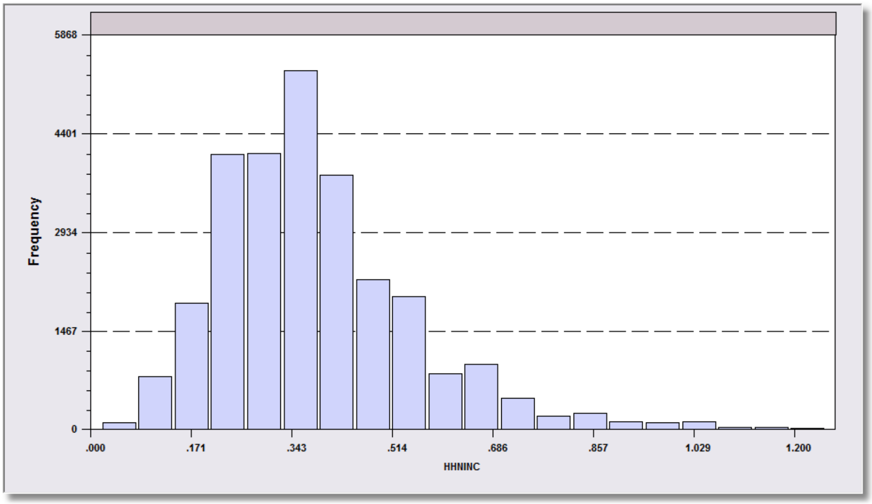

Figure E3.10 Histogram with Fixed Number of Bins in a Specified Range

E3.4.5 Fixed Width Bins in a Range

To specify both the range of variation and the fixed width of the bins, use

HISTOGRAM ; Rhs = variable ; Limits = lower (width) upper $

For example,

HISTOGRAM ; Rhs = hhninc ; Limits = 0 (.05) 3 $

specifies bins [0,.05), [.05,.10), … [2.95,3.00].

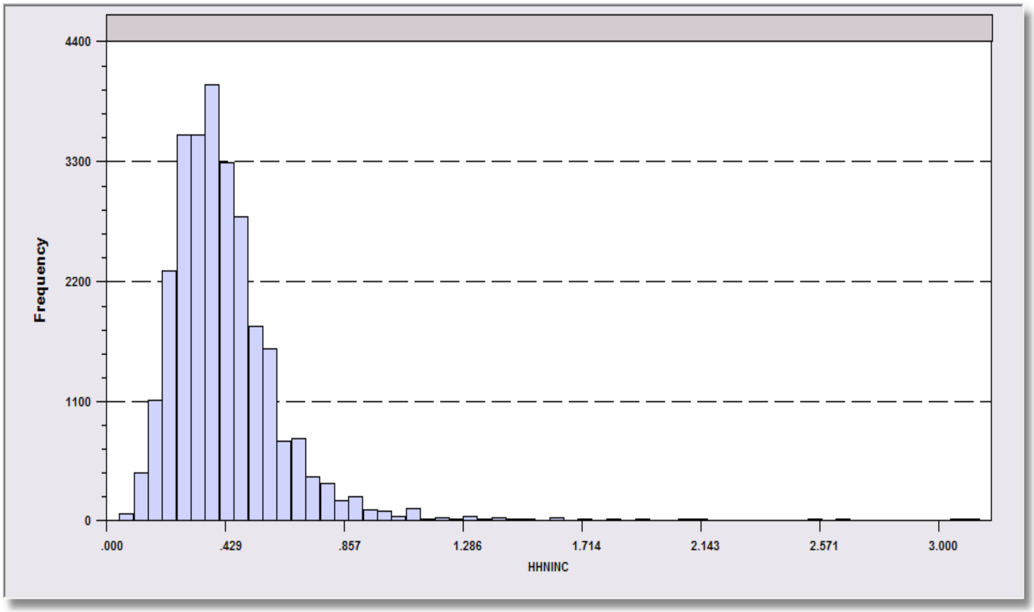

Figure E3.11 Histogram with Fixed Width Bins in a Specified Range

It is possible that the range given does not produce an even number of fixed width bins. In this case, the rightmost bin is shortened to use the remaining range. For example, in the preceding, if the .05 were .07, then there would be a narrow bin at the right; the 43rd bin would be from 2.94 to 3.00

E3.4.6 Fixed Interval Widths

Alternatively, you can specify the width of the interval, and allow the program to determine the number. Do so with

HISTOGRAM ; Rhs = variable ; Width = the desired value $

For example, the histogram for *hhninc* computed earlier could be obtained with

HISTOGRAM ; Rhs = hhninc ; Width = 0.05 $

E3.4.7 Fixed Proportion of Observations in Each Bin

NOTE: If this specification results in more than 499 intervals, a diagnostic will result.

Finally, you can use **HISTOGRAM** to search for the interval limits instead of the frequency counts. The command

HISTOGRAM ; Rhs = variable ; Bin = p $

where '*p*' is a sample fraction (proportion), will obtain the interval boundaries such that each bin contains the specified proportion of the observations.

NOTE: If the specified proportion does not lead to an even set of bins, then an extra, smaller bin is created if the remaining proportion is more than $p/2$. For example, if p is .22, there will be four bins with .22 and one at the right end with .12. But, if the extra mass is less than $p/2$, it is simply added to the rightmost bin, as for p = .16, for which the sixth bin will contain .2 of the observations.

E3.4.8 Comparison to a Normal Distribution

A common exercise is to compare the distribution of a sample to a normal distribution. Add

; Normal

to the **HISTOGRAM** command to produce a normal density superimposed on the histogram. The normal distribution plotted has the same mean and standard deviation of the data. The normal density is plotted within the range of the data. If the sample data are skewed or have extreme observations, this may result in a truncation of the normal distribution. Figure E3.12 shows an example. The data are trimmed to produce the figure. The command is

```
HISTOGRAM ; If [hhninc <= 1.6]
          ; Rhs = hhninc
          ; Int = 50
          ; Title = Household Income (Trimmed: Less than 1.6)
          ; Normal $
```

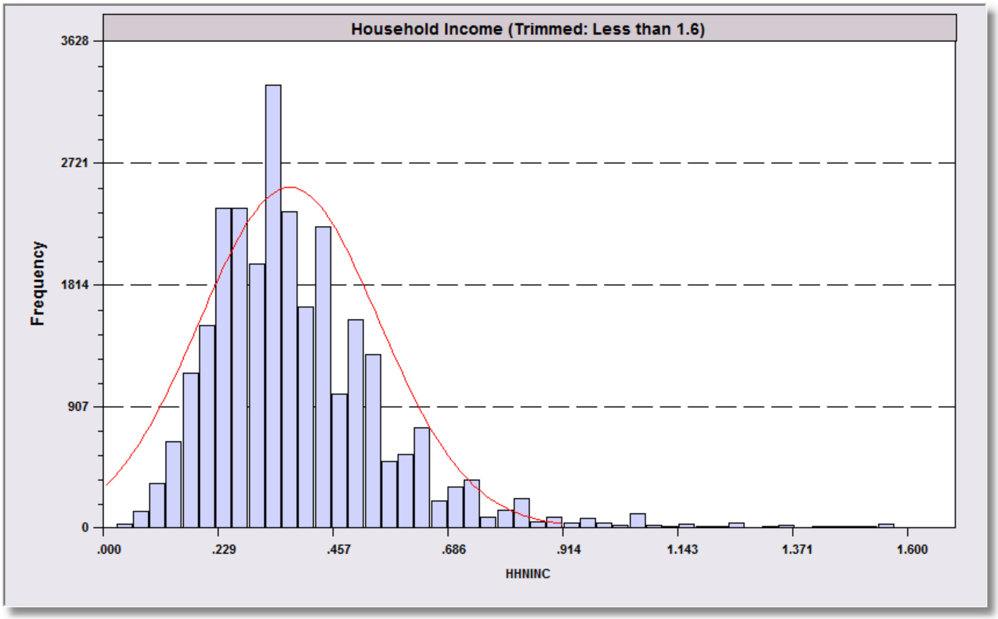

Figure E3.12 Histogram with Normal Distribution

E3.5 Histograms for Discrete Data

The data are first inspected to determine the type and the correct number of bars to plot for a discrete variable. For a discrete variable, the plot can be exact. Up to 500 bars may be displayed: For example, the count of doctor visits in the health care data appear as follows:

HISTOGRAM ; Rhs = docvis
; Title = Number of Doctor Visits $

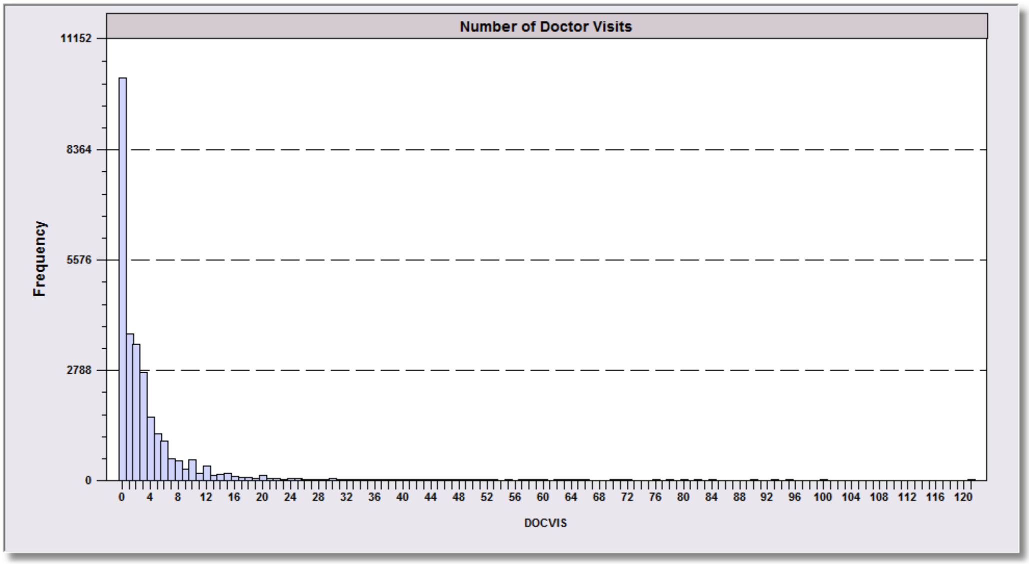

Figure E3.13 Histogram for a Discrete Variable

The long tail of the skewed distribution has rather distorted the figure. The options described earlier can be used to modify the figure. However, those options are assumed to be used for continuous data, which would distort the figure in another way. A more straightforward way to deal with the preceding situation is to operate on the data directly. For example,

```
HISTOGRAM ; If [docvis <= 25]
          ; Rhs = docvis
          ; Title = Number of Doctor Visits $
```

truncates the distribution, but produces a more satisfactory picture of the frequency count.

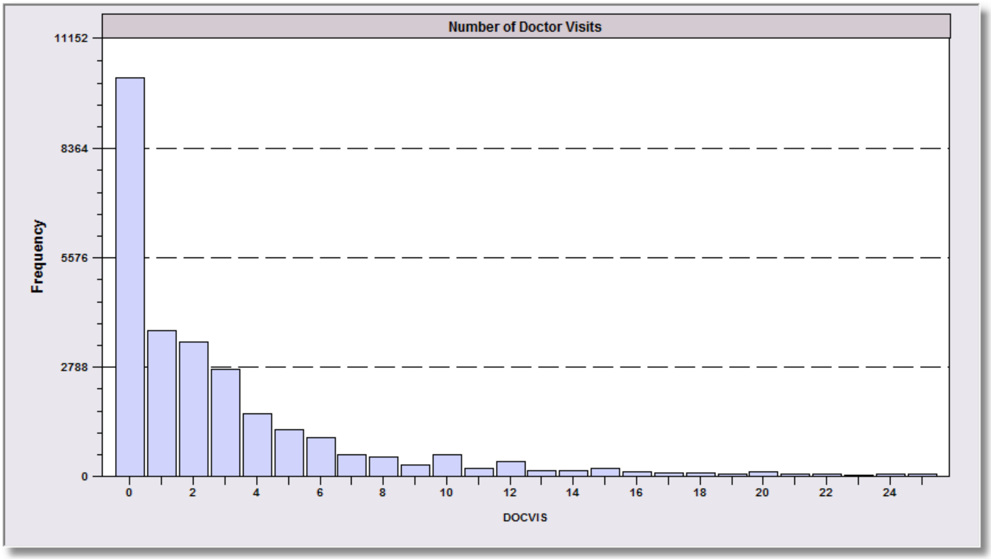

Figure E3.14 Histogram for a Truncated Discrete Distribution

E3.5.1 Bin Labels Scaled to Sample Proportions

Proportions instead of raw frequencies may be plotted by using

; Proportions

The plot is now sample proportions instead of raw frequencies. This affects the labeling of the figure but not its appearance – it will now resemble the density for the variable being plotted. For example, with this option, Figure E3.14 becomes E3.15. Note, the sum of the relative proportions shown in the figure equals 1.0. However, the bars are not scaled to make the areas sum to one.

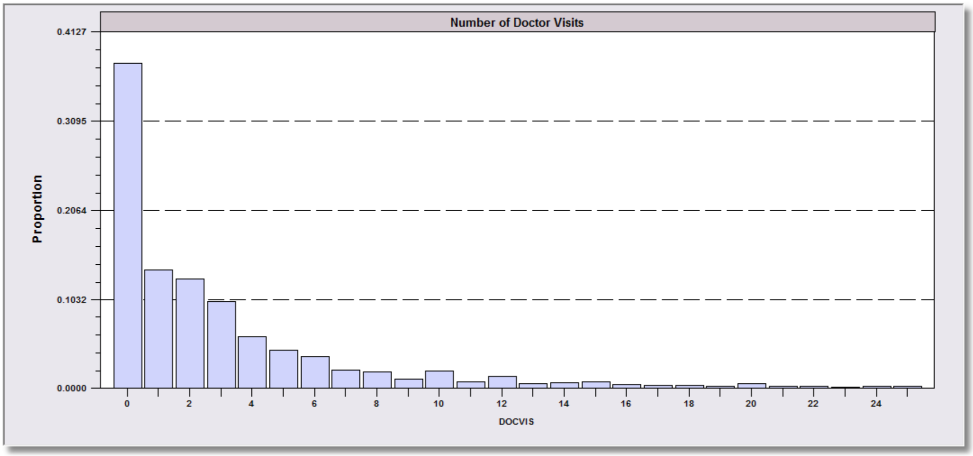

Figure E3.15 Histogram with Relative Frequencies

E3.5.2 Multiple Histograms

To plot up to four histograms in one figure, use

HISTOGRAM ; Rhs = var1, var2 (up to 4) ; All $

An example is shown below in Figure E3.16. Note that if **; All** is omitted, a separate histogram is produced for each variable. Multiple histograms are limited to 40 bins, Figure E3.16 shows a histogram for the two count variables of interest in the health study.

HISTOGRAM ; If [docvis <= 20 & hospvis <= 20] ; Rhs = docvis,hospvis ; All
; Title = Histogram for Hospital Visits and Doctor Visits $

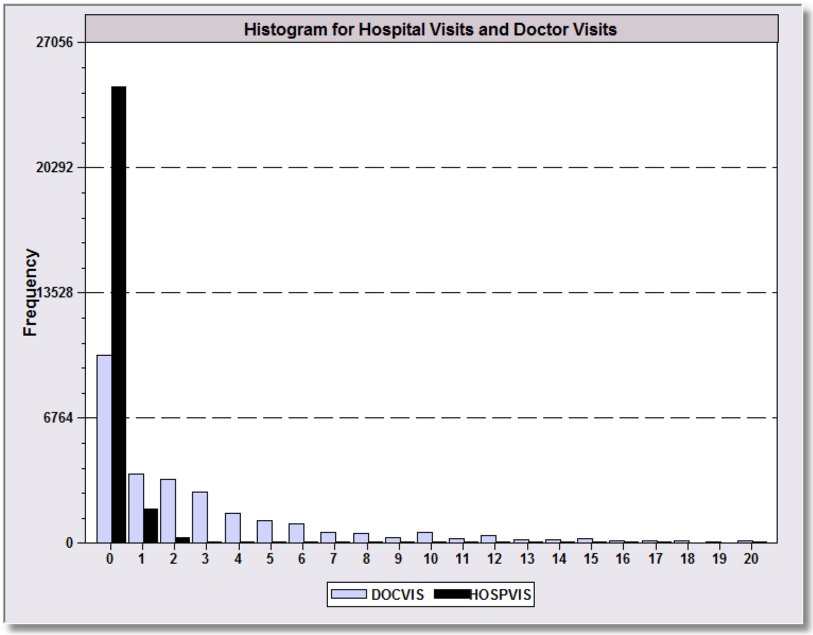

Figure E3.16 Histogram for Two Variables

E3.5.3 Stratification

The specification

; Group = stratification variable
(up to four groups instead of four variables)

may be used to produce the same sort of multiple plot figure, where the separate histograms correspond to different groups. The groups are assigned labels '*name*001,' '*name*002' etc. You may provide your own labels with

; Labels = labels for the groups

The example in Figure E3.17 below is produced using

```
HISTOGRAM ; If [docvis <= 25]
          ; Rhs = docvis
          ; Group = female
          ; Labels = female,male
          ; Title = Hospital Visits Male vs. Female $
```

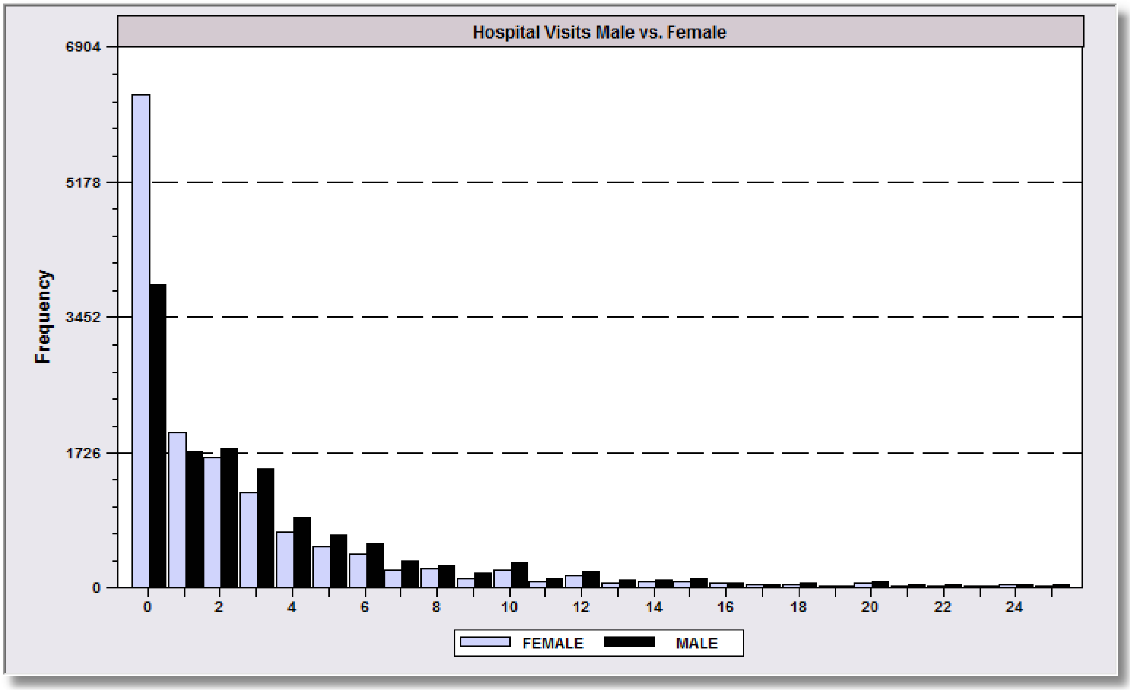

Figure E3.17 Histograms for Two Strata

E3.5.4 Labels for Bins

Bins are generally labeled '1,' '2,' etc. as in the examples above. You may provide your own labels for the bins with

; Choices = labels for the bins, up to 15 bin labels

The following example combines several of the features described above for a data set on mode choice. (The group indicator, *sex*, was simulated for this example – it is not present in the original data set.) The clogit data are used in Chapter E38 to illustrate multinomial choice models.

```
CREATE    ; choice = Trn(-4,0) * mode $
REJECT    ; choice = 0 $
CREATE    ; sex = Rnu(0,1) > .55 $
HISTOGRAM ; Rhs = choice
          ; Choices  = air,train,bus,car
          ; Title = Mode Choice: Sydney-Melbourne Commute
          ; Group = sex
          ; Labels = male,female $
```

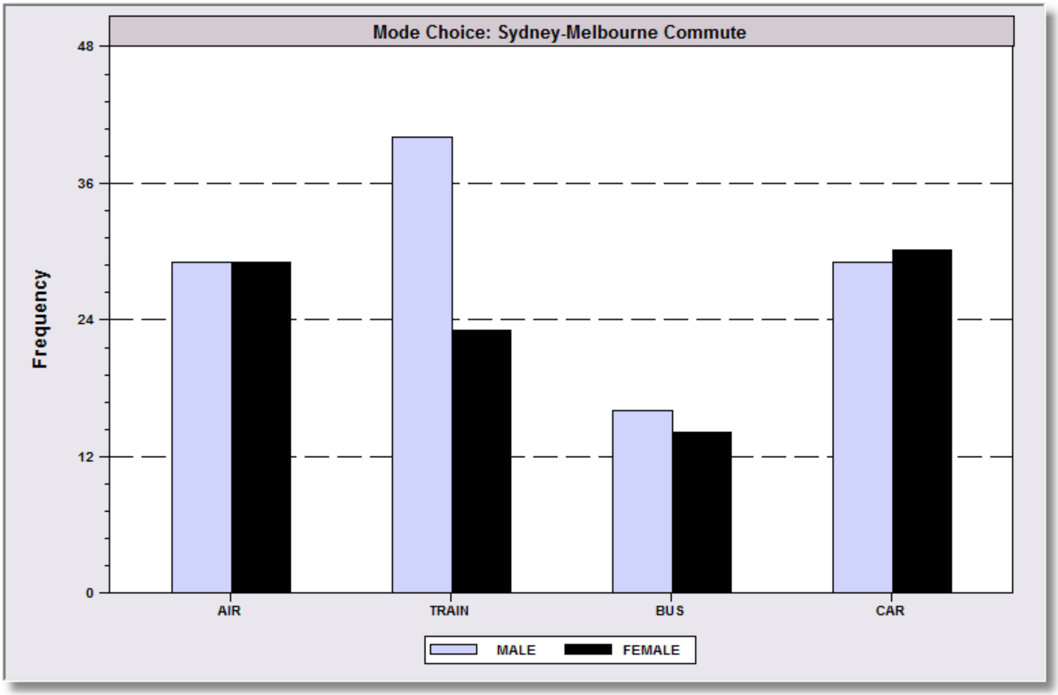

Figure E3.18 Histogram with Strata, Bin Labels and Title

E3.6 Kernel Density Estimation

The basic command for computing and plotting a kernel density estimate for a variable is

KERNEL ; Rhs = the variable $

A title for the figure may be provided by using

; Title = ...< the desired title, up to 60 characters> ...

The kernel density estimator is a device used to describe the distribution of a variable nonparametrically, that is, without any assumption of the underlying distribution. The kernel density function for a single variable is computed using

$$f(z_j) = \frac{1}{n}\sum_{i=1}^{n}\frac{1}{h}K\left[\frac{(z_j - x_i)}{h}\right], j = 1,...,M.$$

The function is computed for a specified set of values z_j, $j = 1,...,M$. Note that each value requires a sum over the full sample of n values. *The default value of M is 100*. The primary component of the computation is the kernel function, K[.], a weighting function that integrates to one. Eight alternatives are provided:

1. Epanechnikov: $K[z] = .75(1 - .2z^2) / \text{Sqr}(5)$ if $|z| \leq 5$, 0 else,
2. Normal: $K[z] = \phi(z)$ (normal density), $-\infty < z < \infty$
3. Logit: $K[z] = \Lambda(z)[1-\Lambda(z)]$ (default) , $-\infty < z < \infty$
4. Uniform: $K[z] = .5$ if $|z| \leq 1$, 0 1 else,
5. Beta: $Z[z] = (1-z)(1+z)/24$ if $|z| < 1$, 0 1 else,
6. Cosine: $K[z] = 1 + \cos(2\pi z)$ if $|z| < .5$, 0 else,
7. Triangle: $K[z] = 1 - |z|$, if $|z| \leq 1$, 0 else.
8. Parzen: $K[z] = 4/3 - 8z^2 + 8|z|^3$ if $|z| \leq .5$, $8(1-|z|)^3$ else.

The other essential part of the computation is the smoothing (bandwidth) parameter, h. Large values of h stabilize the function, but tend to flatten it and reduce the resolution (in the same manner as its discrete analog, the bin width in a histogram). Small values of h produce greater detail, but also cause the estimator to become less stable.

The basic command is

KERNEL ; Rhs = the variable $

With no other options specified, the routine uses the logit kernel function, and uses a data driven bandwidth equal to

$$h = .9Q/n^{0.2} \text{ where } Q = \min(\textit{std.dev.}, \textit{range}/1.5)$$

The command builder for this estimator may be found by selecting either Model:Data Description/Kernel Density or Model:Nonlinear Regression/Kernel. The dialog boxes are the same in both places.

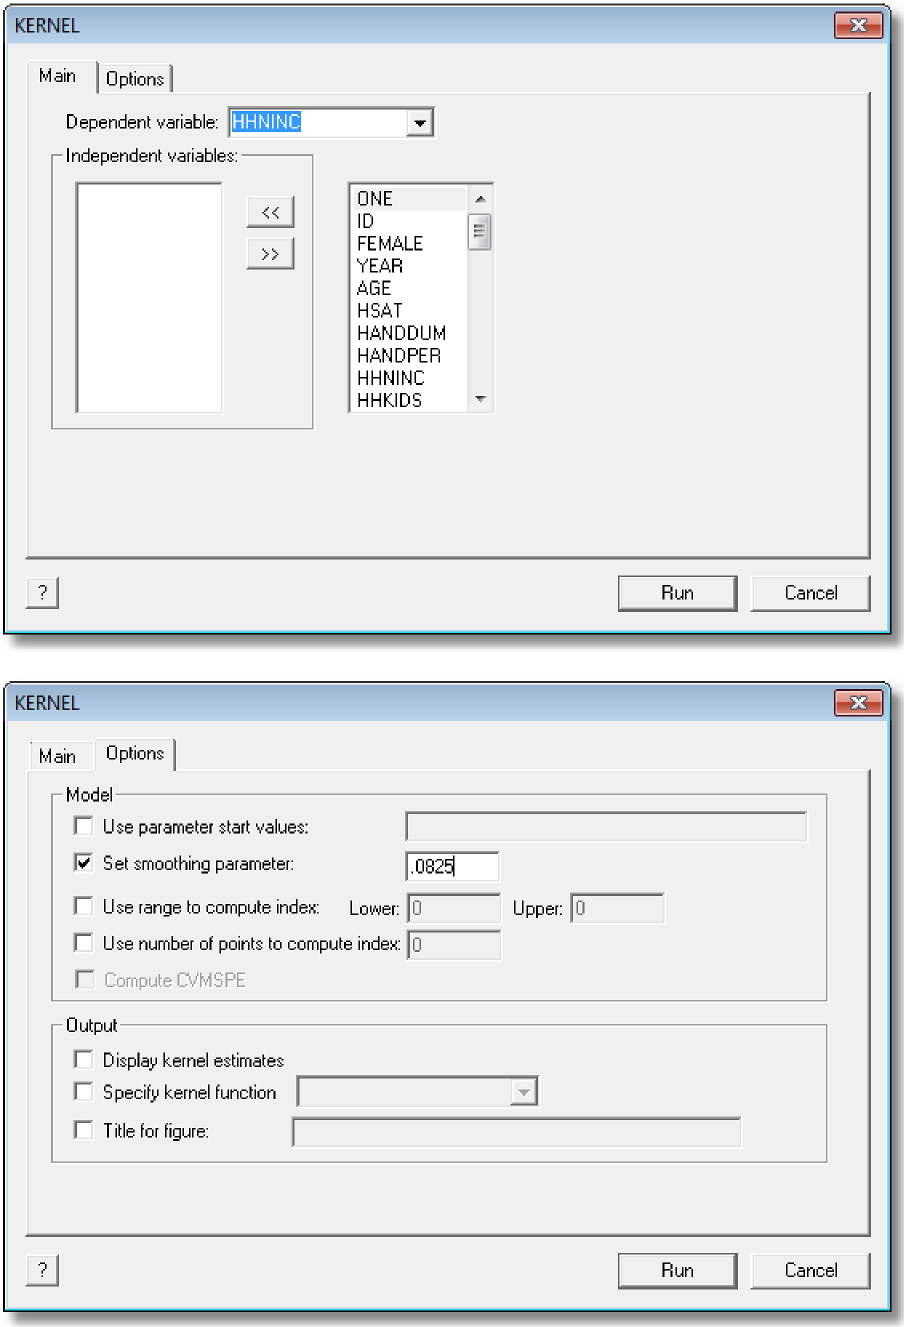

Figure E3.19 Command Builder for Kernel Density Estimator

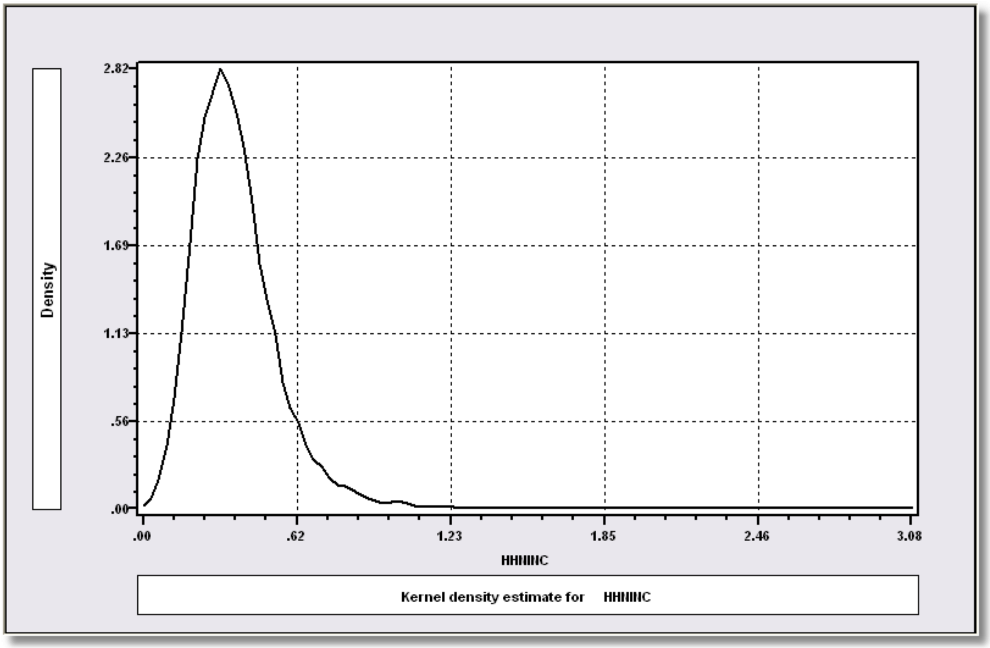
For an example, we will compute the kernel density that is a smoothed counterpart to the histogram for income distribution in Figure E3.5. The command is

KERNEL ; Rhs = hhninc $

The histogram is repeated to show the similarity.



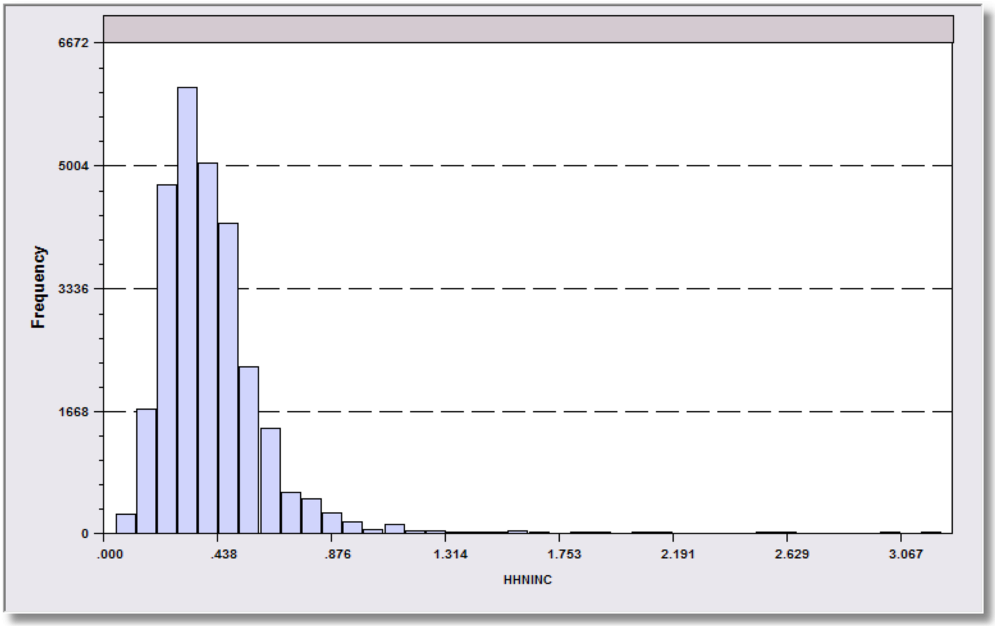


Figure E3.20 Kernel Density Estimator and Histogram for Incomes

The kernel density also produces some summary statistics, as shown below for the example in Figure E3.20.

```
+---------------------------------------+
| Kernel Density Estimator for HHNINC   |
| Observations       =          27326   |
| Points plotted     =            100   |
| Bandwidth          =        .020632   |
| Statistics for abscissa values----    |
| Mean               =        .352135   |
| Standard Deviation =        .176857   |
| Minimum            =        .001500   |
| Maximum            =       3.067100   |
| ----------------------------------    |
| Kernel Function    =       Logistic   |
| Cross val. M.S.E.  =        .000000   |
| Results matrix     =         KERNEL   |
+---------------------------------------+
```

The data used to plot the kernel estimator are also retained in a new matrix named *kernel*. Figure E3.21 shows the results for the preceding plot:

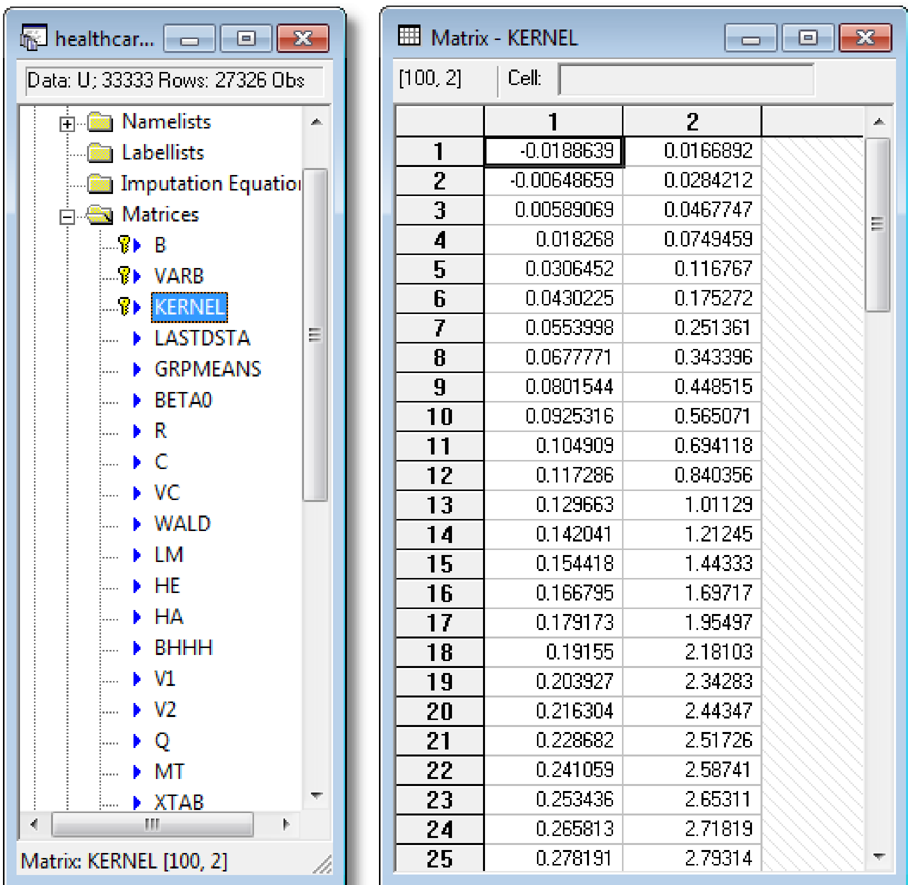

Figure E3.21 Matrix Results from KERNEL

E3.6.1 Options for Kernel Density Estimation

The weighting function for the kernel estimator is specified with

; Kernel = one of the eight types of kernels listed earlier: Epanechnikov, Normal, Logistic, Cosine, Uniform, Beta, Triangle, or Parzen.

The bandwidth may be specified with

; Smooth = the bandwidth parameter.

The default number of points specified is 100, with *zj* = a partition of the range of the variable. You may specify the number of points, up to 1000 with

; Pts = number of points to compute and plot

More than a few hundred points is not helpful, since the resolution of a modern display will not exceed a width of 2,000 points. The set of points z_j is then (for any number of points),

$$z_j = z_L + j*[(z_U - z_L)/M],\ j = 1,...,M\ z_L = \min(x)-h \text{ to } z_U = \max(x)+h.$$

Results of this procedure are a $M\times 2$ matrix named *kernel* in which the first column contains z_j and the second column contains the values of $f(z_j)$ and plot of the second column against the first – this is the estimated density function.

You may fix the limits on the vertical axis of the figure with

; Limits = high, low

This overrides the default limits computed internally. *Note reversal of the usual order.* The alternative specification,

; Limits = low, high

is used to restrict the sample values of the variable used to compute the kernel density estimator to those in the range from low to high. You can also fix the limits on the horizontal axis with

; Endpoints = low, high

Do note that this may conflict with the parameters being used to define the kernel estimator, however. If the range of your data being analyzed is 0-10, for example, and you specify **; Endpoints = 0,5**, the figure may be distorted. The data are not adjusted to conform to the endpoints.

Observation weights may be applied to the kernel estimator. Weights of any sort, including complex survey weights, may be applied, so that the revised estimator is

$$f(z_j) = \frac{1}{n}\sum_{i=1}^{n}\frac{w_i}{h}K\left[\frac{\left(z_j - x_i\right)}{h}\right], \text{ such that } \Sigma_{i=1}^{n} w_i = 1,\ j = 1,...,M.$$

Note that the adjustment of the sum of the weights may be necessary if you specify that only a subsample of the current sample is to be used. As such, when you specify

KERNEL ; Rhs = the variable ; Wts = the weighting variable $

weights are automatically scaled, whether or not you have used use **,Noscale**. As such, you should not use **,Noscale** with this computation. (See Section R8.8.)

Finally, you may add a title to the figure with

; Title = up to 60 characters.

A somewhat neater version of Figure E3.20 which corresponds to Figure E3.8, is produced by

KERNEL ; If [hhninc <= 1.6]
; Rhs = hhninc
; Title = Income Distribution Truncated at 1.6
; Endpoints = 0,1.6 $

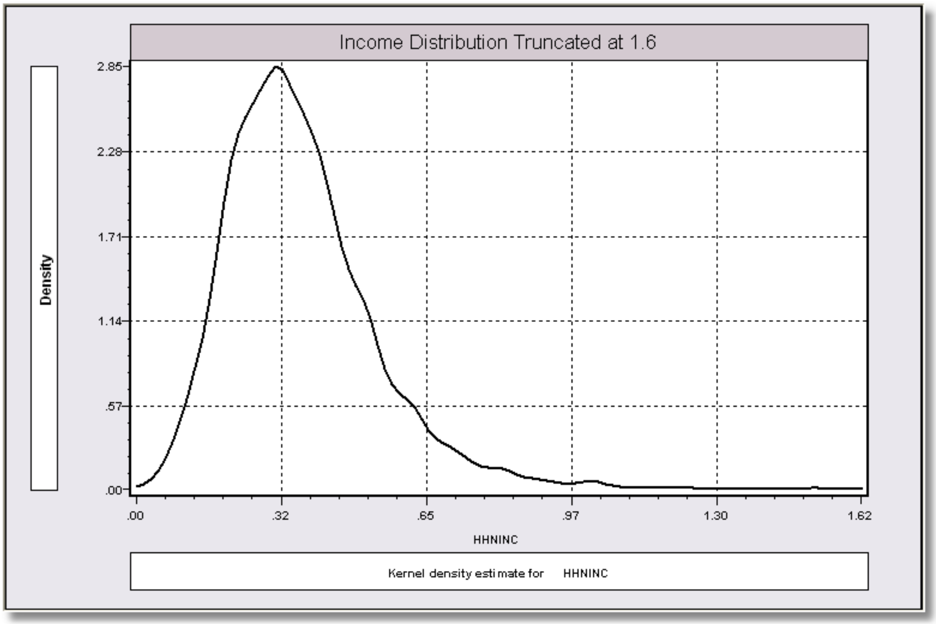

Figure E3.22 Kernel Density Estimator for Truncated Distribution

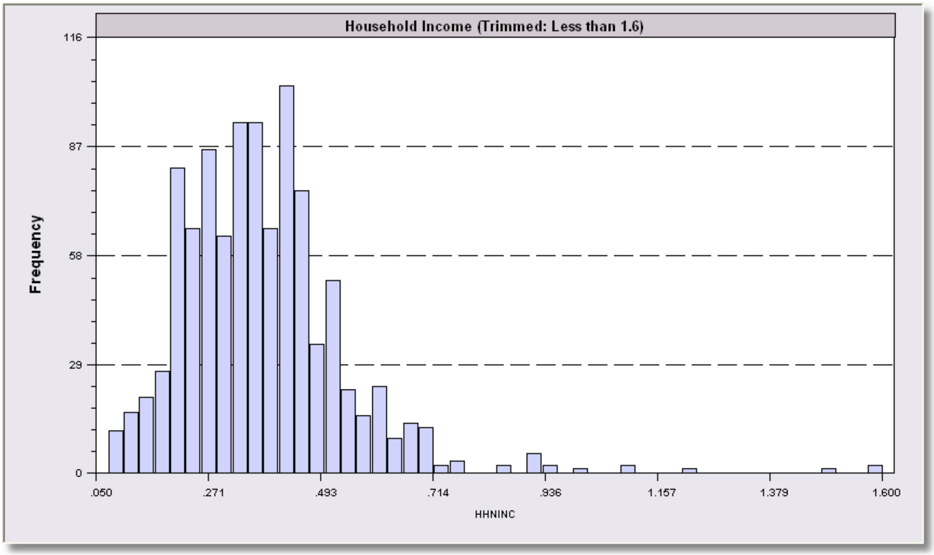

Figure E3.23 Kernel Density Estimator and Histogram for Incomes, with Trimming

E3.6.2 Multiple Kernel Estimators

Multiple kernel estimates can be placed in the same figure by including up to four variables in the Rhs list in the **KERNEL** command. In the example below, estimators of technical efficiency produced by two different stochastic frontier models are compared. (See Chapter E62.)

```
NAMELIST    ; x = one,x1,x2,x3,x4 $
FRONTIER    ; Lhs = yit ; Rhs = x ; Techeff = e_hlfnrm $
FRONTIER    ; Lhs = yit ; Rhs = x ; Techeff = e_expon
            ; Model = Exponential $
KERNEL      ; Rhs = e_hlfnrm,e_expon
            ; Title = Estimates of Technical Efficiency $
```

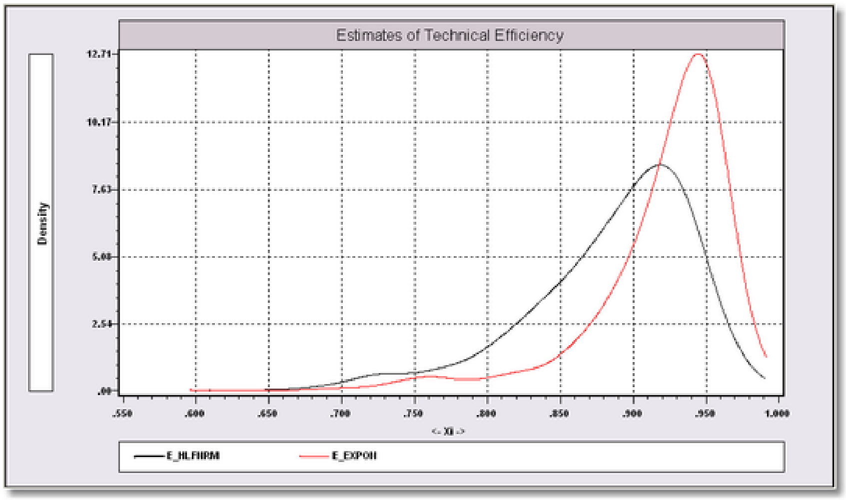

Figure E3.24 Multiple Kernel Estimators

E3.6.3 Sample Strata

To compare subgroups within a sample, use

```
KERNEL     ; Rhs = variable
           ; Group = variable $
```

The group variable partitions the sample in up to five subsamples. In the figure below, the variable female is coded 0 for males and 1 for females, so it partitions the sample into two groups. Labels for the groups may be provided as well with

```
           ; Labels = list of labels
```

The example below compares the responses of men and women to the health status question in the GSOEP data.

```
SAMPLE     ; 1-5000 $
KERNEL     ; Rhs = hsat
           ; Group = female
           ; Labels = men,women
           ; Title = Health Satisfaction: Male vs. Female $
```

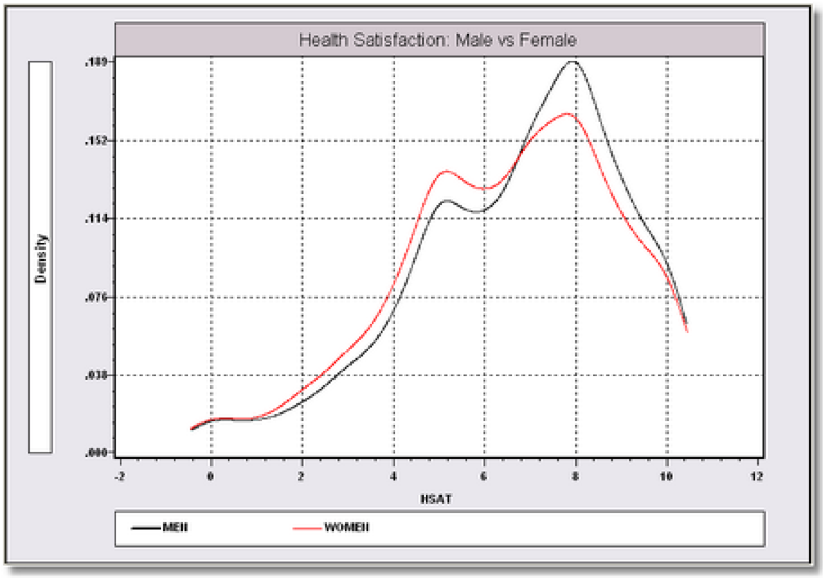

Figure E3.25 Kernel Estimators for Subsamples

E3.6.4 Comparison to Normal

The kernel estimator can be used to examine departures from or similarity to a normal distribution. To superimpose a normal distribution with the same mean and variance as the underlying variable in the kernel estimator, add

; Normal

to the **KERNEL** command. This is a common exercise in the examination of least squares prior to stochastic frontier modeling. The example below displays a kernel estimator and a normal density for the least squares residuals computed with the stochastic frontier models in Section E3.6.2.

REGRESS ; Lhs = yit ; Rhs = x ; Res = u $
KERNEL ; Rhs = u ; Normal
; Title = OLS Residuals with Evidence of Inefficiency $

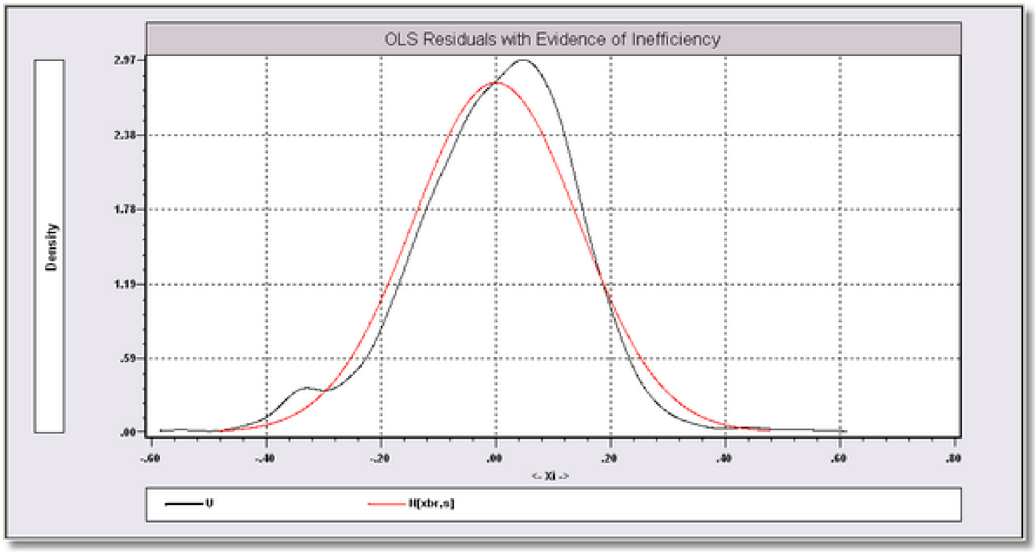

Figure E3.26 Kernel Density Estimator with Normal Density

E3.7 Testing for Normality

Two tests are generally used to test the resemblance of the distribution of a sample to an underlying normal distribution, the Bowman and Shenton (1975) test based on the third and fourth sample moments and the Kolmogorov-Smirnov test based on the sample CDF.

E3.7.1 Normality Test Based on Skewness and Kurtosis

The Bowman and Shenton chi squared statistic for testing against the null hypothesis of normality is

$$\chi^2[2] = N[(m_3/s^3)^2 /6+ (m_4/s^4 - 3)^2/24].$$

where m_3 is the average cubed deviation from the mean (the sample skewness) and m_4 is the average fourth power. In the two cases, the moment is divided by the third or fourth power of the sample standard deviation, respectively. There are several ways to compute this result:

For variables being analyzed with **DSTAT**, you can obtain this result by adding

; Normality test

to the **DSTAT** command. This will change the displayed output to include the statistic and the 'p value' which is the probability that a chi squared variable with two degrees of freedom would exceed this value. The 95% 'critical value' for chi squared[2] is 5.99, so based on this test, you would reject 'normality' at a 95% significance level if your statistic exceeds 5.99. For the least squares residuals used in the example in the previous section, we obtain

DSTAT ; Rhs = u ; Normality test $

```
--------+--------------------------------------------------------------------
Variable|    Mean       Std.Dev.     Minimum      Maximum        Cases Missing
--------+--------------------------------------------------------------------
       U| -.544414E-14   .14016     -.554019      .583301         1482       0
        | Skewness   -.30  Kurtosis     3.80    Chisq=   61.42    Prob = .0000
--------+--------------------------------------------------------------------
```

There are dedicated **CALC** functions for this computation:

CALC ; Sku(variable) $	Computes m_3.
CALC ; Krt(variable) $	Computes m_4.
CALC ; Sdv(variable) $	Computes s.
CALC ; Rb1(variable)$	Computes m_3/s^3.
CALC ; Bt2(variable) $	Computes $m_4/s^4 - 3$.

We can replicate the test result with

CALC ; List ; 1482*Rb1(u)^2/6 ; 1482*Bt2(u)^2/24 $

```
[CALC] *Result*=     21.6501337
[CALC] *Result*=     39.7657231
```

E3.7.2 Kolmogorov Smirnov Test of Normality

The Kolmogorov-Smirnov test is a nonparametric statistic used to test a distributional assumption. For the implementation here, we use the normal distribution as the null hypothesis. The statistic is computed as

$$D = \max_{1 \le i \le N}\left(F(x_i) - \frac{i-1}{N}, \frac{i}{N} - F(x_i) \right)$$

where F is the theoretical CDF being tested (normal). For the specified test,

CALC ; Kst(variable) $

reports the Kolmogorov-Smirnov test statistic. The null distribution is assumed to be the normal distribution. The mean and standard deviation of the normal distribution are estimated from the data. The derivation of the behavior of the test statistic, and the critical values, actually assume that the mean and variance of the distribution are known, not estimated from the data. So, the critical values given below should be viewed as approximate If you do know the mean and standard deviation of the distribution, provide them as the second and third parameters in the function, as in

CALC ; List ; Kst(variable, μ, σ) = Kolmogorov-Smirnov test against N[μ,σ^2].

Critical values of the distribution of the test statistic are as follows:

Sample Size	20	25	30	35	Over 35
95%	.294	.270	.240	.230	1.36/Sqr(*N*)
99%	.356	.320	.290	.270	1.63/Sqr(*N*)

For the least squares residuals used in the preceding example, we obtained

CALC ; List ; Kst(u) $

```
--------------------------------------
Kolmogorov-Smirnov test of F(U       )
vs. Normal[     .00000,      .14016^2]
******* K-S test statistic =  .0743086
******* 95% critical value =  .0353277
******* 99% critical value =  .0423412
Normality hyp. should     be rejected.
--------------------------------------
[CALC] *Result*=       .0743086
```

E4: Covariance and Correlation

E4.1 Introduction

This describes how to obtain covariances and various types of correlation coefficients. Scalar calculations of a single correlation for a pair of variables are given in Section E4.2. Covariance and correlation matrices are shown in Section E4.3. Correlations for discrete variables are described in Section E4.4. Section E4.5 shows how to compute and display cross tabulations

E4.2 Covariance and Correlation for Two Variables

CALC can be used to obtain a single covariance or correlation coefficient:

CALC ; [name =] Cov(variable 1, variable 2) $
or **CALC ; [name =] Cor(variable 1, variable 2) $**

E4.2.1 Kendall's Tau

Kendall's tau is a nonparametric measure of the concordance of the ranks of two variables. It is computed as

$$\tau = \frac{\sum_{i=1}^{N}\sum_{j=1}^{i-1} \operatorname{sgn}(x_i - x_j)\operatorname{sgn}(y_i - y_j)}{N(N-1)/2}, \ \operatorname{sgn}(z) = (\text{-}1,0,1) \text{ if } z\ (>0, =0, >0).$$

The exact distribution is unknown and would depend on the underlying population. Under the null hypothesis that τ equals zero, the distribution of τ is approximately normal with mean zero and variance $[(2N+5)/9]/[N(N+1)/2]$. **CALC** may be used with

CALC ; [name =] Ktr(variable 1, variable 2) $

E4.2.2 Rank Correlation

Spearman's correlation for a pair of sets of ranks is computed as

$$r_{RANKS} = \frac{6\sum_{i=1}^{N}(rank_{i,1} - rank_{i,2})^2}{N(N^2-1)} = \frac{6\sum_{i=1}^{N} d_i^2}{N(N^2-1)}$$

Compute this with for two sets of ranks using

CALC ; [name =] Rkc(variable 1, variable 2) $

E4.3 Covariance and Correlation Matrices

Covariance and correlation matrices may be obtained as part of the output with **DSTAT** or separately using **MATRIX**.

E4.3.1 Matrix Output from DSTAT

After the table of results is given, you may elect to display a covariance or correlation matrix (or both) for the variables. The request is added to the command:

; Output = 1 to obtain the covariance matrix,
; Output = 2 to obtain the correlation matrix,
; Output = 3 for both covariance and correlation matrices.

The matrix displays,

; Output = 1, **2**, or **3**,

will display either the full matrix in the output if it is small enough, or an embedded object if the matrix is too large (larger than 5×5 for a covariance matrix, 7×7 for a correlation matrix). The results for the data above are shown below. The table of statistics is the same, and is omitted. (Display of covariance matrices is difficult as the scale of the entries is the square of the data. Correlations can be displayed in much less cluttered format.) In this example, the covariance matrix appears as an embedded object.

DSTAT ; Rhs = year,gnpdefl,gnp,armdforc,total,agr,nonagr
; Output = 3 $

… other results from **DSTAT**

```

The embedded object (Matrix:COV.MAT) shown above is the covariance matrix created by this command. This matrix, as displayed in the window is read only. However, the matrix can be exported to a spreadsheet program such as *Excel* just by clicking the empty square in the upper left corner, then using edit/copy in *LIMDEP* and edit/paste into *Excel*. The labeling and arrangement of the contents of the matrix will be preserved in a tab delimited format.

E4.3.2 Correlation and Covariance Matrices with MATRIX

Correlation matrices are produced by the matrix functions

MATRIX **[; List] ; [name =] Xcor (namelist for X) $**

which produces a correlation matrix for the variables in the namelist. (Optional specifications are shown in square brackets.) Cross correlations may be produced by using

MATRIX **[; List] ; [name =] Xcor(namelist for X, namelist for Y) $**

The correlation matrix shown in the first form results if X and Y are the same namelist. The observations may be weighted by using

MATRIX **[; List] ; [name =] Xcor(namelist for X, namelist for Y, weights) $**

where weights is a variable that contains the weights. The form **Xcor(X,X,w)** must be used to obtain a weighted correlation matrix. Covariance matrices are obtained by changing **Xcor** to **Xcov** in the preceding.

A matrix of Kendall's tau(x,y) for a set of variables is obtained with

MATRIX **[; List] ; [name =] Xtau (namelist for X) $**

Weights are not supported for the matrix of $\tau(x,y)$ correlation coefficients.

E4.4 Correlations for Discrete Variables

Correlations involving discrete variables are generally not computed using standard Pearson product moment correlation coefficients. Two for strictly discrete variables based on censoring an underlying normal variable are the tetrachoric correlation for two binary variables and the polychoric correlation for two ordered categorical variables or a binary variable and a categorical variable. The biserial correlation described in Section E4.4.3 is used for a binary variable and a continuous variable.

E4.4.1 Tetrachoric Correlation for Binary Variables

The tetrachoric correlation between binary variables d_1 and d_2 is described as the correlation that would be observed if the two variables were normally distributed around fixed means with variance one. Thus,

$$d_{\mathrm{j}} = 1(d_j^* > 0) \mid d_j^* \sim \mathrm{N}[0,1],\ \mathrm{j} = 1,2.$$

If we write this in full, we have the following bivariate model:

$$d_1^* = \alpha_1 + \varepsilon_1,\ d_1 = 1[d_1^* > 0]$$
$$d_2^* = \alpha_2 + \varepsilon_2,\ d_2 = 1[d_2^* > 0]$$
$$(\varepsilon_1,\varepsilon_2) \sim N_2[(0,0),(1,\rho,1)]$$

The correlation coefficient, ρ, is estimated by maximum likelihood. The structure can be seen to define a bivariate probit model in which the two regressor vectors are simply a constant term. The computation can be requested with

TCORRELATION ; Lhs = d1 ; Rh1 = d2 $

There are no other options for this model command. Note that the command is identical to

BIVARIATE PROBIT ; Lhs = d1,d2 ; Rh1 = one ; Rh2 = one $

and you can apply other optional features to this command, such as **; List** if you wish.

On computation, Olsson (1979) is among numerous sources that discuss maximum likelihood estimation of the tetrachoric correlation. The quite simple approach of treating this as the most simple type of bivariate probit model in this fashion seems to have gone unnoticed in the received literature.

In the example below, we have computed the tetrachoric correlation for the two behavioral variables in the health care data, *doctor* = 1[*docvis* > 0] and *hospital* = 1[*hospvis* > 0]. We have used the 1991 wave of the data set. The analysis begins with a descriptive cross tabulation. Crosstabs are described in Section E4.5.

CROSSTAB ; Lhs = doctor ; Rhs = hospital $

```

E4.4.2 Polychoric Correlation for Two Ordered Qualitative Variables

The polychoric correlation is computed similarly to the tetrachoric correlation. The statistic has been recommended to measure the concordance of different judges or raters. Suppose, for example, there are a pair of judges each asked to rate restaurants on a scale from 0 to 4. The statistic is intended to measure the correlation of their ratings. The underlying model is precisely that underlying the bivariate ordered probit model shown in Section E35.9. For each individual (or utility function), we have

$$
\begin{aligned}
y_1^* &= \alpha_1 + \varepsilon_1, \quad y_1 = 0 \text{ if } y_1^* \le 0,\\
&\qquad\qquad y_1 = 1 \text{ if } 0 < y_1^* < \mu_1,\\
&\qquad\qquad y_1 = 2 \text{ if } \mu_1 < y_1^* < \mu_2,\\
&\qquad\qquad \ldots\\
&\qquad\qquad y_1 = J \text{ if } \mu_{J-1} < y_1^* < +\infty.\\
y_2^* &= \alpha_2 + \varepsilon_2, y_2 = 0 \text{ if } y_2^* \le 0,\\
&\qquad\qquad y_2 = 1 \text{ if } 0 < y_2^* < \lambda_1,\\
&\qquad\qquad y_2 = 2 \text{ if } \lambda_1 < y_2^* < \lambda_2,\\
&\qquad\qquad \ldots\\
&\qquad\qquad y_2 = M \text{ if } \mu_{M-1} < y_2^* < +\infty.\\
(\varepsilon_1,\varepsilon_2) &\sim N_2[(0,0),(1,1,\rho)].
\end{aligned}
$$

In this framework, then, ρ is the polychoric correlation. Either variable may be binary. If both are, then the tetrachoric correlation of the preceding section applies. The maximum likelihood estimate of the coefficient is obtained by treating the preceding as a bivariate ordered probit model in which both equations have only a constant term. The calculation is requested with

PCORRELATION ; Lhs = y1 ; Rhs = y2 $

In the example below, we have obtained the polychoric correlation between *docvis* (truncated at 5) and *hospvis* (truncated at 2). Both variables are counts. In this application, we are treating the counts as an indicator of underlying health in a particular dimension. We begin with a descriptive cross tabulation.

SAMPLE ; All $
REJECT ; year # 1991 | docvis > 5 | hospvis > 2 $
CROSSTAB ; Lhs = docvis ; Rhs = hospvis $

```

E4.4.3 Biserial Correlation

The biserial correlation is sometimes used to assess the correlation between a continuous variable, *x*, and a binary variable, *d*. (See Glass and Hopkins (1995).) The computation is

$$r(x,d) = \frac{\bar{x}_{|d=1} - \bar{x}_{|d=0}}{s_x}\sqrt{\frac{n_1 n_0}{n^2}}$$

A standard error for the correlation is approximated by

$$s_{r(x,d)} = \sqrt{\frac{1-r^2(x,d)}{n_1+n_2}},$$

assuming that the sample is large enough that a normal approximation to the t distribution is satisfactory (i.e., greater than about 100). With a small sample, normally distributed, *x* and exogenous *d*, the t distribution is used and the degrees of freedom in the standard error are *n*-2. The biserial correlation, an estimate of the standard error and an estimated confidence interval are obtained with

CALC [; List] ; [name =] Bsr(x,d) $

In the example below, the coefficient is computed for income and the binary indicator for whether the individual has purchased public insurance.

CALC ; List ; Bsr(income,public) $

```
---------------------------------------------
Biserial correlation of INCOME   and PUBLIC
Estimated correlation coefficient = -.19415
Estimated standard error for bsr  =  .00593
Estimated 95%conf. interval=(-.2058,-.1825)
---------------------------------------------
[CALC] *Result*=      -.1941491
```

E4.5 Cross Tabulations

The command for crosstabs based on two variables is

CROSSTAB ; Lhs = rows variable ; Rhs = columns variable $

Use **CROSSTAB** to analyze a pair of discrete variables that are coded 0,1,... up to 49 (i.e., up to 2,500 possible outcomes). The table may be anywhere from 2×2 to 50×50. (Row and column sizes need not be the same.) Observations which do not take these values are tabulated as ‘out of range.’

This command assumes that your data are coded as integers, 0,1,... If you wish to analyze continuous variables, you must use the **RECODE** command (Section R4.7) to recode the continuous ranges to these values.

The categories are automatically labeled ‘NAME=0,’ ‘NAME=1,’..., etc. for the two variables. To provide your own labels and to specify the number of categories for the variables, add

; Labels = list of labels for Lhs / list of labels for Rhs

to the command. Labels may contain up to eight characters. Separate labels in the lists with commas. Cross tabulations may be computed with unequally weighted observations. The specification is

; Wts = variable

as usual. This scales the weights to sum to the sample size. If the weights are replications that should not be scaled, use

; Wts = variable,Noscale

The command builder dialog boxes that you can use to construct the command for CROSSTAB are found by selecting Model:Data Description/Crosstab. The Main and Options pages are shown below.

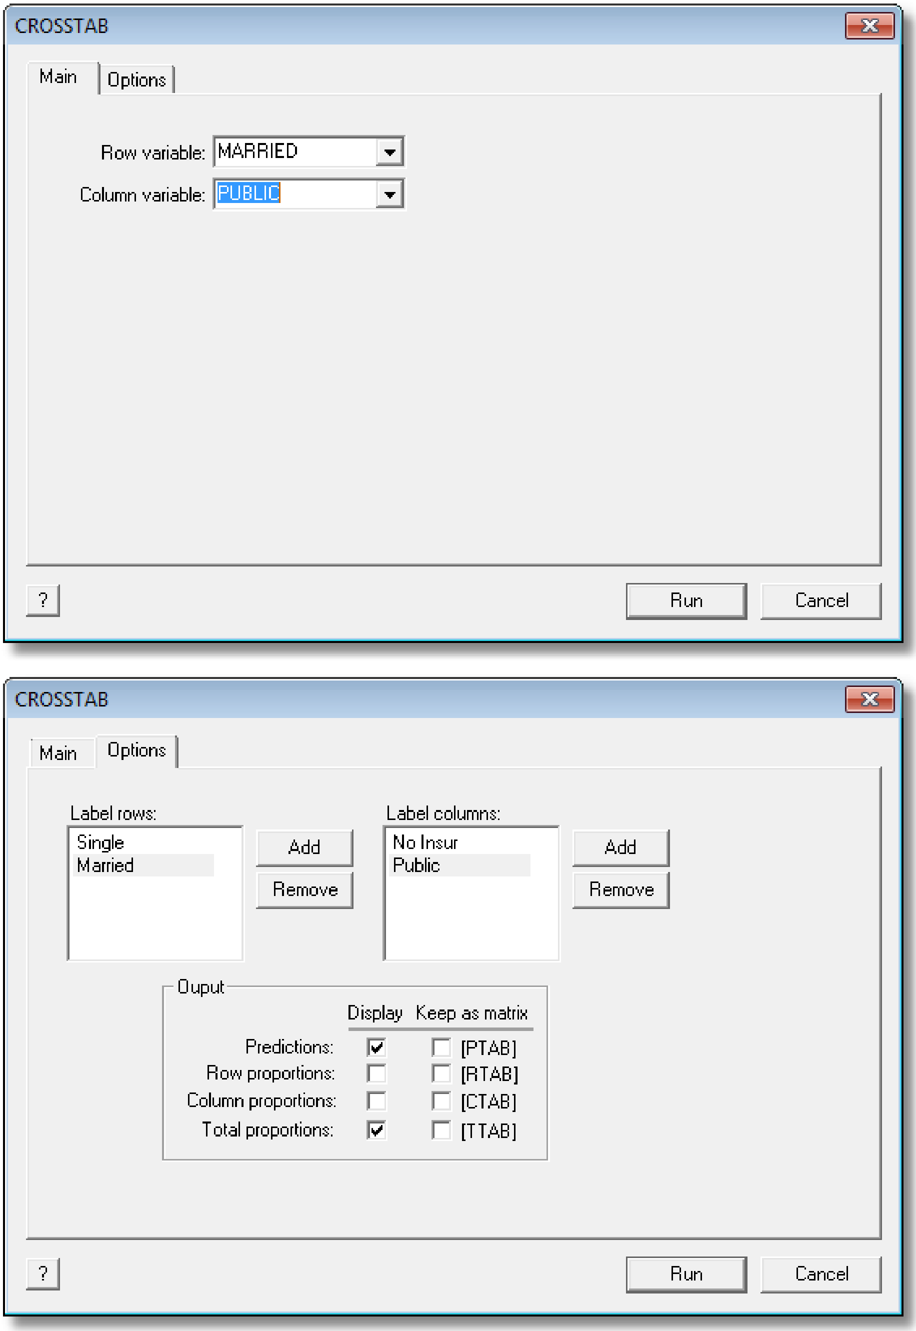

Figure E4.2 Command Builder for CROSSTAB

E4.5.1 Output

The **CROSSTAB** command will produce five types of tables. The default is a simple cross frequency table. Other options are

p = predictions, using the independence model (see below),
r = table entries are row proportions,
c = table entries are column proportions,
t = table entries are total sample proportions.

Use

; Output = any or all of p,r,c,t to request the display.
; Store = any or all of p,r,c,t to request keeping results as matrices.

Matrix *xtab*, the basic frequency table, is kept automatically. Other matrices that will be kept are

ptab if **; Store = ...,p...**
rtab if **; Store = ...,r...**
ctab if **; Store = ...,c...**
ttab if **; Store = ...,t...**

```

```

E4.5.2 Testing the Independence Assumption

Frequency counts are often used for analyzing the hypothesis of independence of two variables. Suppose that the frequency table contains cell counts, n_{ij}, row sums, $n_{i.}$, and column sums, $n_{.j}$, and that there are total of n observations. The predicted cell frequencies are

$$Fij = n\times(n_{i.}/n)\times(n_{.j}/n) = n_{i.}\times n_{.j}/n.$$

Two statistics are computed for testing the independence hypothesis:

$$\text{Chi squared} = \Sigma_i\Sigma_j\,(F_{ij} - n_{ij})^2 / n_{ij}$$
$$G \text{ squared} = \Sigma_i\Sigma_j\, n_{ij}\log(F_{ij} / n_{ij}).$$

Both statistics are reported as zero if there are any cells with zero frequencies, since neither can be computed. Both of these are distributed in large samples as chi squared with degrees of freedom

$$K = (\text{number of rows - 1}) \times (\text{columns - 1}).$$

In addition to the matrices given earlier, the following scalars are kept by this procedure:

gsqrd	will contain G squared.
csqrd	will contain chi squared.
degfrdm	will contain the degrees of freedom, K.

LIMDEP also reports the probability that the chi squared variable would be at least this large (the p value) for the two statistics.

E4.5.3 Analyzing Frequency Data

If your data are already tabulated in the form of a frequency table, you can compute the independence tests, and predicted frequencies as follows:

```
MATRIX      ; nij  =  the table of frequencies $
CROSSTAB    ; Lhs  =  nij $
```

The command is different in that the **; Lhs** specifies a matrix, not a variable, and there is no **; Rhs**. This produces the same results as if the data were individual. No note is made in the results that the data were already tabulated. For example,

```
MATRIX      ; c = [44,52,11,14/12,99,88,21/22,42,86,19] $
CROSSTAB    ; Lhs = c $
```

produces the following:

```
+-------------------------------------------------------------------+
|Cross Tabulation                                                   |
|Row variable is C          (Out of range 0-49:      0)             |
|Number of Rows =  3        (C         =  0 to  2)                  |
|Col variable is C          (Out of range 0-49:      0)             |
|Number of Cols =  4        (C         =  0 to  3)                  |

E5: Descriptive Statistics for Time Series Data

E5.1 Introduction

This chapter will detail some of *LIMDEP*'s time series capabilities. Although *LIMDEP* is primarily oriented to cross section and panel data analysis, some common applications in time series can be handled as well.

E5.2 Box-Jenkins Time Series Identification

To produce a plot of the autocorrelations and partial autocorrelations for a time series variable, use the command

IDENTIFY ; Rhs = variable ; Pds = number of lags $

The number of lags is limited to one quarter of the sample size, and may not exceed 25. It will be reset to the limit value if necessary. The plot is accompanied by a tabulation of the Box-Pierce statistic at each lag for testing the hypothesis that the series is not autocorrelated. (Examples are shown below.)

This procedure creates a scalar named *nlag* which contains the value you give in **; Pds = nlag** and an *nlag*×2 matrix named *acf_pacf* which contains the results.

E5.2.1 Command Builder

The command builder for this computation is accessed by selecting Model:Time Series/Identify/Spectral. The dialog box for **IDENTIFY** requests only the variable (**; Rhs**), the number of lags (**; Pds**), and whether the Burg method is to be used for the partial autocorrelations (**; Alg = Burg**). The Burg specification is the only option for this command. See Figure E5.1.

E5.2.2 Computations

Calculations for this procedure are as follows: Data are $z_1, z_2, ..., z_T$. For lag length K+1, we assemble the following K variables:

$$d_0 = z_{K+1}, \dots z_T$$

$$d_1 = z_K, \dots , z_{T-1}$$

$$d_2 = z_{K-1}, \dots, z_{T-2}$$

$$\dots$$

$$d_K = z_1, \dots, z_{T-K}$$

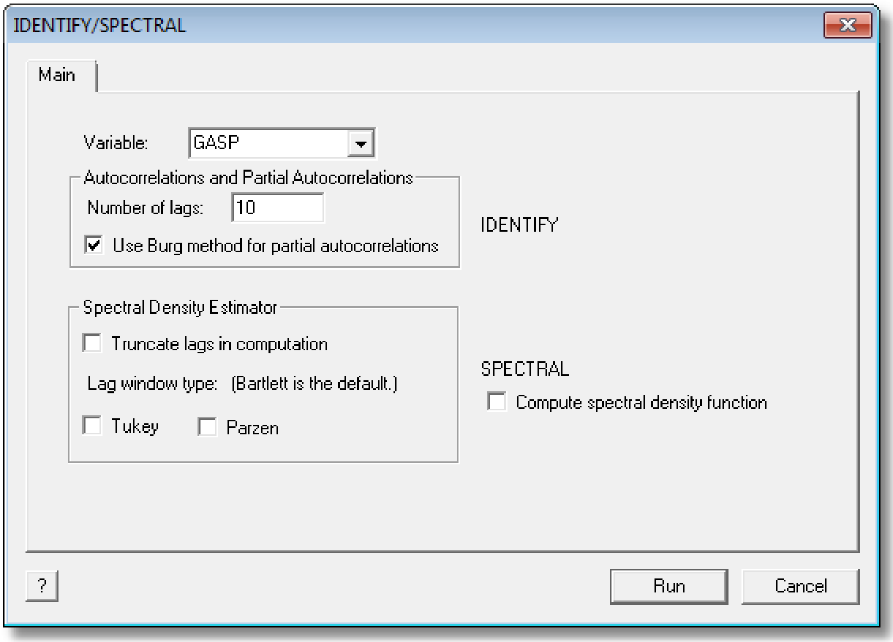

Figure E5.1 Command Builder for Time Series Description

Then, autocorrelations and other statistics are based on simple moments of these K+1 variables, each of which has exactly T-K observations. All moments are based on centered data. Under stationarity, the means should be asymptotically equivalent.

1. Autocovariances: c_i = sample covariance of $[d_i, d_0]$, $i = 0,...,K$,
2. Autocorrelations: r_i = sample correlation of $[d_i, d_0]$,
3. Partial correlations: $\mathbf{C}$ = $(K+1)\times(K+1)$ covariance matrix of ds,

   $\mathbf{c}$ = $K\times 1$ vector $[c_1,...,c_K]$,

   $\mathbf{C}_{(i)}$ = leading $i\times i$ principal submatrix of $\mathbf{C}$, $i = 1,...,K$,

   $\mathbf{c}_{(i)}$ = first i elements of $\mathbf{c}$. Then,

   $r_i{*}$ = last element of $[\mathbf{C}_{(i)}]^{-1}\mathbf{c}_{(i)}$..

For example, the first partial autocorrelation is c_1/c_0 while the second is the second element in the vector

$$\mathbf{r} = \begin{bmatrix} c_0 & c_1 \\ c_1 & c_0 \end{bmatrix}^{-1} \begin{bmatrix} c_1 \\ c_2 \end{bmatrix}.$$

Finally, the Box-Pierce statistic at lag i is $BP_i = (T\text{-}K)\,\Sigma_i\, r_i.^2$. Two summary statistics are presented with the results:

$$\text{Box-Pierce} = (T-K)\sum_{s=1}^{J} r_s^2 ,$$

$$\text{Box-Ljung} = \frac{T}{T+2}\sum_{s=1}^{J} \frac{r_s^2}{T-s} .$$

E5.2.3 The Burg Variant of the PACF

McCullough (1999) and others have argued that using the Yule-Walker equations, as we do in the preceding section, to compute the partial autocorrelation functions produces results that can be numerically unstable and prone to numerical errors. Among the problems of the Yule-Walker approach is its reliance on inversion of the moment matrix. This will be problematic in and of itself in a highly autocorrelated data set. The Burg estimator is computed by a simple recursion, and is relatively more stable and less affected by numerical problems. A few programs have begun to implement the method, but it remains relatively new. The Burg method uses a fairly esoteric procedure documented further in McCullough. For the vector

$$\mathbf{z} = [z_1, z_2, \ldots , z_{T\text{-}1}, z_T]$$

define the circular shift operation

$$c(\mathbf{z}) = [z_T, z_1, z_2, \ldots , z_{T\text{-}1}]$$

and the subvector extraction operation

$$e_{j,k(\mathbf{z})} = [z_j, z_{j+1}, z_2, \ldots , z_{k\text{-}1}, z_k] = \text{elements } j \text{ through } k \text{ of } \mathbf{z}.$$

The dot product of two vectors, $\mathbf{x}$ and $\mathbf{z}$, which is usually denoted $\mathbf{x}'\mathbf{z}$ is computed by the function

$$d(\mathbf{x}, \mathbf{z}) = \mathbf{x}'\mathbf{z}$$

The squared norm of a vector $\mathbf{z}$ is, therefore, $d(\mathbf{z}, \mathbf{z}) = \|\mathbf{z}\|^2$. Finally, define the augmented $T+p$ vector padded with p zeros

$$\overrightarrow{\mathbf{z}}(0) = [z_1, z_2, \ldots , z_{T\text{-}1}, z_T, 0, \ldots, 0]$$

and $$\overleftarrow{\mathbf{z}}(0) = c[\overrightarrow{\mathbf{z}}(0)] = [0, z_1, z_2, \ldots , z_{T\text{-}1}, z_T, 0, \ldots, 0]$$

where the latter is obtained by shifting one of the zeros from the right end to the left so that p-1 zeros remain at the right. With all this in place, the Burg estimator of the partial autocorrelation coefficients is

$$r_i = \frac{2d\left(e_{i+1,T}\left(\overrightarrow{\mathbf{z}}(i-1)\right), e_{i+1,T}\left(\overleftarrow{\mathbf{z}}(i-1)\right)\right)}{\left\|e_{i+1,T}\left(\overrightarrow{\mathbf{z}}(i-1)\right)\right\|^2 + \left\|e_{i+1,T}\left(\overleftarrow{\mathbf{z}}(i-1)\right)\right\|^2}$$

where $$\overrightarrow{\mathbf{z}}(i) = \overrightarrow{\mathbf{z}}(i\text{-}1) - r_i \overleftarrow{\mathbf{z}}(i\text{-}1)$$

and $$\overleftarrow{\mathbf{z}}(i) = c\,[\overleftarrow{\mathbf{z}}(i\text{-}1) - r_i \overrightarrow{\mathbf{z}}(i\text{-}1)].$$

In spite of its seeming complexity, the Burg method is a relatively straightforward recursion which begins with r_1 = the first autocorrelation. The Burg method is requested by adding

; Alg = Burg

to the **IDENTIFY** command.

TECHNICAL NOTE: Here is the algorithm used internally for computing the Burg estimator.

1. Set $N = T + J$, T = number of observations, J = number of partial autocorrelations.

2. Initialize $\mathbf{z}_L = [z_1, z_2, ..., 0, 0, ..., 0]$ = N elements, T of z_t and J zeros.
   Initialize $\mathbf{z}_R$ = circular shift of $\mathbf{z}_L = [0, z_1, z_2, ..., 0, 0, ..., 0]$, 0, $\mathbf{z}$, J-1 zeros.

3. For $i = 1, ..., J$ in recursion, i starts at 1

   a. Move $T - i$ elements starting at i+1 from $\mathbf{z}_R$ into vector $\mathbf{d}_R$,
   b. Move $T - i$ elements starting at i+1 from $\mathbf{z}_L$ into vector $\mathbf{d}_L$,
   c. $r_i = 2\, \mathbf{d}_R'\mathbf{d}_L / (\mathbf{d}_R'\mathbf{d}_R + \mathbf{d}_L'\mathbf{d}_L)$ (dot products involve T-i values),
   d. Make $\mathbf{d}_R = \mathbf{z}_R - r_i\, \mathbf{z}_L$,
   e. Make $\mathbf{d}_L = \mathbf{z}_L - r_i\, \mathbf{z}_R$,
   f. Set first element of $\mathbf{z}_L$ equal to Nth element of $\mathbf{d}_L$,
   g. Move first N-1 elements from $\mathbf{d}_L$ into $\mathbf{z}_L$ starting at second position in $\mathbf{z}_L$,
   h. Move N elements from $\mathbf{d}_R$ into $\mathbf{z}_R$,
   i. Increment i and return to a.

E5.2.4 Application

The data listed in Table E5.1 apply to the U.S. gasoline market from 1953 to 2004. (This data set was assembled from several sources by Professor Chris Bell, Department of Economics, University of North Carolina, Asheville.) We will construct examples using this data set. The data are provided in files named gas.lpj, gas.dat, and gas.csv. We begin by computing the autocorrelations and partial autocorrelations for the gasoline price variable. Relying on the canon of Box and Jenkins, we conclude from this figure that these data are clearly characterized by an AR(1) process.

Based on the Yule-Walker Equations:

IDENTIFY ; Rhs = gasp ; Pds = 10 $

```
Time series identification for GASP
Box-Pierce Statistic =   229.6895      Box-Ljung Statistic  =   260.4700
Degrees of freedom   =         10      Degrees of freedom   =         10
Significance level   =      .0000      Significance level   =      .0000
* => |coefficient| > 2/sqrt(N) or > 95% significant.
PACF is computed using Yule-Walker equations.

GasQ = quantity index of gasoline consumption
GasP = price index for gasoline
GasCPIU = consumer price index
PCInc = real per capita disposable income
PNC = price index for new cars
PUC = price index for used cars
PPT = price index for public transportation
PN = aggregate price index for consumer nondurables
PD = aggregate price index for consumer durables
PS = aggregate price index for consumer services
POP = population in thousands

Table E5.1 Data on the U.S. Gasoline Market

Figure E5.2 shows the new matrix created by the second **IDENTIFY** command.

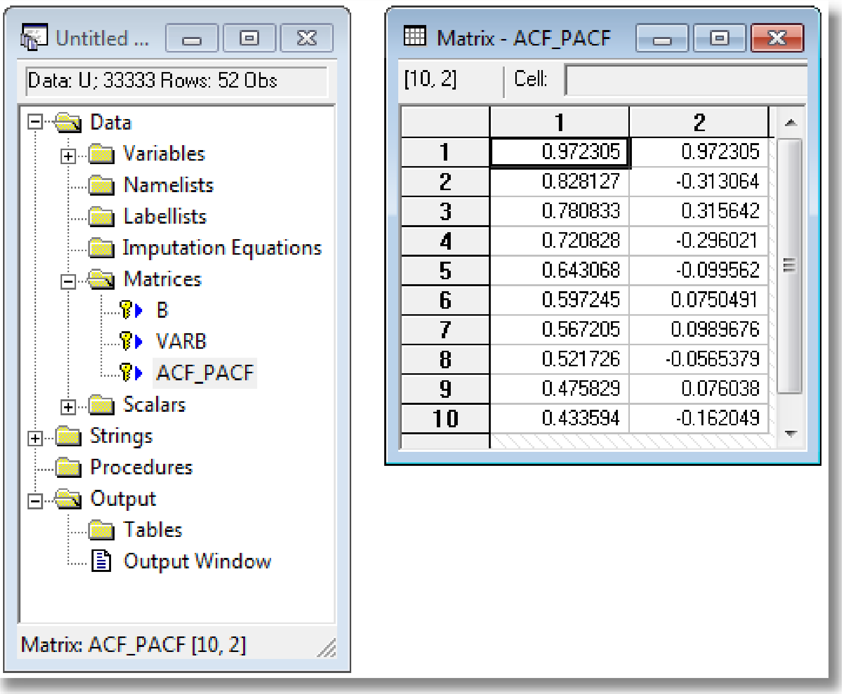

Figure E5.2 Matrix Results from IDENTIFY Command

E5.3 Spectral Density Estimation

The basic command for requesting a spectral density estimator is

SPECTRAL ; Rhs = variable $

The spectral density function or periodogram is used to decompose the variance of a time series. The underlying assumption is that the time series x_t can be written as a weighted sum of underlying series, z_t each varying at a different frequency. The variation in x_t is then decomposed into the contributions made at the different frequencies by each of these underlying series. (Hamilton (1994) is a good reference on time series analysis. Chatfield (1996) is an alternative, somewhat less technical reference to consider.)

We compute the spectrum as follows: (Again, see one of the aforementioned sources for background): For frequencies ranging from 0 to π (the function is symmetric from π to 2π), the spectral density function is computed as the following function of the autocorrelations, r_j:

$$\omega_i = \left(\frac{i-1}{T-1}\right)\pi\,,\ i = 1,\ldots,T,$$

$$f(\omega_i) = \frac{1}{2\pi}\sum_{j=1}^{L} w_j\left[2r_j\cos(j\omega_i)\right],\ L = T\text{-}1 \text{ or } 2\sqrt{T} \text{ if the function is truncated,}$$

where $$r_j = \frac{\sum_{t=j+1}^{T}(x_t - \bar{x})(x_{t-j} - \bar{x})}{\sum_{t=j+1}^{T}(x_t - \bar{x})^2}.$$

The weighting function, w_j is the 'lag window.' Lag windows are used to stabilize the function and to reduce the influence of unstable autocorrelations at longer lags. In addition to the default window (none), $w_j = 1$, you may use any of

Bartlett's window: $$w_j = 1 - \frac{j}{T-1} = B_j$$

Tukey's window: $$w_j = \frac{1}{2}\left[1 + \cos\left(\frac{j\pi}{T-1}\right)\right]$$

Parzen's window: $$w_j = 1 - 6B_j(1 - B_j)^2 \text{ if j} \leq T/2$$

$$= 2B_j^2 \text{ if } j > T/2$$

A second method of stabilizing the estimated function is to truncate the lags in the summation. Note, in the definition, L is the lag length, T-1, or $2\sqrt{T}$ if you elect to truncate the sum.

The general command

SPECTRAL ; Rhs = the variable
; Window = Bartlett, Tukey, or Parzen (optional)
; Truncate (also optional) $

requests these computations. Output from the procedure consists of the plot of the periodogram and a matrix named *freq_sdf* which has two columns. The first is the frequencies, and the second is the function values.

The command builder for **SPECTRAL** uses the same dialog box as **IDENTIFY**, as shown in Figure E5.3

NOTE: The default command in this command builder is **IDENTIFY**. To produce the **SPECTRAL** command, you must check the box to the right of the grouping for the spectral density estimator. (This is marked by the arrow in the figure.)

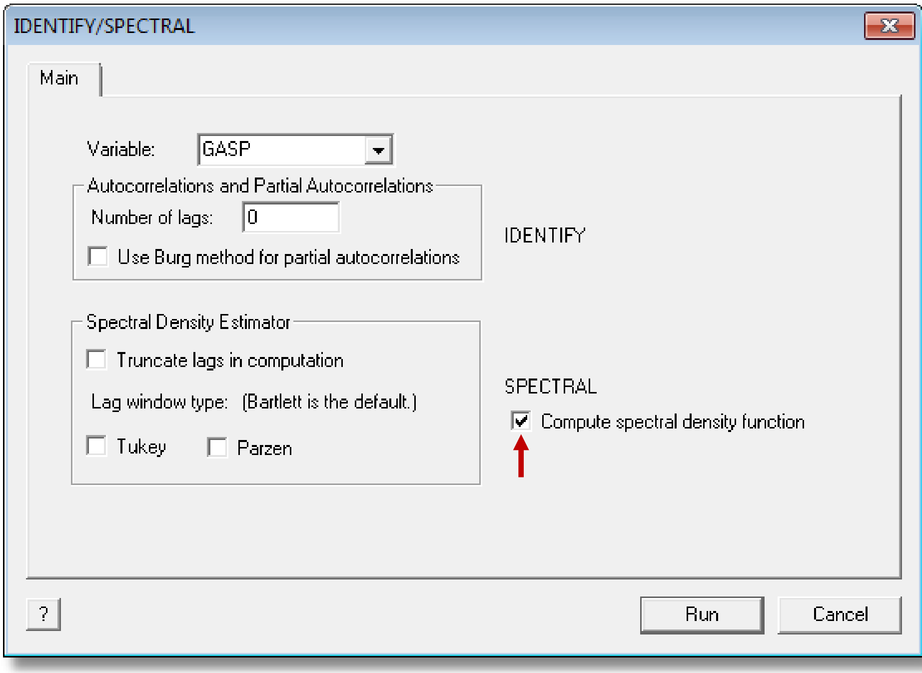

Figure E5.3 Command Builder for Spectral Density Estimation

For example, Figure E5.4 shows the spectral density estimator for the log of per capita income in the gasoline data.

CREATE ; logpcinc = Log(pcincome) $
SPECTRAL ; Rhs = logpcinc $

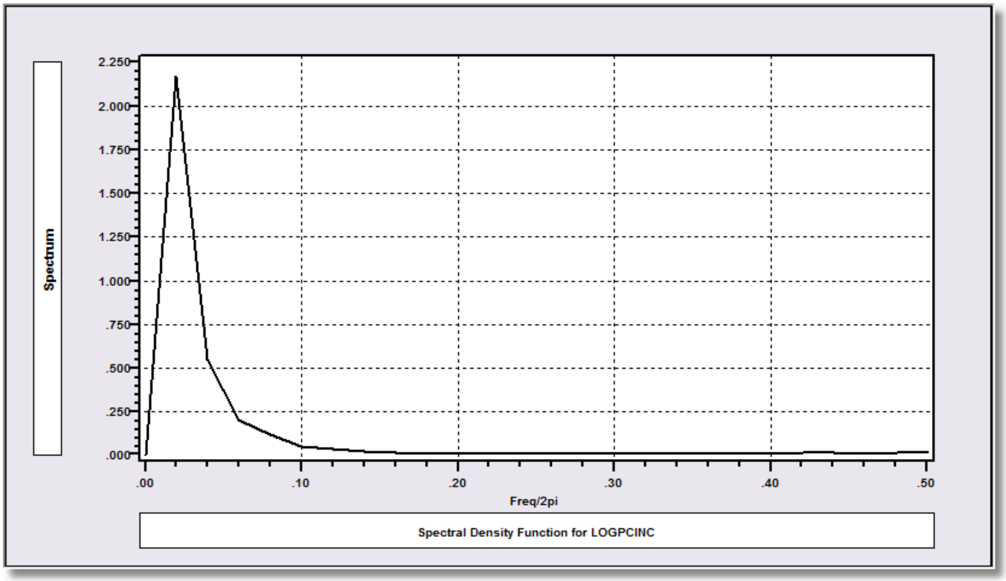

Figure E5.4 Spectral Density Estimator for Log Per Capita Income

E5.4 Phillips-Perron Test for a Unit Root

Various devices have been presented for testing for unit roots in time series data. Most familiar is the Dickey-Fuller (1979) test, which is carried out simply by referring familiar regression statistics to the appropriate table. (See the next section.) Another in wide use is the Phillips-Perron (1988) test, which is carried out by subjecting the residuals from the regression

$$y_t = \alpha + \rho y_{t-1} + \varepsilon_t$$

to a prescribed test procedure. The regression may be computed with additional regressors, a time trend, or without the constant term. The cases in the Phillips-Perron derivation are:

Case 1: No constant term
Case 2: Constant term
Case 4: Constant term and time trend.

(Case 3 is not considered here. See Hamilton (1994) for details.) The procedure is based on two statistics,

$$Z_\rho = T(\hat{\rho}-1) - \frac{1}{2}\left(\frac{T^2 v^2}{s^2}\right)(a - c_0)$$

$$Z_\tau = \sqrt{\frac{c_0}{a}}\left(\frac{\hat{\rho}-1}{v}\right) - \frac{1}{2}(a - c_0)\frac{Tv}{\sqrt{as^2}}$$

$$s^2 = \frac{\sum_{t=1}^{T} e_t^2}{T-K}$$

v^2 = estimated asymptotic variance of $\hat{\rho}$

$$c_j = \frac{1}{T}\sum_{s=j+1}^{T} e_t e_{t-s}\ ,\ \text{j} = 0,\ldots,L = j\text{th autocorrelation of residuals}$$

c_0 = $[(T\text{-}K)/T]s^2$.)

$$a = c_0 + 2\sum_{j=1}^{L}\left(1 - \frac{j}{L+1}\right)c_j$$

The test statistics are referred to the Dickey-Fuller tables. *LIMDEP* uses linear interpolation in a few critical values from the tables: For each statistic, the internal values are for significance levels of .01, .05, and .10, and sample sizes 25, 20, 100, 250, 500 and ∞. The T=25 value is used if the sample is under 25. The value for ∞ is used if T is greater than 500. The hypothesis of a unit root is rejected if the test statistics are less than the critical values given.

The Phillips-Perron test is requested by setting up the AR(1) regression, and adding

; PPT ; Pds = L

where L is the desired number of Newey-West lags for the computation. (Note the definition of a above.)

NOTE: The Newey-West autocorrelation consistent covariance matrix for the OLS estimator is not available when you request the Phillips-Perron test.

You can request this estimator in the command builder by setting up the regression as a linear model, then choosing the Phillips-Perron test instead of the Newey-West estimator. (See the Options page of the **REGRESSION** command builder, which can be found by selecting Model:Linear Models/Regression.)

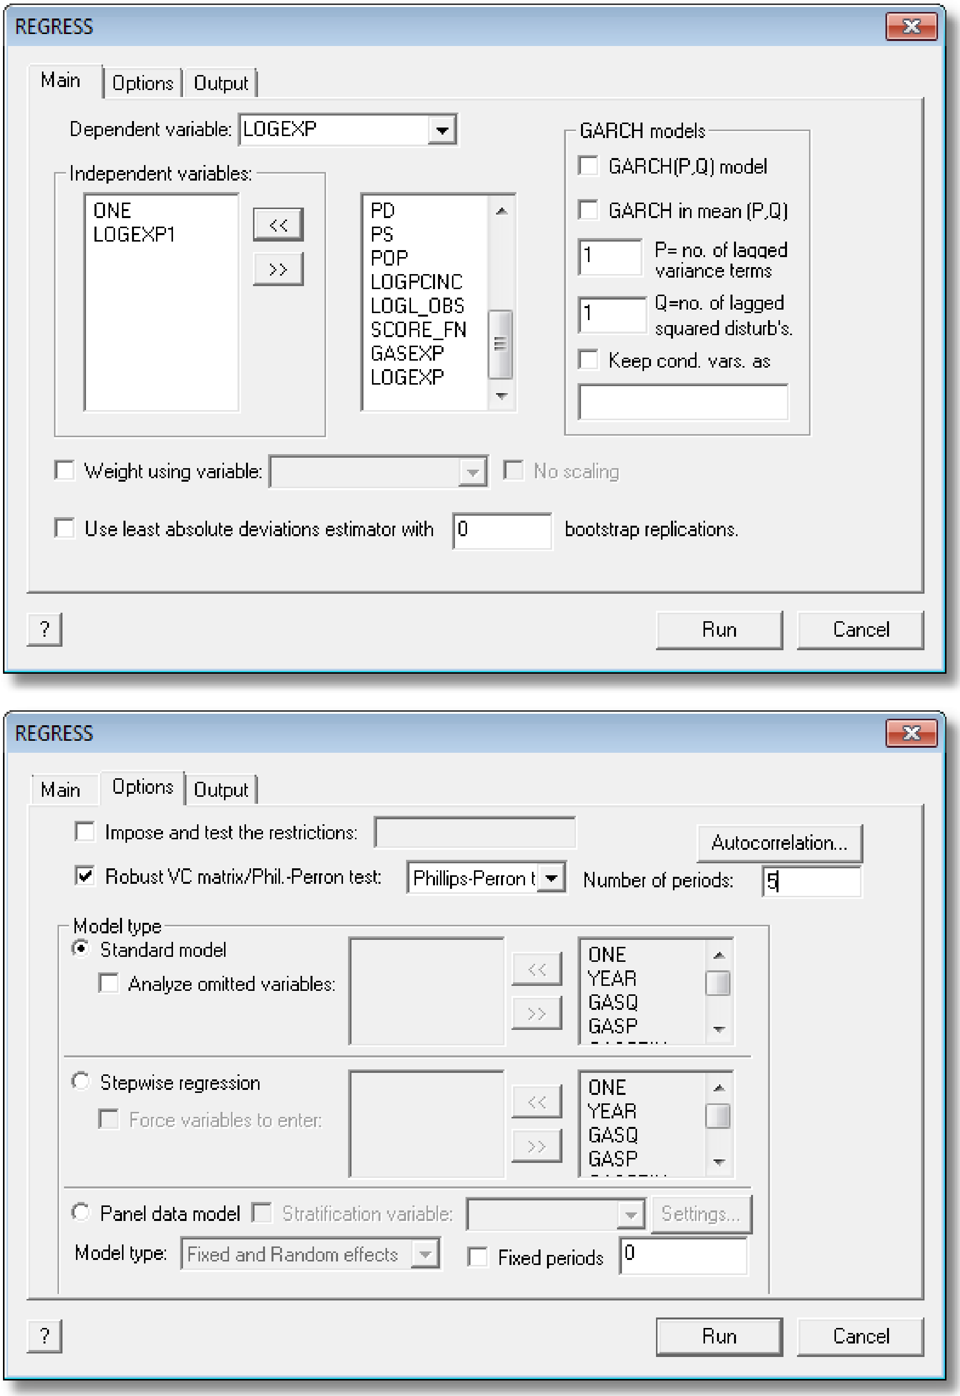

Figure E5.5 Command Builder for Phillips-Perron Test for a Unit Root

For the sample used in the previous example, we have applied the test to the log of per capita gasoline expenditure. The command sequence is

```
SAMPLE     ; All $
CREATE     ; logexp = Log(gasp*gasq) $
CREATE     ; logexp1 = logexp[-1] $
SAMPLE     ; 2-52 $
REGRESS    ; Lhs = logexp
           ; Rhs = one,logexp1
           ; PPT ; Pds = 10 $
```

The results are shown below. Note that the statistic and the critical values are presented in a separate table, with no further action taken. This procedure generates no additional retained values beyond those generated by the regression as usual. The statistics are small and negative, suggesting that the hypothesis of a unit root should not be rejected.

```

```

E5.5 Augmented Dickey-Fuller Tests

The Adf function in **CALC** automates the Dickey-Fuller test for unit roots in time series data. The syntax is

CALC ; Adf (variable, type, lags for augmentation) $

where	*variable*	is the single time series variable to be analyzed,
	type = 1, 2 or 3	for unit root, drift, trend, lags $\geq$ 0,
	lags for augmentation	is the number of additional lagged values to include.

Users are referred to any of the standard texts, e.g., Greene (2011, Chapter 21) for details.

The Phillips-Perron test for a unit root in per capita gasoline expenditure in the preceding section is recalculated here, using the Adf computation instead.

CALC ; Adf (logexp,1,3) $

```
+-----------------------------------------------+
| Augmented Dickey Fuller Test for LOGEXP       |
| Form: Random walk                             |
| Number of lagged differences in model is   3 |
| DF(tau) =    2.44635, DF(gamma) =     .40584 |
| Critical values for    47 observations:      |
| DF(tau)                                       |
| 01 is  -2.62, .025 is  -2.25, .05 is  -1.95  |
| DF(gamma)                                     |
| 01 is -12.80, .025 is  -9.90, .05 is  -7.70  |
+-----------------------------------------------+
```

As before, the statistics are between zero and the critical values, indicating that the hypothesis of a unit root is not rejected.

E6: Scatter Diagrams and Plotting

E6.1 Introduction

This chapter will describe commands for producing high resolution graphs. This feature can be used for simple scatter diagrams, time series plots, and for plotting functions such as log likelihoods. You can print the graphics on standard printers and create plotter files for export to word processing programs such as Microsoft *Word*. Generalities about plotting and the following five commands are described in this chapter:

PLOT	is the standard scatter plotting function,
SPLOT	is for producing several scatter plots at the same time,
MPLOT	is for plotting the elements of matrices,
FPLOT	is for plotting functions of one variable,
CPLOT	is used for creating contour plots

E6.2 Printing and Exporting Figures

The following procedures apply to the various plotting commands described in this chapter as well as to the other uses of graphics in *LIMDEP*, which include: **KERNEL**, **HISTOGRAM**, **SPECTRAL**, **SIMULATE ; Plot**, **PARTIALS ; Plot**, **SURVIVAL**, **DSTAT ; Boxplots**, **DSTAT ; Quantiles ; Plot**, **REGRESS ; Cusums** and **EXECUTE ; Bootstrap**.

LIMDEP uses the standard Windows interface between input and output devices. When a plot appears in a window, you can use File:Print to send a copy to your printer (see Section E6.2.1). You can also save the graph as a Windows metafile (.wmf format) by using File:Save or File:Save As (see Section E6.2.2). Finally, you can simply use Edit:Copy and Edit:Paste to transport the graphic figure into another software program (see Section E6.2.3). For purposes of illustrating these functions, we will use Figure E6.1 which was generated by a **PLOT** command. The figure shows *LIMDEP*'s base format for graphics. Every graph generated is placed in its own scalable window, as shown in Figure E6.2, apart from the project, editing and output windows already open. This window will remain open until you close it. When you are finished reviewing the figure, you should close the window to avoid proliferating windows. You will be prompted to save the graph if you have not already done so.

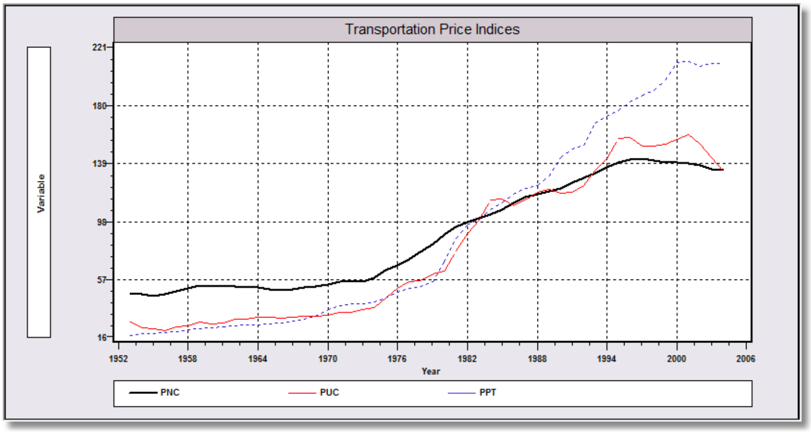

Figure E6.1 Time Series Plot Using the PLOT Command

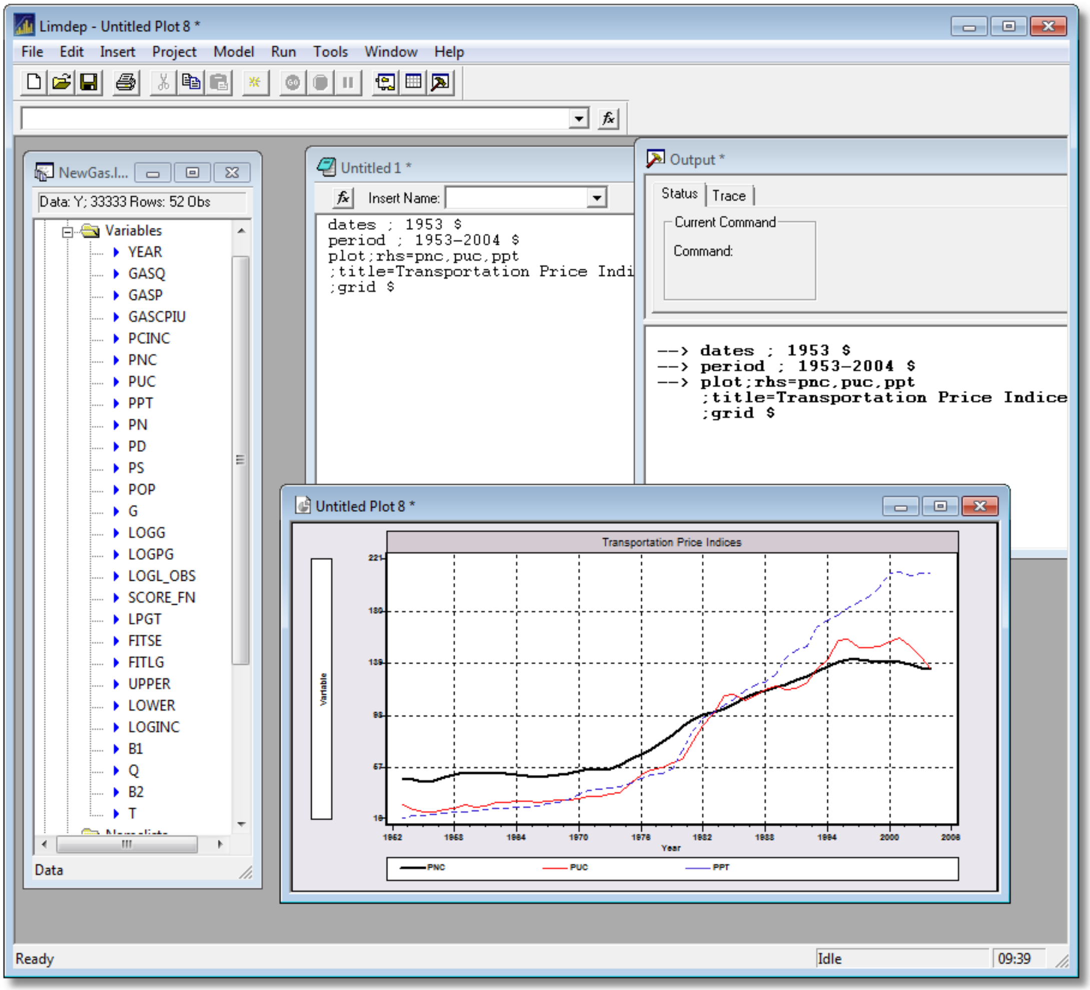

Figure E6.2 *LIMDEP* Desktop with Graphics Window

E6.2.1 Printing

LIMDEP prints graphs in landscape mode. (You can change this to portrait mode by using Page Setup in the file menu.) To print a graph, first make the plot window the active one by clicking the large banner at the top of the window (marked 'Untitled Plot 8*' in Figure E6.2 above). Then, to print without adjustment, select File:Print from the main menu. If you wish to change the size and orientation of a graph, select File:Page Setup first. Windows will handle the printer interface, as in other operations.

TIP: In *LIMDEP*, click the right mouse button inside the graphics window to open a menu with options to Copy, Save As, Page Setup, Print Preview and Print.

E6.2.2 Saving a Graph as a Graphics File

You may save any figure from a graphics window to disk in the Windows metafile (.wmf) format. Select File:Save or File:Save As. This file type is transportable to many other programs, including Microsoft *Word* and *Excel*. For example, in *Word*, click the Insert menu and then select Picture, then From File to import your .wmf file into your *Word* document. The Windows .wmf format includes codes that allow you to scale the figure to whatever size you desire.

E6.2.3 Pasting a Graph into a Document or Spreadsheet

You can also put a copy of your graph in *Word* or *Excel* without first saving it as a .wmf file. Select Edit:Copy in *LIMDEP*, and then select Edit:Paste in your other software to paste the graph into your document or spreadsheet. An example is shown in Figure E6.3. We have used Edit:Copy in *LIMDEP* followed by Edit:Paste in *Excel*, first to transport the data from *LIMDEP*'s data editor, then to transport the scatter plot. Once in *Excel*, the data and accompanying graphic can be viewed together and the graphic can be formatted. In our example, the graphic was resized and a line box was added. The formats used for graphics by *LIMDEP* are standards that are used generally in other commercial packages.

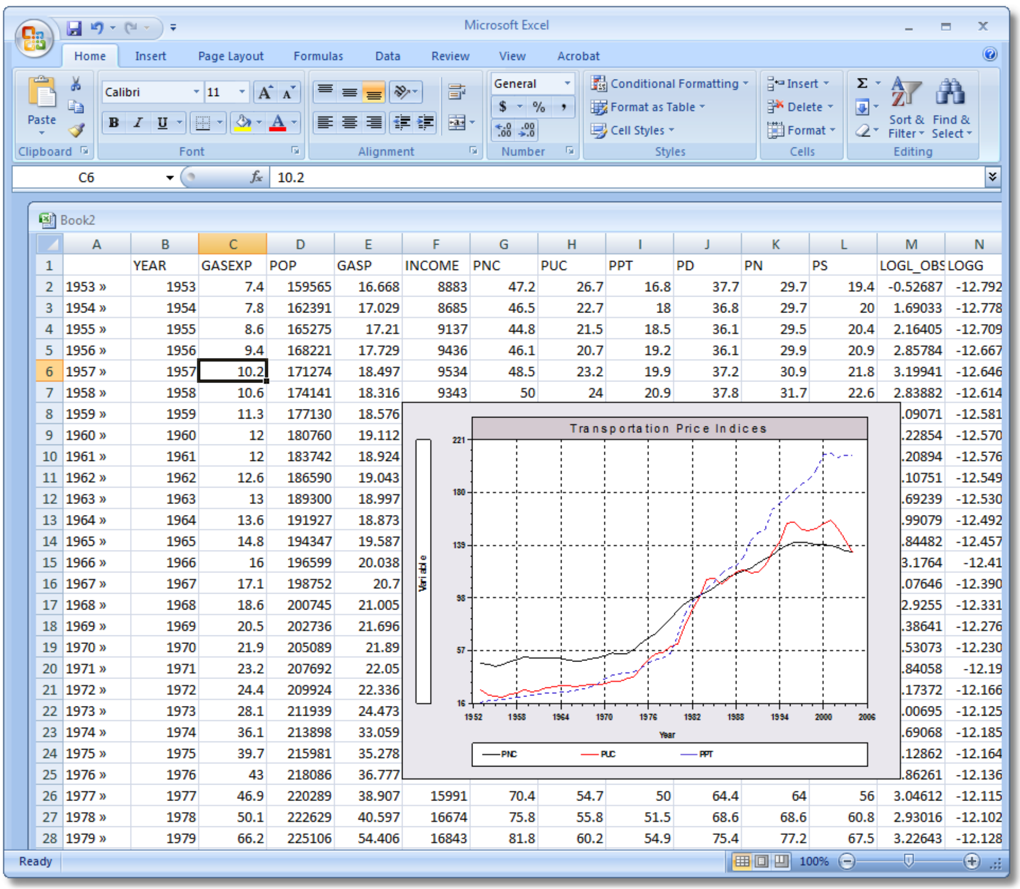

Figure E6.3 *Excel* Spreadsheet with *LIMDEP* Data and Graph Imported

E6.3 The PLOT Command

The command for producing a basic scatter (*XY*) plot of one or more variables against another variable is

PLOT ; Lhs = variable on horizontal axis
; Rhs = variables (up to five) on vertical axis $

Note the reversal of LIMDEP's usual convention. This command puts the Lhs variable on the horizontal axis, whereas a regression might be expected to do the reverse.

You may add a title to the figure by including

; Title = the title to be used

The title is placed at the top of the figure. The vertical axis of the plot is usually labeled with some variable name. You can override this with

; Yaxis = the label to be used, up to eight characters

This will often be useful when you plot a function or more than one variable. A longer descriptive label for the vertical axis can be provided with

; Vaxis = the test string to be used, up to 60 characters

The command builder for **PLOT** may be found by selecting Model:Data Description/Plot Variables. See Figures E6.4 and E6.5.

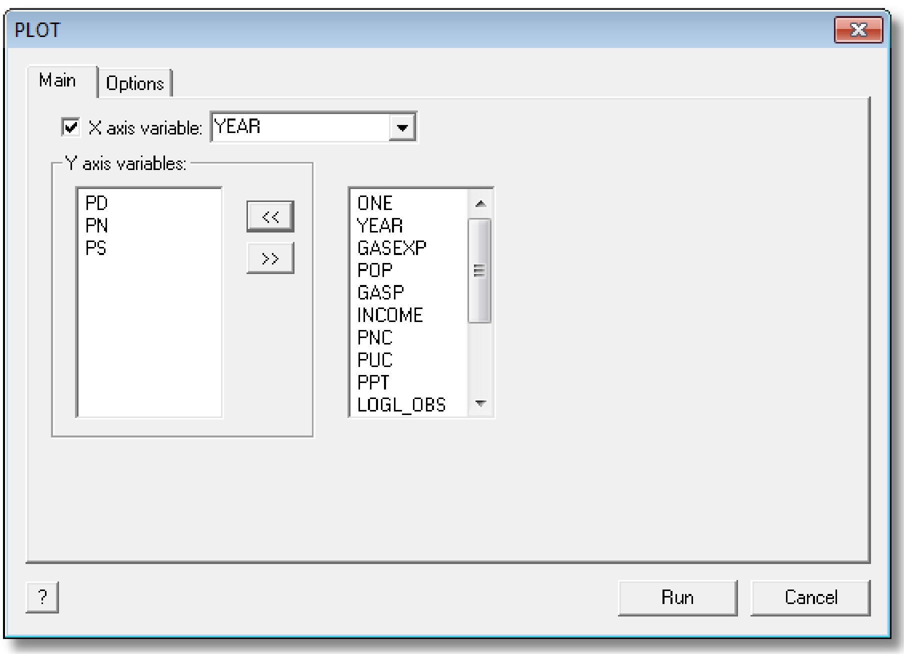

Figure E6.4 Main Page of Command Builder for PLOT

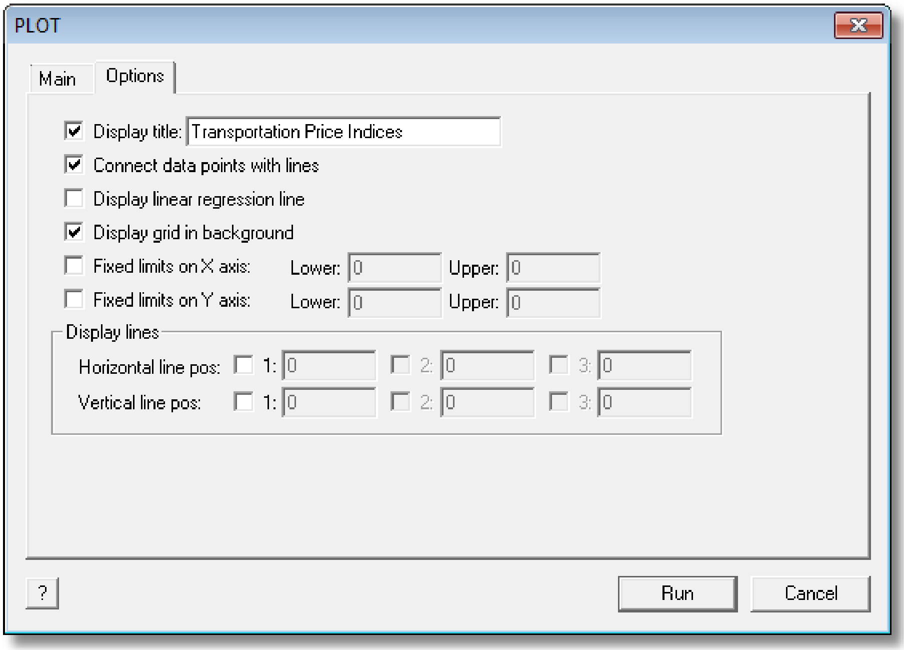

Figure E6.5 Options Page of Command Builder for PLOT

NOTE: The figures displayed here are based on yearly data for the U.S. gasoline market: The data are listed in Section E5.2.4 in Table E5.1.

E6.3.1 Scatter Plot of One Variable Against Another

To produce a scatter plot of one variable (*y*) against another (*x*) variable, the **PLOT** command is given with only a single Rhs variable. The command would be

PLOT ; Lhs = x ; Rhs = y $

Figure E6.6 was produced with the commands listed.

```
CREATE   ; g = gasq/(100*pop/282429) $
PLOT     ; Lhs = g
         ; Rhs = gasp
         ; Title = Simple Plot of Gas against Price $
```

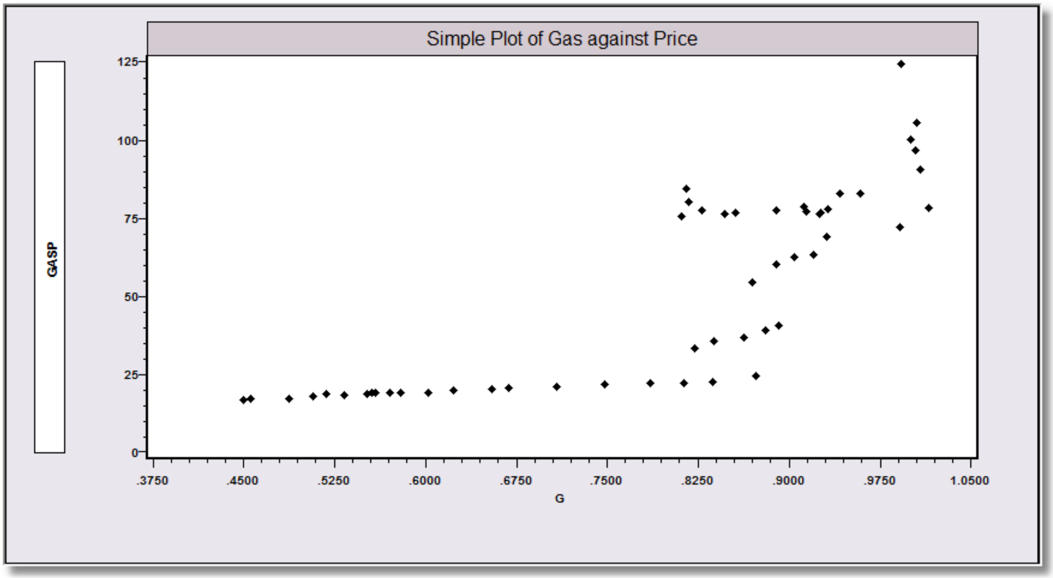

Figure E6.6 Simple Scatter Plot

E6.3.2 Plotting a Simple Linear Regression

To add a regression line to a figure, add

; Regression

to the **PLOT** command. By adding **; Regression** to the preceding command, we obtain the plot in Figure E6.7. You can also obtain this by selecting Display linear regression line in the Options page of the command builder. (In previous versions of *LIMDEP*, the regression equation would replace the title in the figure. In this version, the title appears as a header and the regression equation is placed in the legend at the right of the figure.)

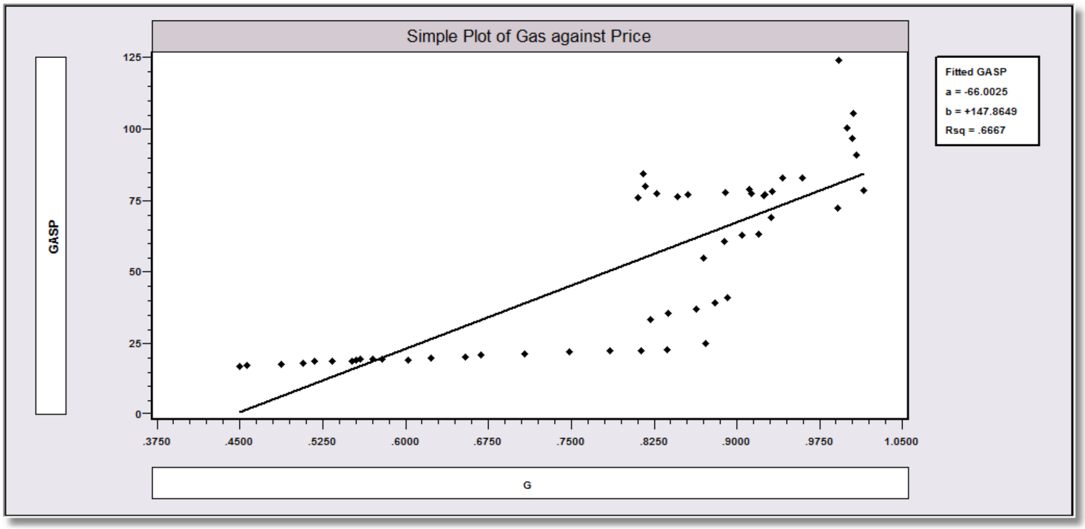

Figure E6.7 Scatter Plot with Linear Regression

E6.3.3 Time Series Plots

Time series plots, that is, plots of variables against the date can be obtained by using **DATES** and **PERIOD** to set up the dating, then omitting the **; Lhs** part of the **PLOT** command. When you omit the **; Lhs** part of the command, it is assumed that this is a time series plot, and the adjacent points are automatically connected. The figure is also automatically labeled with the dates. Figure E6.8 is a time series plot of the three macroeconomic price series for the data above. Note the use of the **; Grid** specification to improve the readability of the figure. (See Section E6.3.6 for details on this specification.)

NOTE: If your data are not dated using **DATES** and **PERIOD**, i.e., they are undated, then if you omit the **; Lhs = variable** in the **PLOT** command, the observations are plotted against the observation number, beginning with Observ.# = 1.

The commands used for Figure E6.8 are

```
DATES       ; 1953 $
PERIOD      ; 1953-2004$
PLOT        ; Rhs = pnc,puc,ppt
            ; Title = Transportation Price Indices
            ; Grid
            ; Vaxis = Prices of New and Cars and Public Transport $
```

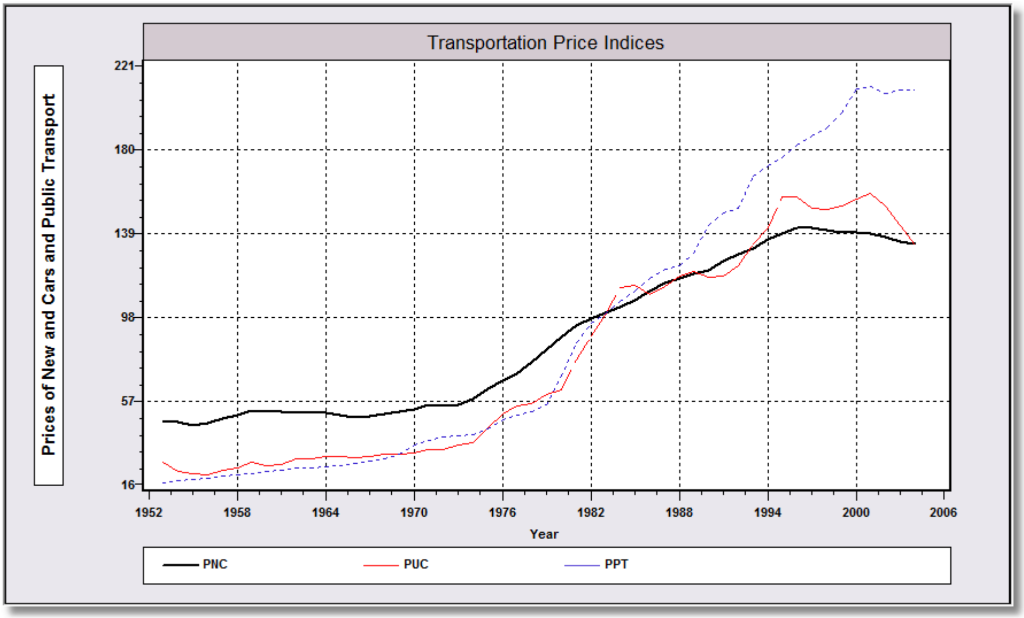

Figure E6.8 Time Series Plot for Several Variables

E6.3.4 Plotting Several Variables Against One Variable

To plot several variables against a single one, just include more than one Rhs variable in the command. The command is

PLOT ; Lhs = variable on horizontal axis
; Rhs = up to five variables to be plotted
; … other options, such as ; Grid and ; Fill $

(Note that the command builder dialog box allows you to specify multiple variables.) A different line style is used for each variable if you use **; Fill**. (The time series plot above is an example in which the Lhs variable is the automatically supplied date.) A different type of point is constructed for each if you are using a cross section. Generally, **PLOT** with **; Fill** (see the next section) creates a figure with one or more line plots, joining segments at the points, but suppressing any symbols for the points. The symbols (dots, stars, etc.) may be retained with **; Symbols**. The **; Regression** command is ignored if more than one variable is being plotted. An example is shown in Figure E6.9:

PLOT ; Rhs = pn,pd,ps
; Lhs = year
; Title = Scatter Plot of Price Series
; Yaxis = Prices
; Grid
; Fill
; Symbols $

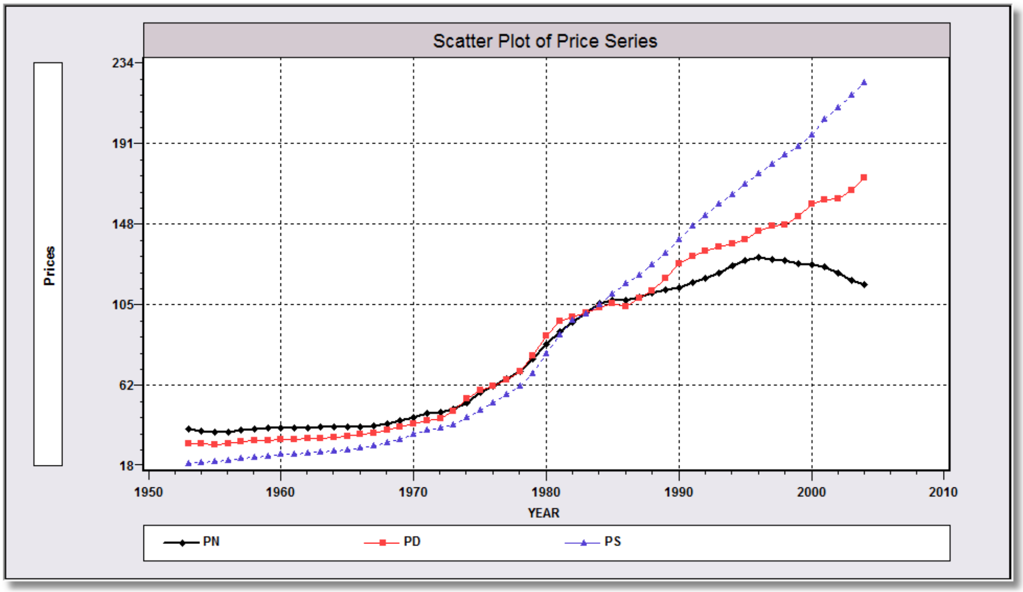

Figure E6.9 Multiple Plots in the Same Figure

NOTE: This is not a time series plot, in spite of the fact that *year* is the variable on the horizontal axis. Although at this point, *LIMDEP* does know that these are time series data, it does not know that '*year*' is a date variable; *year* is just another variable in the data set. If you omit the **; Lhs = variable** specification in the command, *LIMDEP* will label the *x* axis 'YEAR,' but this is not with respect to a variable in your data set; it is the date labeling that you gave in your **DATES** command. To see this at work, note that even if you did not have a variable named *year* in your data set, you could obtain a time series style plot with yearly observations, and labeled as such.

It might be useful in a figure to differentiate between certain variables by creating a line plot for some while plotting only the symbols for others. Plotting fitted and actual values in a regression, as in Figure E6.7, would be a common application. If the function being plotted is not a linear regression, or is some other function of a variable, you can create a scatter plot for some variables and a line plot for others by using

```
PLOT        ; Lhs = variable for horizontal axis
            ; Rh1 = variables to be shown with symbols only
            ; Rh2 = variables to be shown with a line plot
            ; … any other options $
```

In the example shown in Figure E6.10, we have computed a semilog regression, then plotted the predicted and actual values for the retransformed data.

```
REGRESS     ; Lhs = Log(hhninc) ; Rhs = one,educ ; Keep = loginc_f $
CREATE      ; inc_f = Exp(loginc_f) $
PLOT        ; Lhs = educ
            ; Rh1 = hhninc
            ; Rh2 = inc_f
            ; Grid
            ; Title = Predicted and Actual Income vs. Education
            ; Yaxis = Income $
```

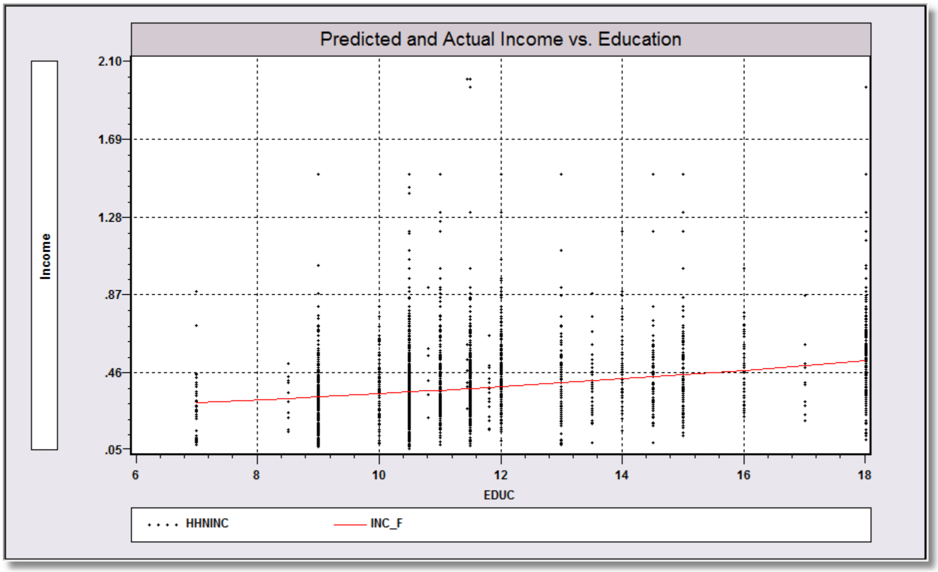

Figure E6.10 Simultaneous Scatter and Line Plots

E6.3.5 Combining Plots

You can combine up to five plots in the same field by using the command

```
PLOT        ; Lhs = variablex1, variablex2, …
            ; Rhs = variabley1, variabley2, …
            ; … any other options $
```

In this specification, each *y* variable is plotted against the corresponding *x* variable, all in the same plotting field. The field is dimensioned to be large enough to accommodate all of the graphs in the single figure. (Note that if your variables do not have similar scales, this can create a very unattractive figure.) Figure E6.11 plots one of the aggregate price indexes against another and one of the micro- indices against another in the same figure.

```
PLOT        ; Rhs = pn,ppt
            ; Lhs = pd,puc
            ; Fill
            ; Title = Price Indexes
            ; Vaxis = PN vs. PD and PPT vs. PUC $
```

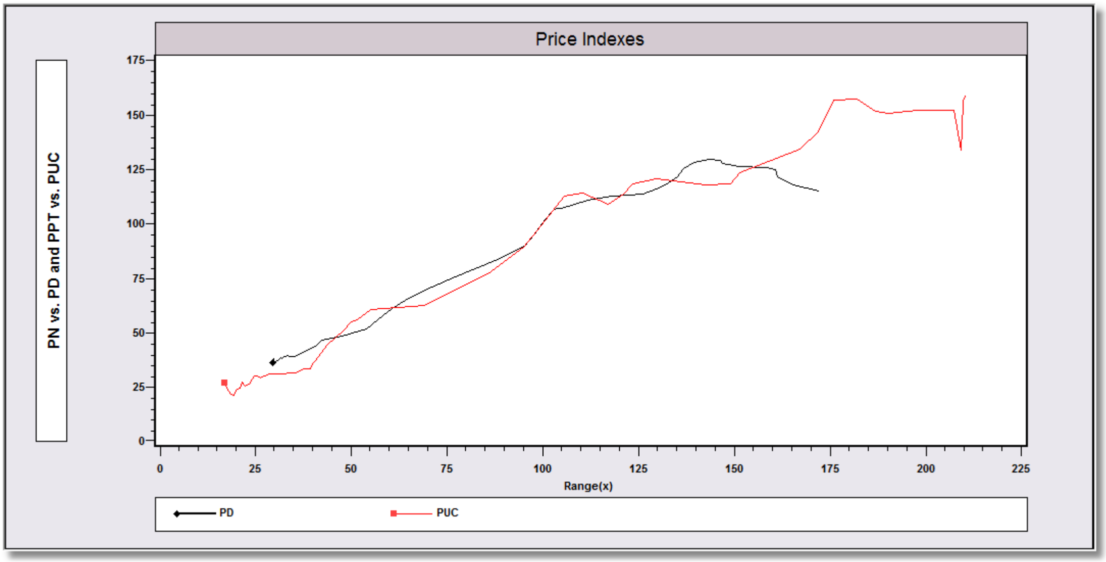

Figure E6.11 Simultaneous Plots

E6.3.6 Options for Scaling and Labeling the Figure

Scaling

The limits for the vertical and horizontal axes are chosen automatically so that every point appears in the figure. Boundaries are set by the ranges of the variables. You can override these settings as follows:

To set the limits for the horizontal axis use **; Endpoints = lower value, upper value**
To set the limits for the vertical axis use **; Limits = lower value, upper value**

HINT: If you plot variables of very different magnitudes in the same figure, or if your series has outliers in it, the scaling convention that seeks to include every point in the graph may severely distort your figure.

NOTE: If the endpoints or limits that you specify push any points out of the figure – *x* or *y* values are outside the limits – then the specifications are ignored, and the original default values are used.

For example, the top panel in Figure E6.12 is the same as Figure E6.6, produced by the command below without the specification of the endpoints and limits. The lower panel shows the effect of expanding the limits

```
PLOT        ; Rhs = gasp
            ; Lhs = g
            ; Title = Gasoline Consumption vs. Price
            ; Yaxis = Gas_Cons
            ; Grid
            ; Limits = 0,125       ?  Set the vertical axis limits
            ; Endpoints = 0,1.2  $  Set the horizontal axis limits
```

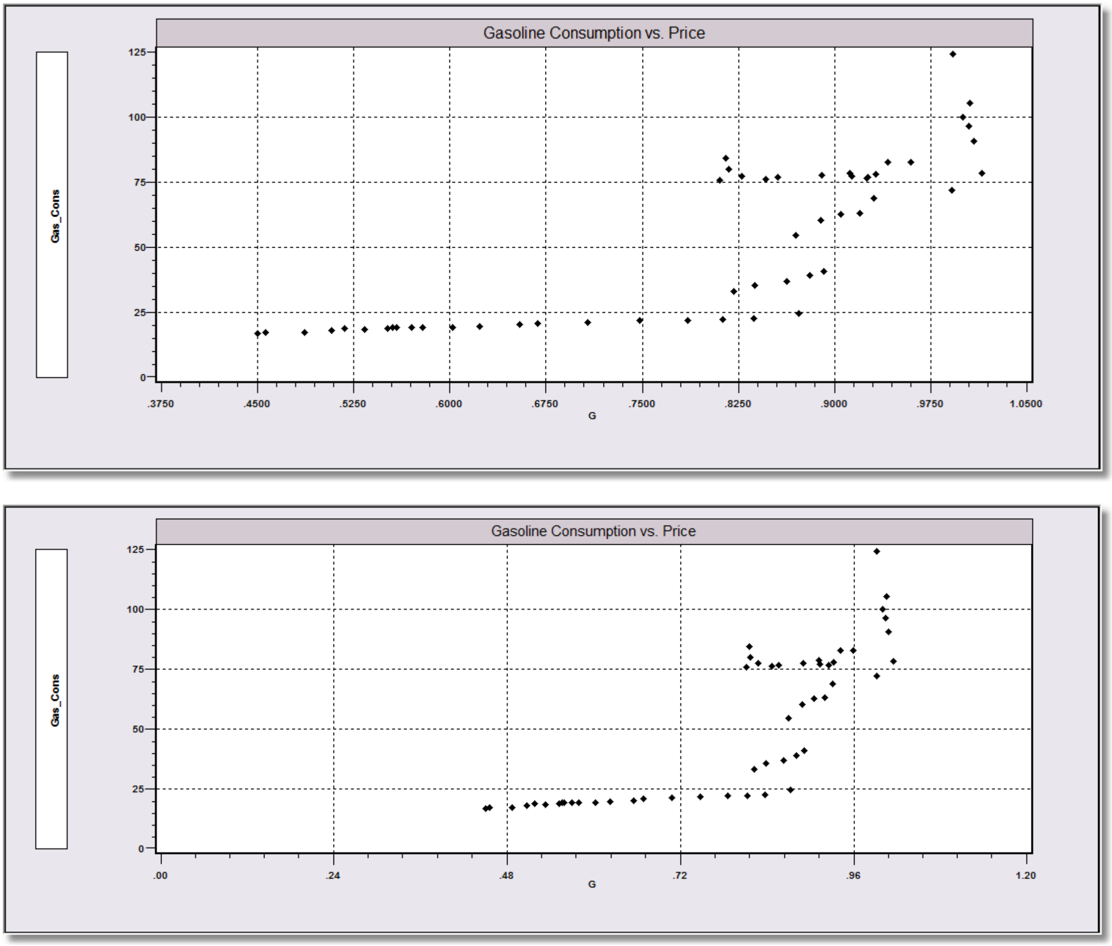

Figure E6.12 Scatter Plots with Rescaled Axes

The following describe some devices for changing the appearance of the figure, and creating particular types of graphs. Some of these have been used in the examples above. More extensive applications appear below.

Grids and Lines in the Plotting Field

It is sometimes helpful when plotting to put a grid in the figure. This makes it easier to relate the points in the graph to the distances on the axes. You may request a grid to be placed in the figure with

; Grid

This divides the screen into a grid of rectangles using dotted bars. The option was used in several of the preceding examples. You may also put horizontal and/or vertical lines in the figure at specific numerical benchmarks. The syntax is

; Spikes = up to five value(s) to put vertical lines at particular values
; Bars = up to five value(s) to put horizontal lines at particular values

The vertical or horizontal line is drawn from axis to axis, the full width or height of the box. Figure E6.13 uses these devices to focus on the means in a regression.

Connecting Points in the Plotting Field

If you are plotting a function or a time series, it may also be useful to connect adjacent points. To do so, add

; Fill

to the command. One way you might use this device would be to draw a function by creating a set of equally spaced values, then plotting the function of these values, connecting the points to create the continuous function. This device was used above in Figures E6.9 and E6.11.

For an example, the following fairly involved program plots the predicted values from a regression with the upper and lower confidence limits for the forecasts. Lines are placed in the figure at the point of means. The underlying computations are based on the bivariate regression

$$\log g_t = b_1 + b_2 \log pg_t + e_t$$

where g_t is the gasoline consumption variable and pg_t is the corresponding observation on the price variable, and b_1 and b_2 are the least squares constant and regression slope. The prediction and associated confidence limits are

$$\log \hat{g}_t = b_1 + b_2 \log pg_t$$

$$s_{ft} = \text{ forecast standard error (estimated)} = s\sqrt{1+\frac{1}{n}+\frac{\left(\log pg_t - \overline{\log pg}\right)^2}{\sum_{t=1}^{T}\left(\log pg_t - \overline{\log pg}\right)^2}}$$

confidence limits = $\log \hat{g}_t \pm t^* \times s_{ft}$

where *s* is the estimated standard error of the regression and *t** is the appropriate critical value from the table of the t distribution. The following does all of these computations and plots the forecast limits for 100 points which span the observed range of *pg*. The end results are shown in Figure E6.13. (The figure lacks the textbook butterfly shape because for these data, the forecast standard error is dominated by the term 1+1/*n*.)

Compute the regression using the sample data and collect statistics

```
SAMPLE      ; 1-52 $
CREATE      ; logg = Log(g)
            ; logpg = Log(gasp) $
REGRESS     ; Lhs = logg
            ; Rhs = one,logpg $
CALC        ; minlpg = Min(logpg)
            ; maxlpg = Max(logpg)
            ; delta =  (maxlpg - minlpg) / 100
            ; meanlpg = Xbr(logpg)
            ; vlpg = (n-1)*Var(logpg)
            ; meanlg = Xbr(logg)
            ; critcalt = Ttb(.95,degfrdm) $
```

Base the remaining computations on 100 generated points.

```
SAMPLE      ; 1-100 $
```

First, create 100 equally spaced points in the range of *pg*.

```
CREATE       ; lpgt = minlpg + delta * Trn(0,1)
```

Obtain forecast standard error and predicted values.

```
            ; fitse = s * Sqr(1 + 1/nreg + (lpgt - meanlpg)^2/vlpg)
            ; fitlg = b(1) + b(2) * lpgt
```

Compute the confidence limits.

```
            ; upper = fitlg + critcalt * fitse
            ; lower  = fitlg  - critcalt * fitse $
```

Now, plot all three series, marking the means of the two variables.

```
PLOT        ; Lhs = lpgt
            ; Rhs = fitlg,upper,lower
            ; Fill
            ; Bars = meanlg
            ; Spikes = meanlpg
            ; Yaxis = Fitted_LG
            ; Title = Forecast Interval for Fitted LogG $
```

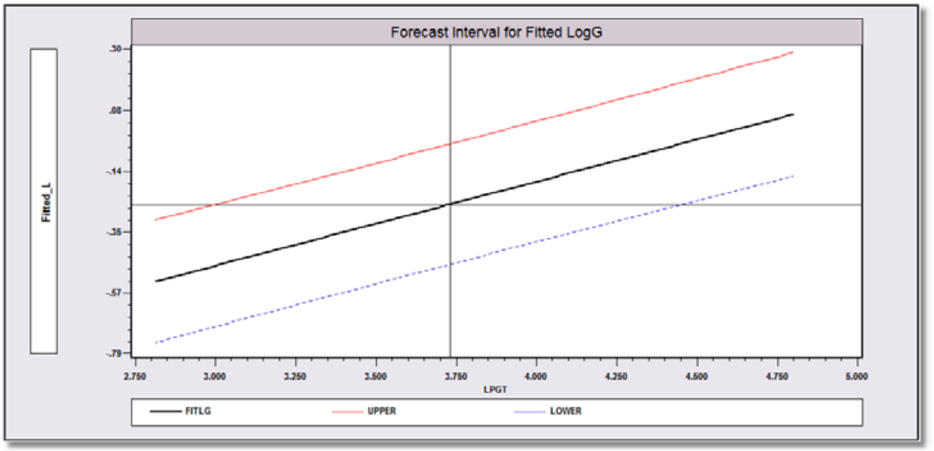

Figure E6.13 Plot of a Forecast Interval

The foregoing could be automated in a procedure. It might lack generality, however, as it is limited to simple bivariate regressions. This result can be replicated with the automatic procedure provided by the **SIMULATE** command. Figure E6.14 produces an interval estimate for the same regression. The commands are

```
SAMPLE      ; 1-52 $
REGRESS     ; Lhs = logg
            ; Rhs = one,logpg $
SIMULATE    ; Scenario: & logpg = minlpg(delta)maxlpg
            ; Plot(ci) $
```

The familiar butterfly effect can be seen in Figure E6.14. Note, the difference between E6.13 and E6.14 is that in E6.13, we have produced a 'forecast interval,' using the textbook formula that includes the variation of the unobserved disturbance. This is the source of the leading 1 under the square root. In Figure E6.14, we have simulated the dependent variable by computing a confidence interval for the fitted values in the regression, not a forecast interval. The interval in Figure E6.14 is correspondingly narrower because the leading 1 in the computation of the standard error is not included.

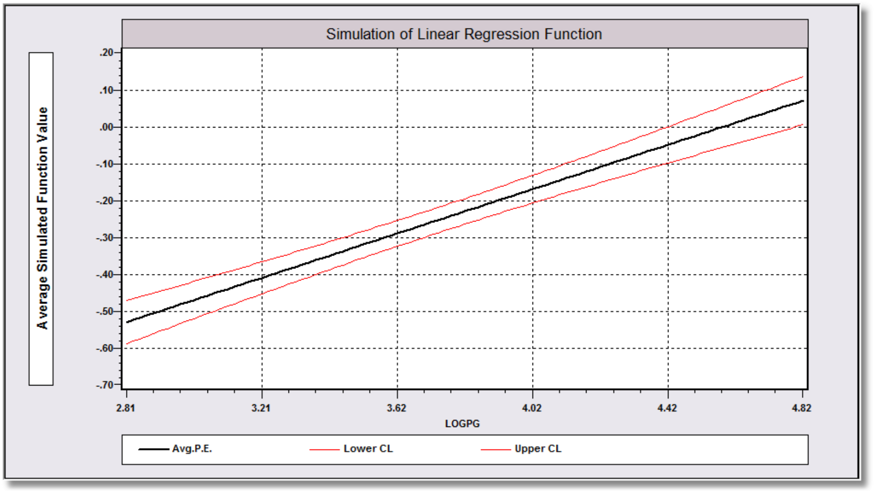

Figure E6.14 Prediction Interval Using SIMULATE

E6.3.7 Fenceposts Plot

A plot that displays vertical distances from the horizontal axis to the point in the field (it will resemble a row of fenceposts) is obtained by adding

; Post

to the **PLOT** command. This form of the figure may take a couple experiments to obtain the desired result, as it is necessary to adjust the location of the horizontal axis. The symbol (dot) that would normally appear in the figure absent the post can be included at the top (or bottom) of the post by adding

; Symbol

to the command.

The following example illustrates. The data used in the plot are a panel of data on 48 states for 17 years used in Munell (1990). The data were downloaded from the website for Badi Baltagi's text: http://www.wiley.com/legacy/wileychi/baltagi/supp/PRODUC.prn (*Econometric Analysis of Panel Data* (2005)). Figure E6.15 displays the within group (state) residual variances based on a loglinear regression of log of public capital on a constant, the log of gross state product and the log of total employment.

```
SAMPLE      ; 1-816 $
REGRESS     ; Lhs = Log(p_cap) ; Rhs = one,Log(gsp),Log(emp)
            ; Res = e $
CREATE      ; Esq = e^2 $
CREATE      ; vstate = Group Mean(esq, Str = state) $
REJECT      ; YR < 1986 $ (Use only last year of the data)
PLOT        ; Lhs = state ; Rhs = vstate
            ; Post
            ; Endpoints = 0,50 ; Limits = 0,.2 ; Grid
            ; Title = Residual Variance by State $
```

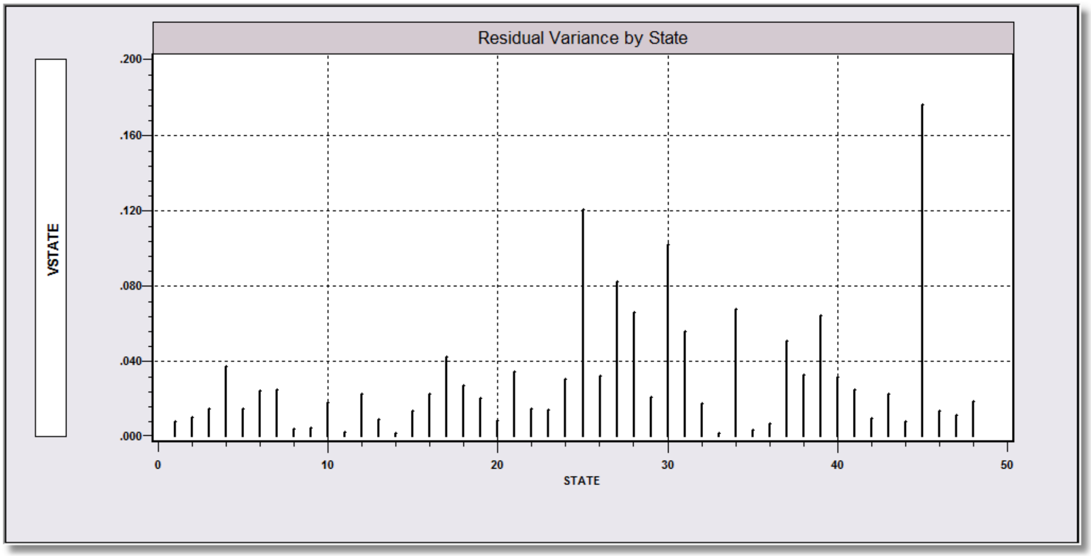

Figure E6.15 Fencepost Plot of Residual Variances by State

E6.3.8 Centipede Plot

When you send an Lhs variable and two Rhs variables to **PLOT**, you can produce a plot which puts the two values above the corresponding Lhs value and draws a vertical line between them with a dot in the center. This is a particular type of plot that we label a centipede plot, because of its appearance which will be clear shortly. The figure is requested with

```
PLOT        ; Lhs = one variable
            ; Rhs = two variables
            ; Centipede
            ... (all other options for plot are the same) $
```

In the following example, we compute a regression for each of the 48 states in the panel data set used in the preceding example. We then construct the 95% confidence limits for a confidence interval for the 48 estimated coefficients on the third variable. The centipede plot shows how the confidence limits vary from state to state. The horizontal bar at zero reveals which of the estimates are significantly different from zero – that is, those for which the confidence interval does not contain zero. To make this convenient, we use a procedure to do the computations in a loop.

```
SAMPLE      ; 1-816 $
MATRIX      ; bi = Init(48,1,0) ; si = Init(48,1,0)$
PROCEDURE
INCLUDE     ; New ; State = i $
REGRESS     ; Lhs = Log(p_cap)
            ; Rhs = one,Log(gsp),Log(emp)
            ; Quietly $
MATRIX      ; bi(i) = b(3) $
CALC        ; sdi = Varb(3,3) ; sdi = Sqr(Sdi) $
MATRIX      ; si(i) = sdi $
ENDPROC $
EXECUTE     ; i = 1, 48 $
CALC        ; tstar = Ttb(.975,14)$
MATRIX      ; upper = bi + tstar*si ; lower = bi - tstar*si $
SAMPLE      ; 1-816 $
REJECT      ; Yr < 1986 $
CREATE      ; b_upper = upper(state) ; b_lower = lower(state) $
PLOT        ; Lhs = state
            ; Rhs = b_lower,b_upper
            ; Centipede
            ; Endpoints = 0,48
            ; Bars = 0
            ; Vaxis = Confidence Limits
            ; Title = Confidence Limits for Employment Elasticity by State $
```

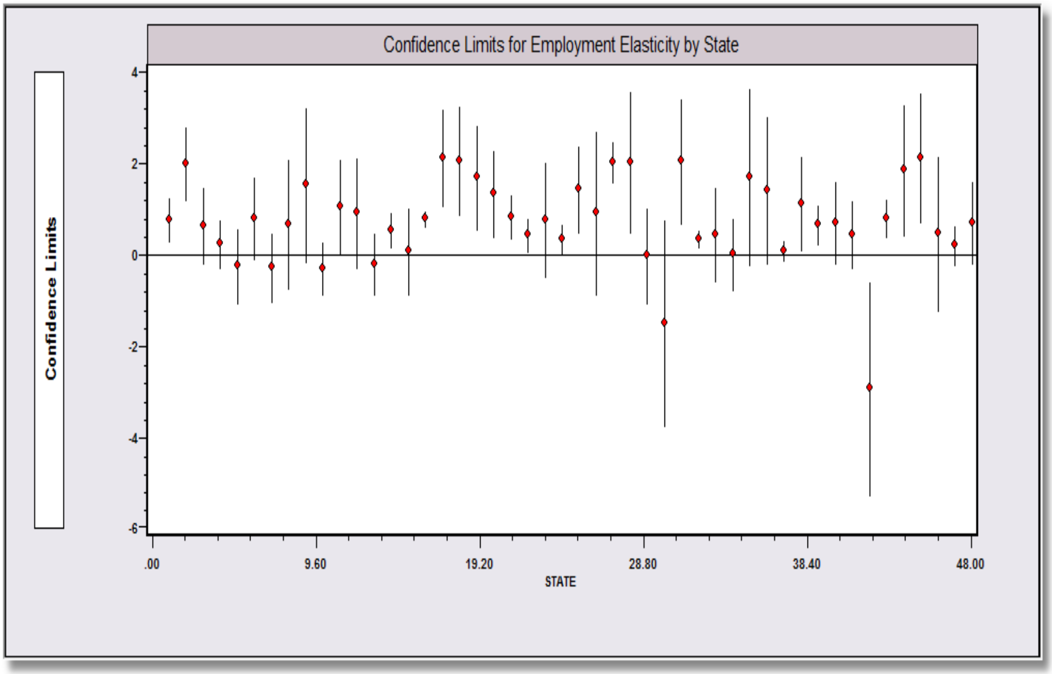

Figure E6.16 Centipede Plot of Confidence Intervals for b(log*employment*)

E6.3.9 A Program for Plotting Confidence Regions

In the example below, which is a general program, a confidence ellipse is drawn for two coefficient estimates. The one dimensional confidence intervals are also drawn. The computation is as follows: The confidence ellipse is the set of points (β_1,β_2) for which

$$F = ½[(b_1 - \beta_1)^2 s_{22}/D + (b_2 - \beta_2)^2 s_{11}/D - 2(b_1 - \beta_1)(b_2 - \beta_2)s_{12}/D] = F^*$$

where F^* is the critical value from the appropriate F table; b_1 and b_2 are the parameter estimates; s_{11}, s_{12}, and s_{22} are estimated asymptotic (co)variances of b_1 and b_2; and $D = s_{11}s_{12}(1-r_{12}^2)$ is the determinant of the 2×2 covariance matrix. The ellipse is defined over values of b_1 and b_2 for which the equality is met. The procedure will do this computation for any model.

The program is used here to produce a confidence region for the price and income coefficients in an equation for the gasoline market examined earlier. The commands used to produce the figure are

```
SAMPLE      ; 1-52 $
CREATE      ; g = gasq/(100*pop/282429) ; logg = Log(g) $
CREATE      ; loginc = Log(pcinc) ; logpg = Log(gasp) $
REGRESS     ; Lhs = logg ; Rhs = one,logpg,loginc $
EXECUTE     ; Proc = confregn(2,3) $
```

Figure E6.17 below shows the results of the computation. The procedure is listed below.

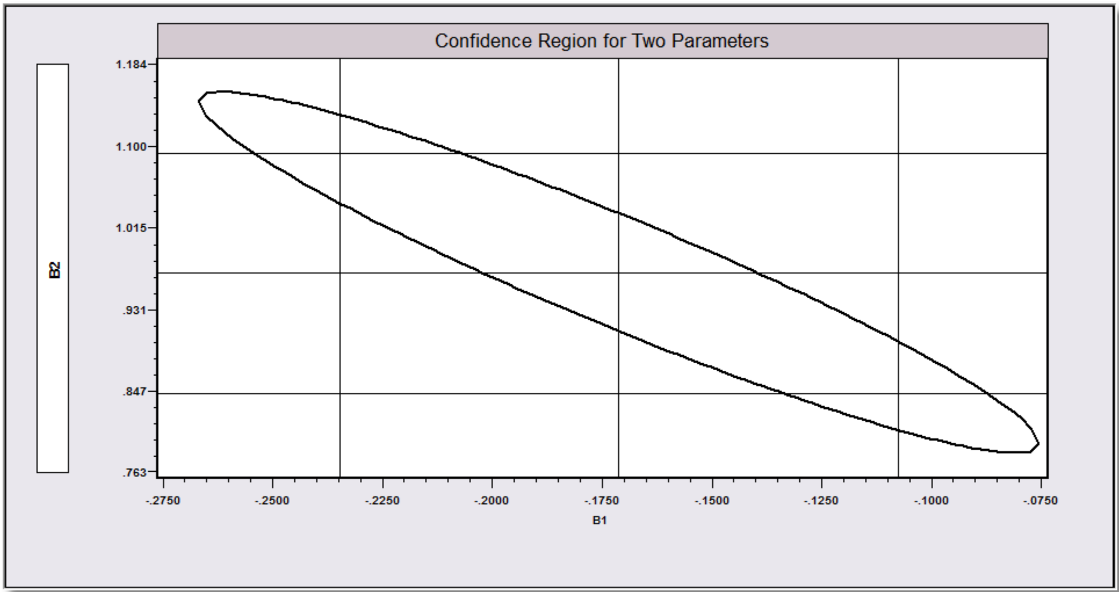

Figure E6.17 Confidence Region for Two Parameters

Compute confidence ellipse and confidence regions for two coefficients. The program does not require the model to be a regression model. It may be used with any model estimated by the program. Theoretically, if the model is not a classical regression model, a large sample appeal to the Wald statistic and asymptotic normality of the estimates is needed. Use the following three steps:

Step 1. Store the procedure.
Step 2. Estimate the model.
Step 3. Execute the following procedure.

No modification is necessary. The plot will contain the confidence ellipse and individual confidence intervals for the selected parameters. The first coefficient is labeled $b1$ and the second is labeled $b2$. The procedure will do the plot for any pair of coefficients.

```
PROC = confregn ( coef1 , coef2 ) $
```

Gather the coefficients, variances, standard errors, t and F values. Do the computations for the intervals. **CALC** obtains the values for the range of $b1$ for the plot.

```
CALC      ; sb1b1 = Varb(coef1,coef1) ; sb1 = Sqr(sb1b1) ; c1 = b(coef1)
          ; sb2b2 = Varb(coef2,coef2) ; sb2 = Sqr(sb2b2) ; c2 = b(coef2)
          ; sb1b2 = Varb(coef1,coef2) ; q12 = sb1b2/sb1b1
          ; u  = Sqr(sb2b2 - sb1b2*q12)
          ; fc = Ftb(.95,2,(n-kreg))
          ; tc = Ttb(.95,(n-kreg))
          ; max = Sqr(2*fc*sb1b1)
          ; min  = -max
          ; db1  = (max - min)/100 $
SAMPLE    ; 1-201 $
```

Plot 201 points in an ellipse. The first 100 are the lower part, the second 100 are the upper part. Point 201 equals point 1, so the ellipse is closed. Compute *b*1-*beta*1 then *b*2-*beta*2 as a function of *b*1-*beta*1, then *b*1 and *b*2.

```
CREATE      ; If(_obsno <= 100) b1 = min+Trn(1,1)       * db1
            ; If(_obsno >   100) b1 = max-(Trn(1,1)-100)* db1
```

The first line contains a protection against taking the square root of a negative number.

```
            ; q = u*Sqr(0 ! (2*fc - b1*b1/sb1b1))
            ; If(_obsno <= 100) b2 = c2 + b1 * q12 + q
            ; If(_obsno >   100) b2 = c2 + b1 * q12  -  q
            ; b1 =  b1 + c1
            ; If(_obsno = 201) b1 = b1[-200]
            ; If(_obsno = 201) b2 = b2[-200] $
```

These are the one dimensional upper and lower confidence bounds for the two coefficients. Top, bot, etc. make the box a little bigger.

```
CALC        ; ucb2 = c2 + tc*sb2 ; lcb2 = c2 - tc*sb2
            ; ucb1 = c1 + tc*sb1 ; lcb1 = c1 - tc*sb1
            ; top = 1.025 * Max(b2) ; bot = .975 * Min(b2)
            ; lft = .975 * Min (b1) ; rt = 1.025 * Max(b1) $
```

Finally, plot the ellipse with the confidence limits and a bar and spike to show the original coefficients, themselves.

```
PLOT        ; Lhs = b1 ; Rhs = b2
            ; Bars = ucb2,lcb2,c2 ; Spikes = ucb1,lcb1,c1
            ; Limits = bot,top ; Endpoints = lft,rt ; Fill ; Nosort
            ; Title = Confidence Region for Two Parameters $
ENDPROC
```

The preceding program is written specifically for a linear regression model with normally distributed disturbances – it is based on the F statistic for the joint test of the significance of the two coefficients. It can be made more general by setting it up for the Wald (chi squared) statistic that would rely on the asymptotic distribution. The following lists the corresponding program, without the surrounding annotation. It is executed the same as in the earlier program.

```
PROC  = confregn ( coef1 , coef2 ) $
CALC       ; sb1b1 = Varb(coef1,coef1) ; sb1 = Sqr(sb1b1) ; c1 = b(coef1)
           ; sb2b2 = Varb(coef2,coef2) ; sb2 = Sqr(sb2b2) ; c2 = b(coef2)
           ; sb1b2 = Varb(coef1,coef2) ; q12 = sb1b2/sb1b1
           ; u = Sqr(sb2b2 - sb1b2*q12)
           ; max = Sqr(5.99*sb1b1) ; min = -max ; db1 = (max - min)/100 $
SAMPLE     ; 1-201 $
CREATE     ; If(_obsno <= 100) b1 = min + Trn(1,1)        * db1
           ; If(_obsno >   100) b1 = max - (Trn(1,1)-100) * db1
           ; q = u*Sqr( 0 ! (5.99 - b1*b1/sb1b1))
           ; If(_obsno <= 100) b2= c2 + b1 * q12 + q
           ; If(_obsno >   100) b2= c2 + b1 * q12 -  q
           ; b1 = b1 + c1
           ; If(_obsno = 201) b1 = b1[-200]
           ; If(_obsno = 201) b2 = b2[-200] $
CALC       ; ucb2 = c2 + 1.96*sb2 ; lcb2 = c2 - 1.96*sb2
           ; ucb1 = c1 + 1.96*sb1 ; lcb1 = c1 - 1.96*sb1
           ; top  = Max(b2) + .1*Abs(Max(b2))
           ; bot  = Min (b2)  - .1*Abs(Min(b2))
           ; lft   = Min (b1)  - .1*Abs(Min(b1))
           ; rt    = Max(b1) + .1*Abs(Max(b1)) $
PLOT       ; Lhs = b1 ; Rhs = b2
           ; Bars = ucb2,lcb2,c2 ; Spikes = ucb1,lcb1,c1
           ; Limits = bot,top ; Endpoints = lft,rt ; Fill ; Nosort
           ; Title = Confidence Region for Two Parameters$
ENDPROC
```

E6.3.10 Sorting the Data Before Plotting

The **PLOT** command contains a switch **; Nosort** which is used to request the plotting program not to sort the values of the variable on the horizontal axis (carrying all those for the vertical axis, of course) before plotting. The sort is normally done when you use **; Fill** to connect points so that the plot looks like a function and not a jumble of lines. When you plot a time series, this sort is not necessary since dates are already sorted by construction. But, it might be necessary if you are plotting a cross section of values. The following experiment demonstrates: The data on *x* are randomly drawn from the standard normal distribution, but *y* is a simple, deterministic quadratic function of *x*. The results are shown in Figure E6.18. The plot on the left shows the expected result. The plot on the right shows what happens if the data are not sorted.

```
SAMPLE     ; 1-100 $
CREATE     ; x = Rnn(0,1) ; y = .3 * (x-1)^2 $
PLOT       ; Lhs = x ; Rhs = y ; Fill $  Then, we add ; NoSort
```

Data sorted before plotting as usual **Data not sorted before plotting**

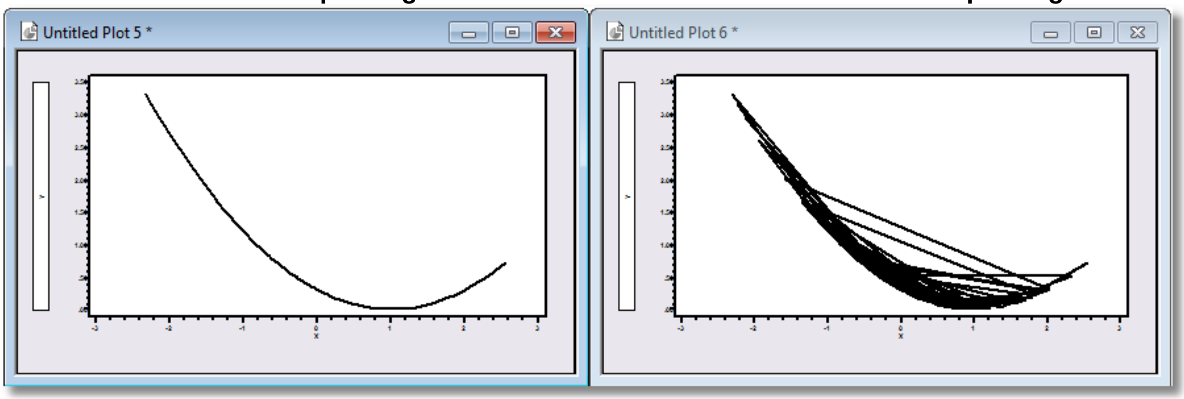

Figure E6.18 The Effect of Sorting the Lhs Variable in PLOT ; Fill ... $

This issue is relevant in our confidence region plot because of the way it is constructed. The data on b_1 are

$$b_1(min), b_1(min)+db1, b_1(min)+2db1 \ldots b_1(max), b_1(max)-db1, b_1(max)-2db1, \ldots, b_1(min)$$

so the series ascends from $b_1(min)$ to $b_1(max)$ in equal steps, then descends from $b_1(max)$ to $b_1(min)$ in equal steps. This allows us to draw a figure that (if it were done slowly enough for you to watch it) would move the pen across the field from left to right (the lower half of the ellipse), then move back across the field from right to left (the upper half of the ellipse). This is necessary because, in fact, the ellipse is not a function; the values the horizontal axis are not each associated with a single *y*. If the confidence ellipse is plotted with the sort, Figure E6.19 results; intriguing, perhaps, but not what we had in mind.

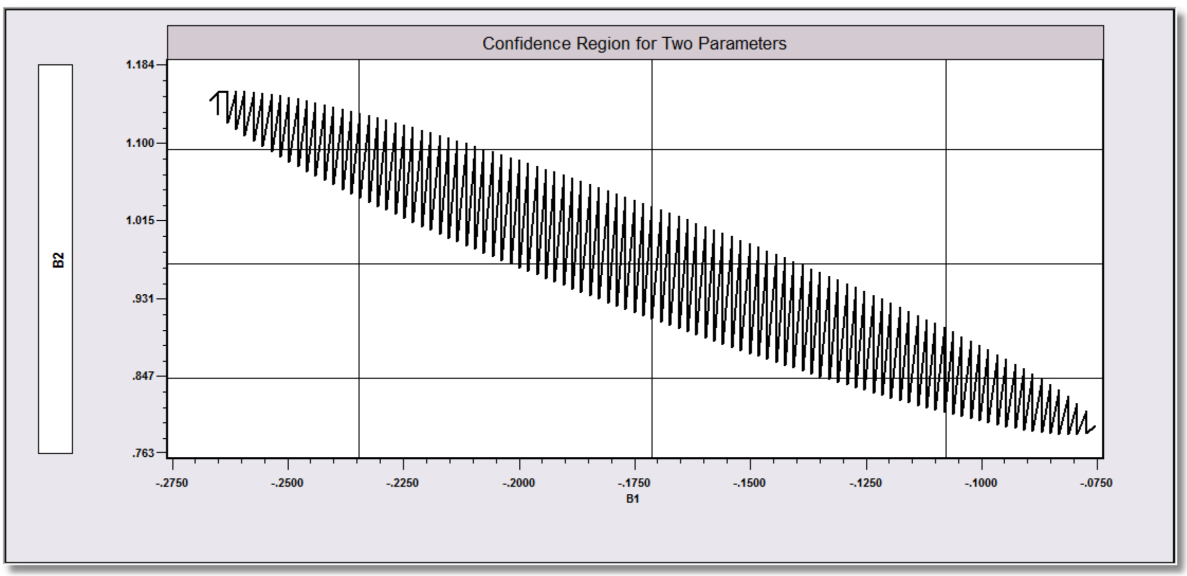

Figure E6.19 Function Plot with Inappropriate Sorting

E6.3.11 Plotting a Function

Frequently, a simple way to plot a function is to plot the function values at a set of equally spaced points and connect the dots in the figure. The following produces Figure B.3 in Greene (2011, page 1023), where the density of the t distribution is plotted for several values of the degrees of freedom parameter: The following plots the density of *t* for 2, 10, 40, and (essentially) infinite degrees of freedom.

```
SAMPLE      ; 1-101 $                Plot and connect 100 segments
CREATE      ; t = Trn(-4,.08) $      Values -4 to +4 in steps of .08
```

This procedure obtains the value of the density over a grid of values contained in variable *t*, and puts them in a variable passed as *fn*.

```
PROC = tdensity(fn,t,d) $
CREATE      ; fn = Gma((d+1)/2)/Gma(d/2) / Sqr(d*pi) * (1+t*t/d)^(-(d+1)/2)$
ENDPROC $
```

Compute for 2, 10, 40, infinity (last is N(0,1)). Then plot the four densities in the same figure.

```
EXECUTE     ; Proc = tdensity(t2,t,2) $
EXECUTE     ; Proc = tdensity(t10,t,10) $
EXECUTE     ; Proc = tdensity(t40,t,40) $
CREATE      ; tinf = N01(t) $
PLOT        ; Lhs = t ; Rhs = t2,t10,t40,tinf ; Fill intervals ; Yaxis = Density
            ; Title = t Densities with Different Degrees of Freedom $
```

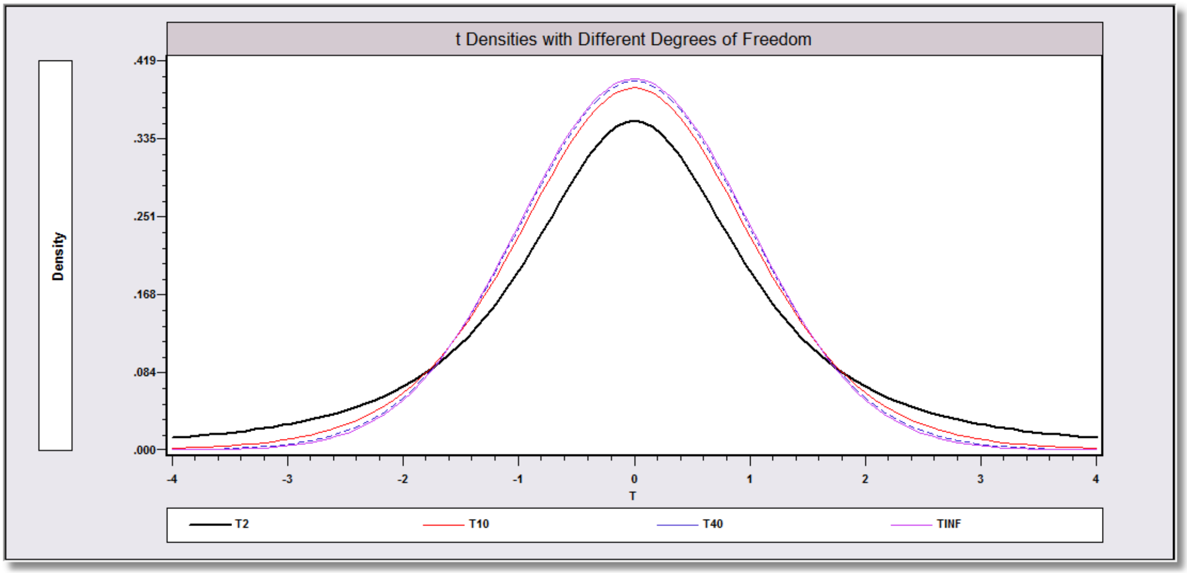

Figure E6.20 Plot of t Density with Varying Degrees of Freedom

An area under the function being plotted can be filled by using

; Area = Left, Right

in the command. This has the effect of filling the figure from the left margin (negative infinity) to *Left* and from *Right* to the right margin (positive infinity). The following familiar figure shows the upper and lower 2.5% critical regions for a t distribution with 40 degrees of freedom.

```
SAMPLE      ; 1-1000 $
CREATE      ; t = Trn(-4,.008) $       Values -4 to +4 in steps of .08
EXECUTE     ; Proc = tdensity(t40,t,40)$
CALC        ; t025 = Ttb(.025,40) ; t975 = -t025$
PLOT        ; Lhs = t ; Rhs = t40
            ; Yaxis = density
            ; Title = Upper and Lower 95% Critical Values for t[40]
            ; Area = t025,t975 $
```

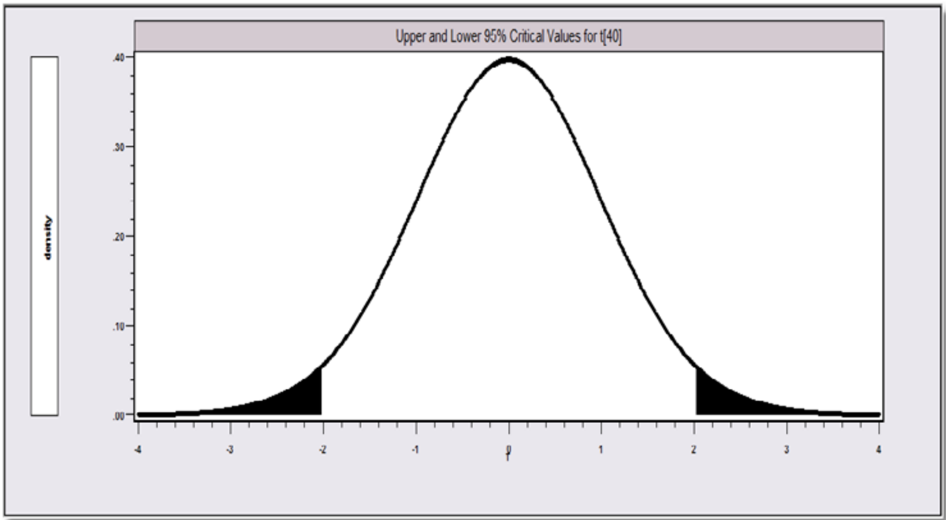

Figure E6.21 Critical Regions for the t[40] Distribution

You can hide the left tail area by making *Left* low enough to be out of the picture, such as -5 in the figure above and the right area by making *Right* large enough to be out of the picture (e.g., +5 above). In order to obtain a complete fill, the number of points plotted should be at least 500. If the area has gaps, they will close when you resize the graph.

A function plot for a discrete variable with a small number of values will appear like the top panel of Figure E6.22 which plots a Poisson probability distribution. Connections between the dots are meaningless (there is no function value for xp = 2.5). Nonetheless, it is customary to accentuate the plot by including the connections. For this sort of figure, use

; Fill ; Symbols

The commands are:

```
SAMPLE      ; 1-10 $
CREATE      ; xp = Trn(0,1)$
CREATE      ; prob_xp = Exp(-2)*2^xp/Gma(xp+1) $
PLOT        ; Lhs = xp ; Rhs = prob_xp

            ; Grid
            ; Vaxis = Poisson Probability $
```

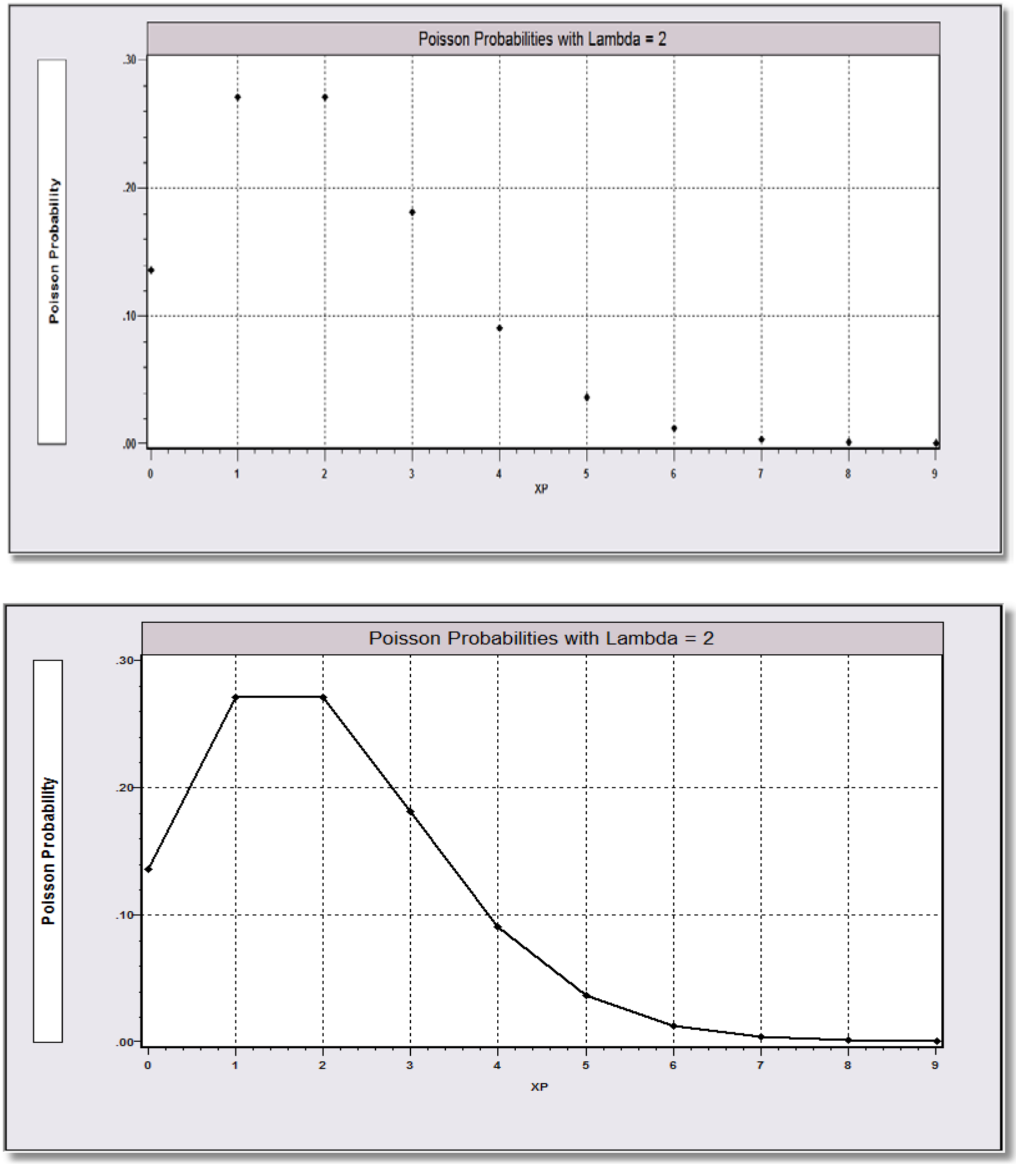

Figure E6.22 Poisson Probabilities

E6.3.12 Stratified Scatter Plots

A scatter plot can be stratified by a stratification variable, so that the values associated with each stratum can be given a different symbol in the figure. You may plot up to five strata in the same figure. The command format is

PLOT ; Lhs = variable on horizontal axis
; Rhs = variable on vertical axis
; Str = stratification variable which takes values 1, 2, ... up to 5
[any other options – all available except ; Fill and ; Regression] $

Figure E6.23 shows a plot of *age* vs. *income* stratified by marital status using the health care system data that we used in Section E3.3 (histograms). In order to reduce the density of the plot, only a small subsample of observations is used

SAMPLE ; 1-500 $
CREATE ; married = married + 1 $
PLOT ; Lhs = age
; Rhs = hhninc
; Str = married
; Title = Income vs. Age for Married and Nonmarried $

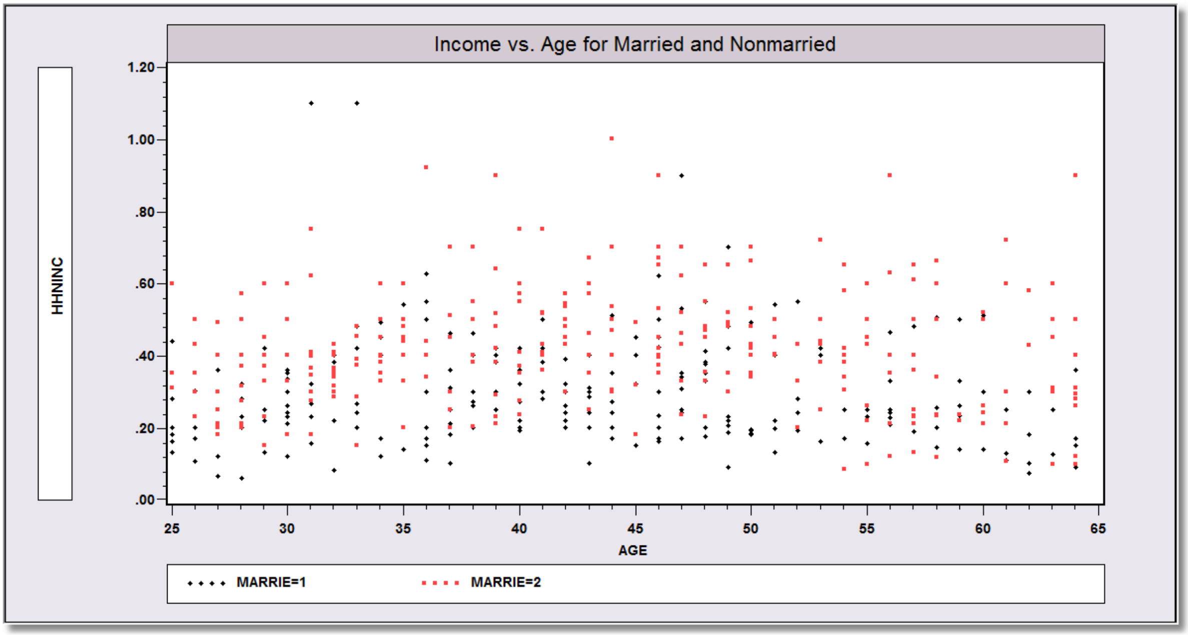

Figure E6.23 Scatter Plot with Stratification

E6.4 Multiple Scatter Plots – The SPLOT Command

The command for computing and plotting several scatter diagrams simultaneously is

SPLOT ; Rhs = list of from three to five variables $

This command requests a simultaneous plot of every variable in the list against every other variable. This can produce up to 4×5 = 20 plots at the same time. (Variables are not plotted against themselves.) The command builder is the same as the first page for **PLOT** and can be accessed by selecting Model:Data Description/Multiple Scatter Plots. There are no options or other specifications for this command. An example in which we obtain simultaneous scatter plots for five of the price indices in the gasoline market data appears in Figure E6.24.

SPLOT ; Rhs = pn,pd,ps,pnc,puc
; Title = Aggregate and Transport Price Indexes $

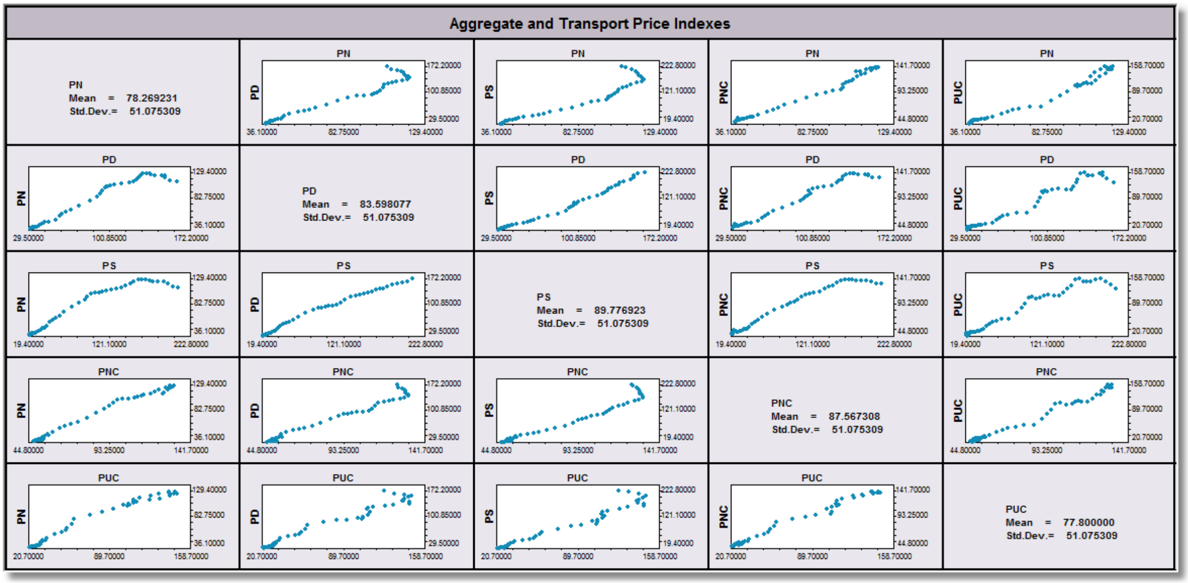

Figure E6.24 Multiple Scatter Plots with SPLOT

E6.5 Plotting Matrices – The MPLOT Command

The command for plotting the values in one matrix against those in another is

MPLOT ; Lhs = matrix 1 ; Rhs = matrix 2 $

The plot is in the same fashion as a pair of variables. All other options are the same as in the **PLOT** command. The graph is produced by treating the corresponding elements of the two matrices as if they were observations on a pair of variables. Only one Rhs matrix may be given. All other options, such as **; Limits**, **; Fill**, etc. are the same as for **PLOT**. We consider two examples below. The command builder for **MPLOT** is the same as for **PLOT.** It can be accessed by selecting Model:Data Description/Plot Matrix.

E6.5.1 Plotting Autocorrelation and Partial Autocorrelation Functions

The **IDENTIFY** command described in Chapter E5 produces character graphic plots of the autocorrelation and partial autocorrelation functions for a variable. It also saves these results as a matrix, *acf_pacf*, so if you want to produce sharper figures, you can use **MPLOT**. The program segment below shows how to obtain such a plot for the ACF and PACF for any time series. (The character plot will actually be more informative since it also lists the test statistics.)

Get the ACF and PACF.

```
IDENTIFY    ; Rhs = the variable ; Pds = the value you choose $
```

(We used *PD* in the gasoline data for our example.) Find out how many lags were used.

```
CALC        ; lags = Row(acf_pacf) $
```

Extract the two columns of the results matrix.

```
MATRIX      ; acf = Part(acf_pacf,1,lags,1,1) ; pacf = Part(acf_pacf,1,lags,2,2) $
```

Use a trick to create a matrix containing 1,2,...

```
SAMPLE      ; 1 - lags $
CREATE      ; t = Trn(1,1) $
MATRIX      ; k = t $
```

Now, plot the figures.

```
MPLOT       ; Lhs  = k ; Rhs = acf,pacf
            ; Limits = -1,1 ; Bars = 0 ; Symbols
            ; Title = ACF and PACF for Price Index for Durable Goods $
```

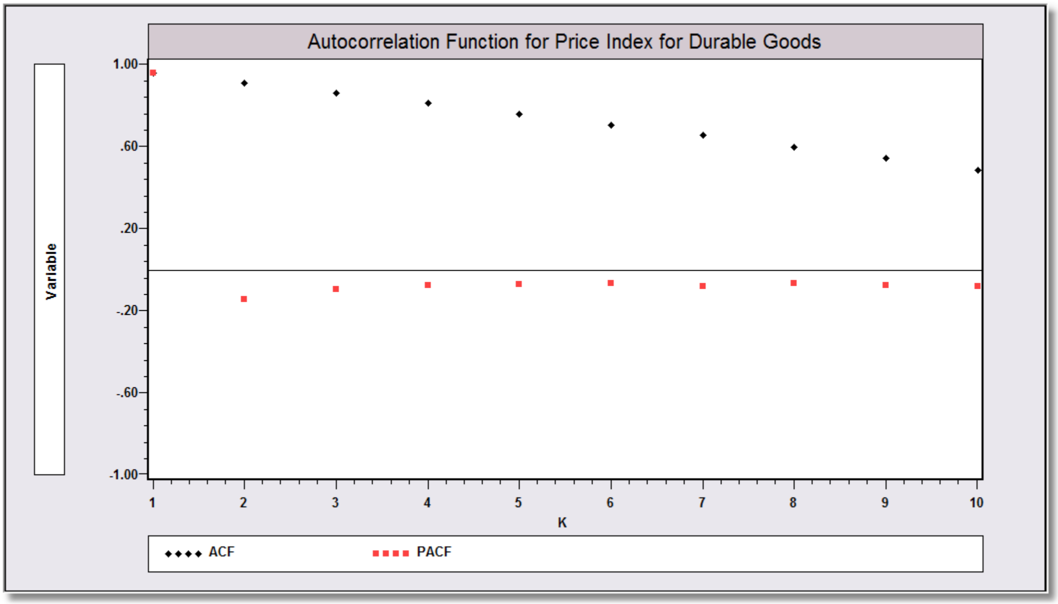

Figure E6.25 ACF and PACF for Durable Goods Price Index

E6.5.2 Examining an Estimation Criterion (Log Likelihood) Function

The next example involves a graphical analysis of a nonlinear least squares problem. The example is taken from Greene (2011). A generalized production function is written

$$\log y + \theta y = \beta_1 + \beta_2 \log k + \beta_3 \log l + \varepsilon.$$

The log likelihood function for this model, concentrated over $\sigma^2 = \mathrm{Var}[\varepsilon]$, is

$$\log L = \Sigma_i [\log(1 + \theta y_i) - \log y_i] - (n/2)[1 + \log(2\pi) + \log(\mathbf{e'e}/n)]$$

where $\mathbf{e'e}$ is the sum of squared residuals in the least squares regression of $\log y+\theta y$ on the Rhs variables. Conditioned on θ, the MLE is OLS, and we scan over θ to find the MLE. The data are set up as follows:

IMPORT $

```
state,valueadd,capital,labor,estabs
Alabama          126.148        3.804      31.551     68
California      3201.486      185.446     452.844   1372

              ; Vaxis = Log Likelihood
              ; Title  = Log Likelihood for a Generalized Production Model $
```

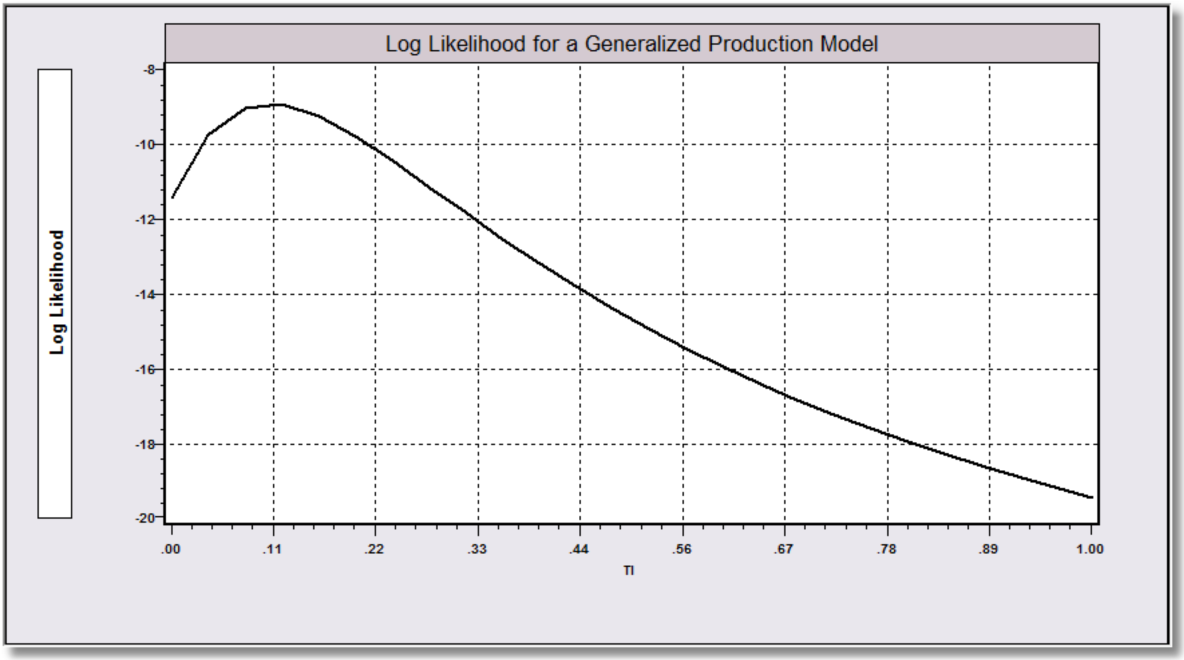

Figure E6.26 Matrix Plot of a Log Likelihood Function

E6.6 Plotting Functions – The FPLOT Command

The command for plotting a function of one variable is

FPLOT ; Fcn = function definition
; ... several other mandatory specifications $

The full, general form of the command is

SAMPLE ; 1 $
FPLOT ; Fcn = the function definition of f(x| any other variables)
; Labels = x ... any other variables
; Plot (x)
; Start = an interior point in the range of x
; Pts = number of points to plot
; Limits = lower,upper limit of range of x over which to plot
; Endpoints = lower,upper limits for horizontal axis (optional) $

There are no other options for this plotting function. The command has this structure because it is also used with the **MINIMIZE** command, described in Chapter E66. The function definition may use any of the features described in Section E14.3 and Chapter E66 for functions for the **MINIMIZE** command. The purpose of the **; Start = value** part of the command is for you to provide a point at which *LIMDEP* can test the function definition that you have given to see if it is computable. If it is, processing continues. The function may involve any number of parameters specified by the **; Labels** specification. The **; Plot(x)** must specify one of the variables in the **; Labels** list.

The **SAMPLE ; 1 $** command is used to prevent needless computing. This command can be used to plot a function which is a sum of terms where the sum is taken over the current sample. But, for a simple function such as the one examined in the example below, this summing operation would just compute and add the same function *n* times.

You may specify the desired limits on vertical axis with third and fourth values in the **; Limits** specification. The first and second give the range of variation on the horizontal axis for the variable being plotted. They do not control the limits on the actual graph plotted. Plot limits for the horizontal axis (only to control the display) are specified with **; Endpoints = lower,upper**. These must widen the interval specified by **; Limits = lower,upper**. They may not narrow it at either end. Thus, for example, the command containing **; Limits = 0,1 ; Endpoints = -1,2** evaluates the function for the variable ranging from zero to one, then constructs a graph in which the horizontal axis contains a range from minus one to two. There will be blank space in the graph from minus one to zero on the left of the plotted function, and from one to two on the right.

The command builder dialog box for the **FPLOT** command is found in the Model: Numerical Analysis/Plot Function option. An illustration appears with the example below.

The following is the example in Section E4.3 of Greene (2011, page 1108), maximizing over ρ and β the function

$$F(\rho,\beta) = \rho\log\beta - \log\Gamma(\rho) - 3\beta + \rho - 1.$$

At the maximum, we must have $\partial F/\partial\beta = \rho/\beta - 3 = 0$ which implies that at the solution, $\beta = \rho/3$. Considering only these points, then, the concentrated function to be maximized is

$$F^*(\rho) = \rho\log(\rho/3) - \log\Gamma(\rho) - 1.$$

We do this graphically with

```
SAMPLE    ; 1 $
FPLOT     ; Fcn = r*Log(r/3) - Lgm(r) - 1
          ; Labels = r
          ; Plot(r) ; Start = 5
          ; Pts = 100 ; Limits = 1,16 $
```

The command builder that will produce this command is shown in Figure E6.27.

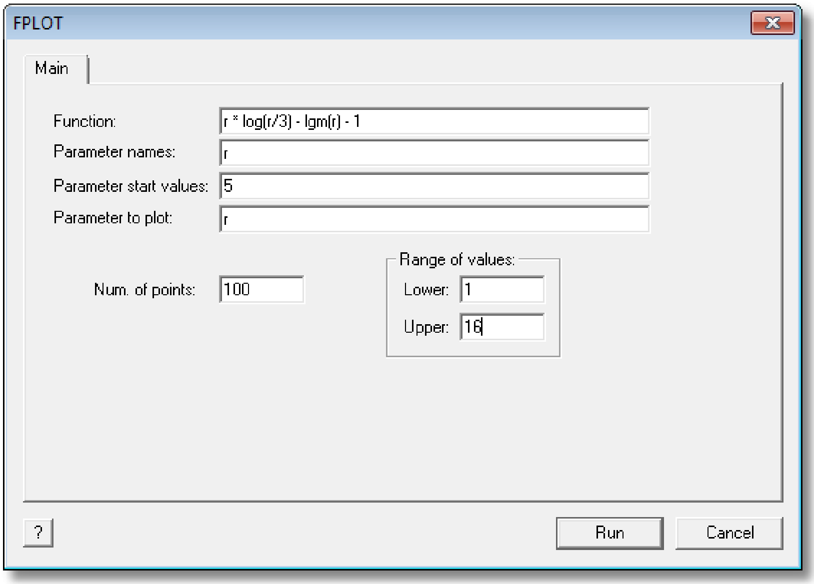

Figure E6.27 Command Builder for FPLOT

The results in Figure E6.28 reveal that the maximum is near 5.2. (The correct value is 5.23.)

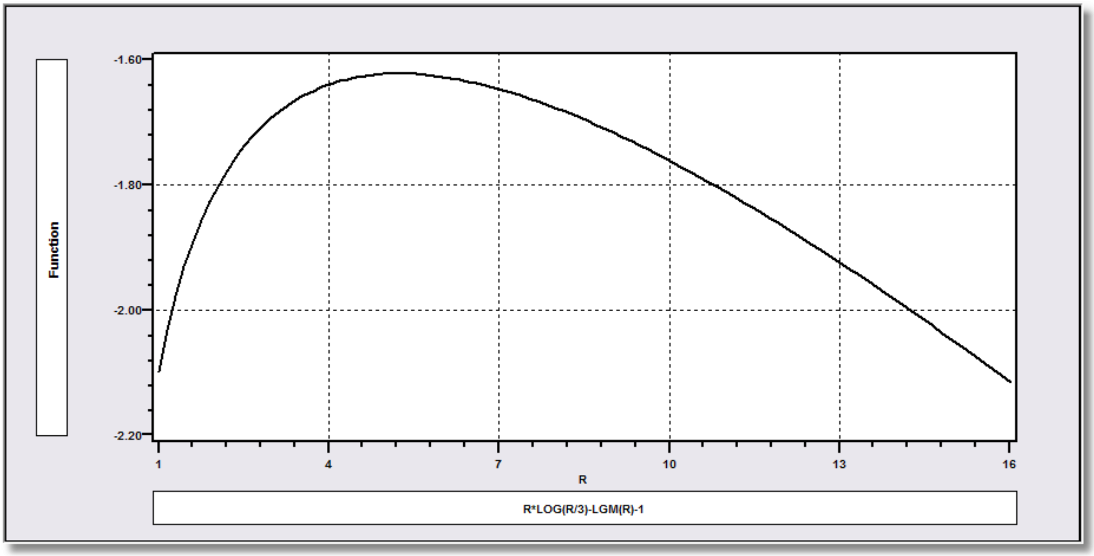

Figure E6.28 Function Plot of a Concentrated Log Likelihood

E6.7 Contour Plots – The CPLOT Command

CPLOT may be used to plot contours of a function in two dimensions. The feature may be used to plot contours of a function

$$f(x1,x2 \mid x3,\ldots) = c$$

for values of c. We have used it in the example below to plot the contours of a log likelihood function. For a probit model, the command format is

```
CPLOT       ; Fcn = any function of at least two arguments
            ; Labels = the labels in the function
            ; Plot(x,y) = two of the variables identified by the labels
            ; Pts = number of evaluation points
            ; Start = the usual values
            ; Limits = xlow,xhigh,ylow,yhigh
            ; Title = desired title $
```

The function can be a log likelihood or any other function. In Figure E6.29, we have plotted the function that was examined in the previous section,

$$F(\rho,\beta) = \rho\log\beta - \log\Gamma(\rho) - 3\beta + \rho - 1.$$

The commands are

```
SAMPLE      ; 1 $
CPLOT       ; Fcn = ro*Log(beta) - Lgm(ro) - 3*beta + ro - 1
            ; Labels = beta,ro
            ; Plot(beta,ro)
            ; Start = 2,5
            ; Limits = .1,5,1,16
            ; Pts = 150
            ; Title = Contour Plot of Log Likelihood $
```

This procedure does a very large amount of computation and the plot takes a while to draw. The function is computed Pts^2 times to produce the grid of values. Then, the plot itself is quite involved. The first example below involves a simple function of two parameters, but no data, so the sample is set to one observation at the outset. Figure E6.29 takes about ten seconds to produce. The second example below is computed for the log likelihood of a probit model in a sample of about 4,000 observations and six parameters. This procedure takes several minutes to complete. Note, finally, contour plots are difficult to plot when the function has more than one model. The implementation here will not perform well if the function has hills and valleys. It is constructed to handle a unimodal function such as the straightforward log likelihood functions shown in the examples.

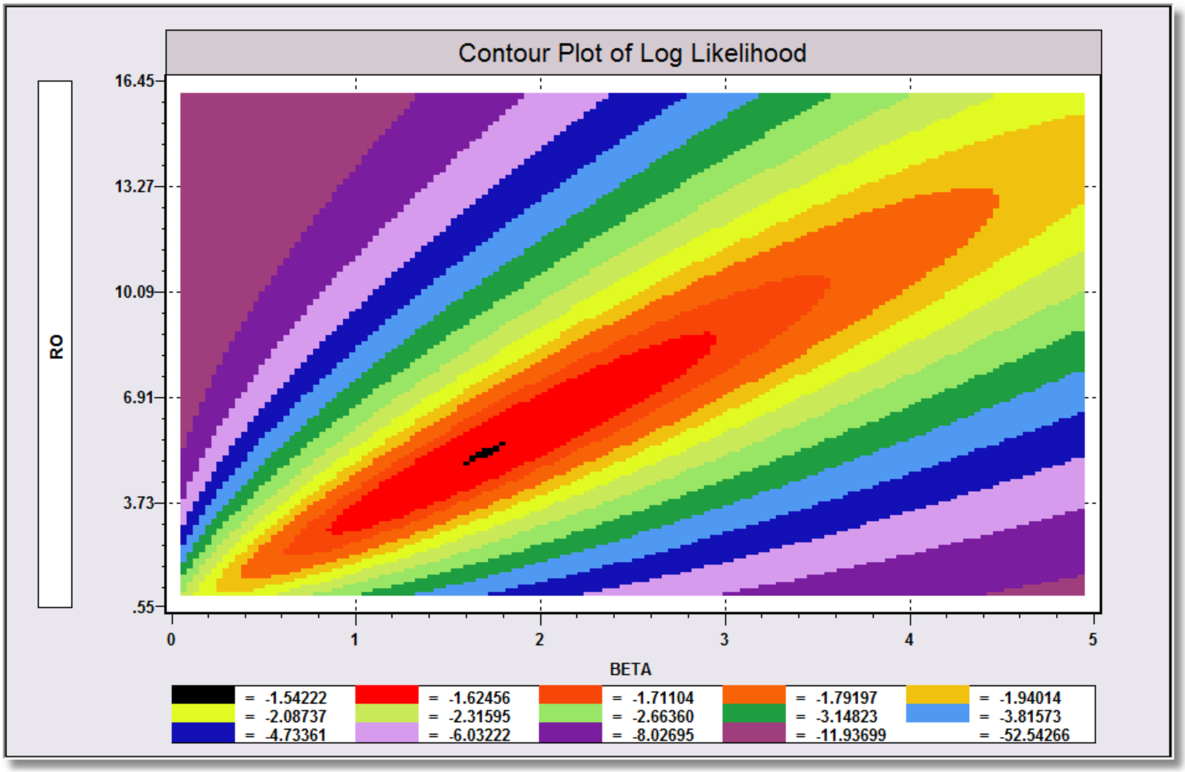

Figure E6.29 Contour Plots

The computations for a probit model are as follows: The estimator maximizes the log likelihood over six parameters. The contour plot examines the log likelihood function in the space of the coefficients on female and educ, which for convenience have been made the first and second parameters in the function.

```
INCLUDE     ; New ; year = 1991 $
PROBIT      ; Lhs = doctor
            ; Rhs = female,educ,one,age,married,hhninc $
CPLOT       ; Fcn = Log(Phi((2*doctor-1)*
                  (b1*female+b2*educ+b3+b4*age+b5*married+b6*hhninc)))
            ; Start = b
            ; Limits = .3,.5,-.03,.01
            ; Pts = 25
            ; Plot(b1,b2)
            ; Labels = b1,b2,b3,b4,b5,b6
            ; Title = Log Likelihood for Probit Model $
```

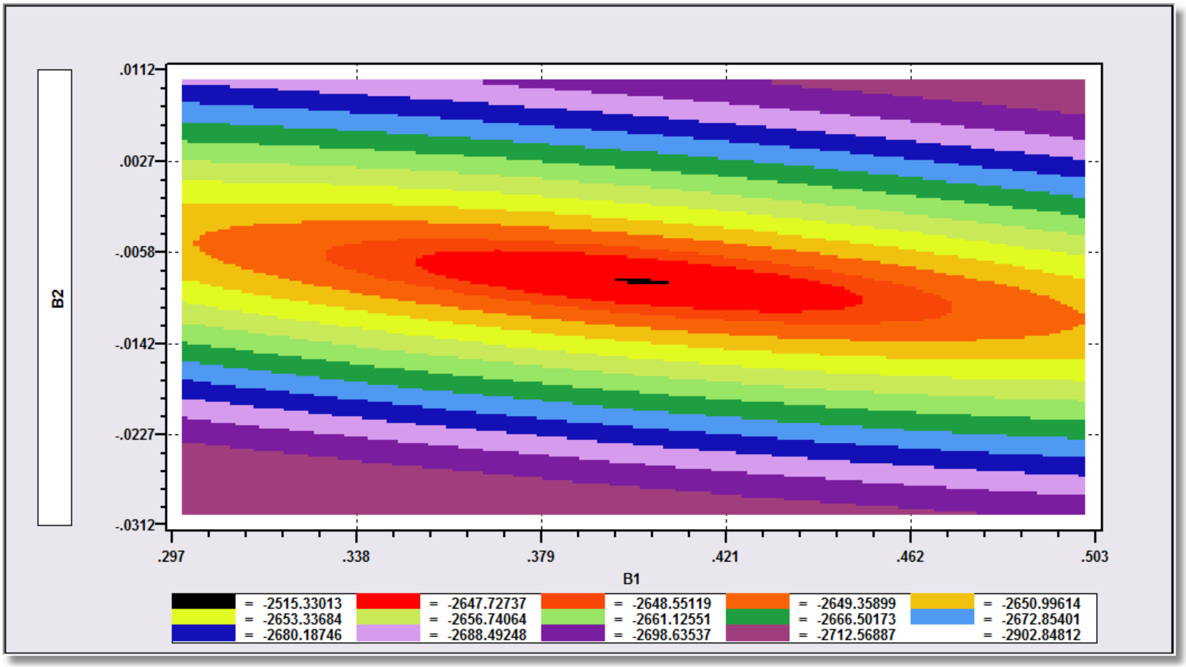

Figure E6.30 Contour Plot for Probit Log Likelihood

E7: Linear Regression – Estimation

E7.1 Introduction

This chapter will detail estimation of the single equation, linear regression model

$$y_i = x_{i1}\beta_1 + x_{i2}\beta_2 + \ldots + x_{iK}\beta_K + \varepsilon_i$$
$$= \mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i,\ i = 1,\ldots,n.$$

The full set of observations is denoted for present purposes as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}.$$

The initial stochastic assumptions are the most restrictive for the linear model:

$$E[\varepsilon_i | \mathbf{X}] = 0 = E[\varepsilon_i]\ \forall\ i \quad \text{(zero mean)}$$
$$\text{Var}[\varepsilon_i | \mathbf{X}] = \text{Var}[\varepsilon_i] = \sigma^{2,}\ \forall\ i \quad \text{(homoscedastic)}$$
$$\text{Cov}[\varepsilon_i, \varepsilon_j | \mathbf{X}] = \text{Cov}[\varepsilon_i, \varepsilon_j] = 0\ \forall\ i, j \quad \text{(nonautocorrelation).}$$

More general models are described in the chapters to follow.

E7.2 Least Squares Regression Command

The basic command for the classical linear regression model is

REGRESS ; Lhs = dependent variable
; Rhs = regressors $

A constant term is *not* automatically included in the Rhs. If your model should contain a constant, you must include *one* among the Rhs variables. (Unless the model specifically dictates that there should be no constant term (as in certain time series settings), you should always include it.)

NOTE: Remember that *LIMDEP* does not automatically include a constant term in the equation. If you want one, be sure to include *one* among the Rhs variables.

The Rhs list may also include lagged variables, logs of variables, interaction terms, powers of variables, and so on. This is discussed further in Section E7.5. This command requests a linear ordinary least squares regression of the Lhs variable on the set of Rhs variables. The standard output from the procedure is listed in the next section.

This is the basic regression model. The limit on the number of parameters which may appear in the model is about 148 if you use no other specifications. If you use any of the optional procedures listed below, reduce this maximum to 146 to allow for the additional space needed for the computations.

The Main page of the command builder for the basic regression model appears below. This command builder is obtained by selecting Model:Linear Models/Regression. The minimum information provided from this dialog box is the Lhs and Rhs variables, as shown in Figure E7.1. Other options are discussed below.

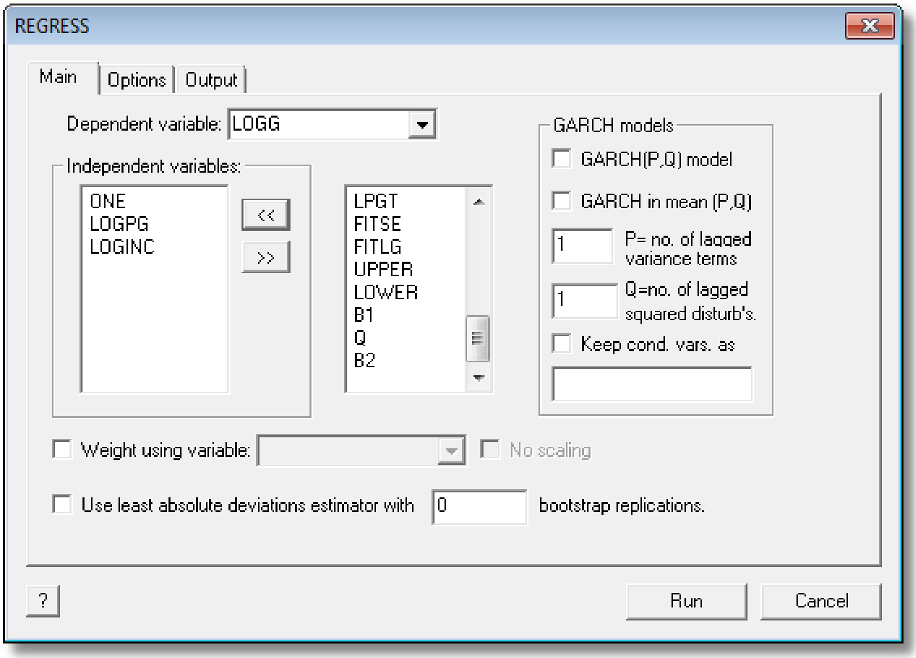

Figure E7.1 Main Page of the Command Builder for REGRESS

E7.3 Computing the Least Squares Coefficients

Least squares regression is based on the central estimation results

$$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y},$$
$$\mathbf{e} = \mathbf{y} - \mathbf{X}\mathbf{b}$$

and the subsequent results that are derived from these. However, in order to maximize the accuracy of the computation, *LIMDEP* does not compute the least squares regression coefficients directly using the standard matrix algebra formula when it can be avoided. Consider the general case, ignoring practical considerations for the moment. The data matrix, **X**, can be written in its *QR* decomposition as

$$\mathbf{X} = \mathbf{Q}\mathbf{R}$$

where **Q** is $n \times K$, **R** is $K \times K$, $\mathbf{Q}'\mathbf{Q} = \mathbf{I}$ and **R** is upper triangular. Using the *QR* decomposition of **X** in order to compute the least squares coefficients, rather than using an inversion method to apply the matrix formula allows extremely accurate solutions. (See the NIST benchmarks in Section E7.11.) Note, however, that using this method requires replication of the data matrix, so if **X** is very large, this may be impractical; *LIMDEP* uses the *QR* method if $n \times K \leq 33{,}000$ and if $n \leq 6{,}000$. If either of these constraints is exceeded, *LIMDEP* computes the moment matrix and inverts it using the *LU* decomposition method. This is an accurate inversion method, as good as or better than the common Cholesky method (which is used elsewhere in *LIMDEP*). (This does not place a limit on the number of observations you can use. If your data set has several million observations, you can still use all of *LIMDEP*'s estimation programs.)

Before attempting to compute a linear regression, *LIMDEP* makes one all out attempt to prevent you from using bad data to compute a linear model. We search for the condition of more than one variable with no variation in the model – one such variable, the constant, is to be expected.

More than one means trouble. The set of variables is examined. If more than one variable shows a variance less than 10^{-20}, we conclude that the regression is not estimable. In this case, a diagnostic such as the following (produced by a query from a user) will appear:

```
Variable MU1      always =     6.43751. No variation!
Variable D_C1     always =    -2.35884. No variation!
Regression cannot be computed. Collinearity
```

NOTE: *LIMDEP never* decides to just drop a few variables for you and compute the regression using those that remain. That decision is up to you, not the software. If your data are perfectly collinear because variables are identical, or because you have variables that have no variation, *LIMDEP* stops the estimation at that point, with a diagnostic of the problem.

E7.3.1 Results Produced by REGRESS

The linear regression produces a set of results such as the one below for the gasoline data used at several points in the earlier chapters: The command and results are as follows:

REGRESS ; Lhs = logg
; Rhs = one, logpg,loginc,Log(pnc),Log(puc),Log(ppt) $

NOTE: You can suppress all results in the command by including **; Quietly**. Why would you do this? You might be interested in producing only the retrievable results, but not actually seeing the surrounding regression results. For example, if you are computing a bootstrap estimator by computing the same regression for, say, 1,000 different random subsets of your sample, chances are, you are not interested in the visible results of the 1,000 regressions. Rather, only the sample variance of the 1,000 vectors of coefficients is of interest.

The statistics reported are as follows:

- The model framework – linear least squares regression
- The date and time when the estimates were computed
- Name of the dependent variable
- Mean of Lhs variable $\bar{y} = (1/n)\Sigma_i y_i,$
- Standard deviation of Lhs variable $s_y = \left\{[1/(n-1)]\sum_{i=1}^{n}(y_i-\bar{y})^2\right\}^{1/2}$
- Name of the weighting variable if one was specified
- Number of observations $= n,$
- Number of parameters in regression $= K,$
- Degrees of freedom $= n\text{-}K,$
- Sum of squared residuals $\mathbf{e}'\mathbf{e} = \sum_{i=1}^{n}(y_i-\hat{y}_i)^2 = \sum_{i=1}^{n}(y_i-\mathbf{x}_i'\mathbf{b})^2$
- Standard error of e $s = \sqrt{\mathbf{e}'\mathbf{e}/(n-K)}$
- R^2 $R^2 = 1 - \mathbf{e}'\mathbf{e}/\sum_{i=1}^{n}(y_i-\mathbf{x}_i'\mathbf{b})^2$
- Adjusted R^2 $\bar{R}^2 = 1 - (n\text{-}1)/(n\text{-}K)[1 - R^2]$
- F statistic $F[K\text{-}1,n\text{-}K] = [R^2/(K\text{-}1)] / [(1\text{-}R^2)/(n\text{-}K)]$
- Prob value for F $Prob_F = \text{Prob}[F(K\text{-}1,n\text{-}k)] > \text{observed } F$
- Log likelihood $\log L = \text{-}n/2[1 + \log 2\pi + \log(\mathbf{e}'\mathbf{e}/n)]$
- Restricted log likelihood $\log L_0 = \text{-}n/2[1 + \log 2\pi + \log(s_y^2\ (\text{n-1})/\text{n})]$
- Chi squared[K-1] $\chi^2 = 2(\log L - \log L_0)$
- Prob value for chi squared $Prob_{\chi 2} = \text{Prob}[\chi^2(K\text{-}1)] > \text{observed chi squared}$
- Akaike Information Criterion $AIC = (\log L - K)/(n/2) - (1 + \log 2\pi)$
- Bayes Information Criterion $= \log[\text{e}'\text{e/n}) + \text{k} \log(\text{n})/\text{n}$

In time series settings, the results will also contain

- Durbin-Watson $dw = \Sigma_{t=2}^{T}(e_t - e_{t-1})^2 / \Sigma_{t=1}^{T}e_t^2$
- Autocorrelation $r = 1 - dw/2.$

The R^2 and related statistics are problematic if your regression does not contain a constant term. For the linear model, *LIMDEP* will check your specification, and issue a warning in the output, as shown below. In the results below, we have used the same **REGRESS** command, but omitted the constant term.

REGRESS ; Lhs = logg
; Rhs = logpg,loginc,Log(pnc),Log(puc),Log(ppt) $

```

Note that the analysis of variance computations are now omitted.

Some additional notes about the standard least squares computations: (These are among our FAQs.) *The log likelihood can be positive!* It will be if $\mathbf{e'e}/n \le 0.058549$, and nothing in the model prevents this. Log likelihoods are only guaranteed to be negative for discrete choice models. If your model does not contain a constant term, then the restricted log likelihood that assumes only a constant term is meaningless in your model, and you should not use it as a basis for likelihood ratio tests.

Finally, the main table of regression results contains, for each Rhs variable in the regression:

- Name of the variable,
- Coefficient b_k,
- Standard error of coefficient estimate = se_k = the square root of the kth diagonal element of $s^2(\mathbf{X'X})^{-1}$
- t ratio for the coefficient estimate $t_k = b_k / se_k$
- Significance level of each t ratio based on the t distribution with $[n-K]$ degrees of freedom = p value = Prob$[t(n-K)] >$ observed t_k
- Confidence interval for coefficient. The default confidence level is 95%. You can change this with **; Clevel = value**, where *value* ranges from .05 to .99.

Footnotes to the table will often document computations that are not obvious or might not be well known, such as how the RESET test is computed. (See Section E7.9.2.)

E7.3.2 Retrievable Results

The retrievable results which are saved automatically by the **REGRESS** command are

Matrices: *b* = slope vector = $(\mathbf{X}'\mathbf{X})^{-1}\,\mathbf{X}'\mathbf{y}$
varb = estimated covariance matrix = $[\mathbf{e}'\mathbf{e}/(n\text{-}K)](\mathbf{X}'\mathbf{X})^{-1}$

Scalars:

ssqrd	=	$\mathbf{e}'\mathbf{e}/(n\text{-}K)$
rsqrd	=	R^2
s	=	s
sumsqdev	=	sum of squared deviations, $\mathbf{e}'\mathbf{e}$
rho	=	autocorrelation coefficient, r
degfrdm	=	$n\text{-}K$
sy	=	sample standard deviation of Lhs variable
ybar	=	sample mean of Lhs variable
kreg	=	number of independent variables, K
nreg	=	number of observations used to compute the regression, n Note, this may differ from the sample size if you have skipped missing values.
logl	=	log likelihood
exitcode	=	0.0 unless the data were collinear or OLS gives a perfect fit

Last Model: *b_name* where the names are the Rhs variables.
(See **WALD** in Chapter R14.)

Last Function: Conditional mean = $\mathbf{b}'\mathbf{x}$

The results listed above are all replaced by each regression. For example, after a **REGRESS** command is given, the names *b* and *varb* can be used in subsequent **MATRIX** and **CALC** commands for any computation. For example,

```
NAMELIST    ; x = x1,x2,x3,x4,one $
REGRESS     ; Lhs = y ; Rhs = x $
```

produces a 5×1 vector *b* and a 5×5 matrix *varb*. A subsequent **MATRIX** command might be

```
MATRIX      ; c = b(1:4) ; vc = Varb(1:4,1:4) ; wald = c'<vc>c $
```

This computes a Wald statistic for testing the hypothesis that the first four elements of β are zero. The last function noted above is used by **SIMULATE** to compute predictions (see the end of Section E7.6), by **PARTIALS** to compute partial effects (see Section E7.5) and by **DECOMPOSE** for Oaxaca decompositions (see Chapter R12).

E7.3.3 Results that Can Be Computed with MATRIX and CALC

Many of the particular statistics listed above can be computed with the **MATRIX** and **CALC** commands without producing all of the visible regression results. These functions can be used, for example, in computing regression results as parts of other kinds of programs.

Any of the regression results shown above can be reproduced with **MATRIX**. Here are a few of the computations. All depart from the definitions of the sample and regressor matrix:

SAMPLE ; ... or
INCLUDE ; ... or
PERIOD ; ... $
NAMELIST ; x = one,... $
CREATE ; y = ... the dependent variable $ Now, we have a common notation.
NAMELIST ; ny = y $ (Some functions require namelists, even if only one variable.)

You can compute the following regression statistics with **MATRIX** and **CALC**:

- Coefficients:

  MATRIX ; slopes = **Xlsq(x, y) or <x’x> * x’y**

- Sum of squares:

  MATRIX ; sumofsqs = **y’y - y’x * <x’x> * x’y**.
  MATRIX ; sumofsqs = **Rcpm(x,ny)**

- Covariance matrix for least squares slopes:

  MATRIX ; vc = {1/(n-Col(x))} * Rcpm(x,ny) * <x’x> $ (Uses **CALC** in { }.)

Other results can be computed with **MATRIX** as well, but since these are all scalars, it is likely to be easier to compute them with **CALC**, which also has several regression based statistics built into its functions. The ‘*x*’ and ‘*y*’ in the functions below are the namelist and variable defined above. For the statistics below to have their usual meaning, *x* should contain a constant term.

Rsq(*x*,*y*)	= R^2 in regression of *y* on *x*,	$1- \sum_{i=1}^{n}(y_i-\hat{y}_i)^2 / \sum_{i=1}^{n}(y_i-\overline{y})^2$
Tss(*x*,*y*)	= total sum of squares,	$\sum_{i=1}^{n}(y_i-\overline{y})^2$
Ess(*x*,*y*)	= error, or residual sum of squares,	$\sum_{i=1}^{n}(y_i-\hat{y}_i)^2$
Xss(*x*,*y*)	= explained sum of squares,	$\sum_{i=1}^{n}(\hat{y}_i-\overline{y})^2$
Ser(*x*,*y*)	= standard error of regression,	$\left(\frac{1}{n-K}\sum_{i=1}^{n}e_i^2\right)^{1/2}$
Lik(*x*,*y*)	= log likelihood function,	$\frac{-n}{2}\left[1+\ln 2\pi+\frac{1}{n}\sum_{i=1}^{n}e_i^2\right]$

You can use any of these in subsequent commands. For example, to replicate the F statistic for testing the hypothesis that all coefficients are zero, you could use

CALC ; fstat = (n - Col(x)) * Xss(x,y) / Ess(x,y) / (Col(x) - 1) $

Of course, **MATRIX**, **CALC**, and **CREATE** commands may all be combined in programs that do any regression based computation you'd like.

E7.3.4 Beta Coefficients

Researchers are sometimes interested in 'beta coefficients' instead of the original regression coefficients. Beta coefficients are the linear regression coefficients that would result if data were standardized – centered around the mean then divided by the standard deviation – before computing the regression. In principle, there is no need to compute this regression separately; these coefficients can be computed from the original regression results by multiplying each regression coefficient by the ratio of the standard deviation of the dependent variable to the standard deviation of the respective independent variable. However, standardizing the data is a minor operation that produces the appropriate standard errors as well. The following example demonstrates for a small model:

CREATE ; s_logg = Std(logg) ; s_logp = Std(logpg) ; s_loginc = Std(loginc) $
REGRESS ; Lhs = s_logg ; Rhs = s_logp, s_loginc, one $

We include the redundant constant term so that the estimator will report the analysis of variance results.

```

E7.4 Stepwise Regression

LIMDEP will compute a least squares regression by the 'forward stepwise' method. The command is

REGRESS ; Lhs = ...
; Rhs = ... as usual (one may be omitted)
; Alg = stepwise $

Stepwise regression can also be selected from the Options page of the **REGRESS** command builder as shown in Figure E7.7. This command treats all variables in the Rhs list as candidates for entrance to or deletion from the equation. The constant term is always inserted automatically, so you can omit *one* from the Rhs list. (This is one of only a small handful of cases in which a constant term is assumed for you.) You can force a set of variables to be included in the equation with

; Rh2 = list of variables

With this specification included, the final equation will include all variables in the Rh2 list and those in the Rhs list which pass the tests for inclusion. The limits on the total number of variables in the Rhs and Rh2 lists are 70 in each.

Other options available for this form of the command are the usual for the linear regression model, including **; List**, **; Res = name**, and **; Keep = name**. These are described in detail in the following sections. The results which are saved by this command are exactly the same as those for the regression command described earlier

LIMDEP will pause between steps and ask you if you want to continue (take another step). You can suppress this dialogue and instruct the program to continue until all variables that satisfy the entry criterion have been entered by adding

; Output = 5

The stepwise regression method (see Kennedy and Gentle (1980)) is as follows: With a given set of variables already in the equation,

Step 1. Find the variable not yet entered which will raise R^2 by the largest amount. Enter it if the squared t ratio on that variable after it is entered exceeds the critical F ratio from the table for the appropriate degrees of freedom.

Step 2. Next, among the set of variables already entered, including the one from Step 1, if *one* was entered, find the one which leads to the smallest reduction in R^2 when it is deleted. Delete it if its squared t ratio is less than the critical F ratio.

After Steps 1 and 2, exit if any of the following criteria are met:

- The same variable was entered then deleted.
- All variables are entered.
- No variable can enter or exit.
- Fifty cycles are attempted.

The diagnostic statistics presented at each step are the standard analysis of variance results. The Mallows C_p criterion is

$$C_p = \mathbf{e'e} / s^2 + 2(P+1) - T$$

where **e′e** is based on the P included variables at the time and s^2 is $\mathbf{e'e}/(n\text{-}K)$ with all variables included. The limiting value, with all variables included is $2(P+1)$.

In the example below, we reestimated the gasoline consumption equation with all price variables. The command forces the log of the gasoline price and the log of income to remain in the equation, and uses the stepwise method to select among the micro- and macroeconomic price indices. (Note, this example illustrates the danger of relying on the mechanical selection of variables. If **; Rh2** is not used to force the gasoline price to remain in the model, it does not appear in the final specification.)

REGRESS ; Lhs = logg
; Rhs = logpnc,logpuc,logppt,logpn,logpd,logps
; Rh2 = logpg,loginc
; Alg = stepwise
; Output = 5 $

```

E7.5 Interactions and Partial Effects

When the regression contains nonlinearities and interaction terms, such as logs of variables, squares or cross products of variables, the raw coefficients in the model do not reveal the actual relationship between the dependent variable   Consider the regression model

$$\log(income) = \beta_1 + \beta_2\, age + \beta_3\, age^2 + \beta_4\, educ + \beta_5\, female + \beta_6\, educ{\times}female + \varepsilon.$$

In this regression model, the coefficients are semi-elasticities. However, none of them give the relevant effect of a variable on log(*income*). For example, the effect of *age* is not β_2, it is $\beta_2 + 2\beta_3 age$, the female differential is not β_5, it is $\beta_5 + \beta_6 educ$, and the impact of *educ* is not β_4, it is $\beta_4 + \beta_6\, female$. Each of these could be easily computed after the linear regression (with a hand calculator if necessary). However, if one wants to compute standard errors and/or confidence intervals for the coefficients, that is rather more complicated. For example, the estimator of the standard error for the impact of *age* on log(*income*) is

$$\text{Est.Std.Err}(age \text{ effect}) = [\text{Var}(b_2) + 4age^2\text{Var}(b_3) + 4age\text{Cov}(b_2,b_4)]^{1/2},$$

which is likely to be quite inconvenient. The **PARTIALS** command is provided for this purpose, and fully automates the computation.

Using **PARTIALS** to compute effects of nonlinearities is done in a second step after the regression. The first step involves specifying the regression with the nonlinearities specified explicitly in the equation. For the example, the following are two ways to compute the regression, where we use the health satisfaction data used in earlier examples for the illustration:

```
SAMPLE        ; All $
INCLUDE       ; New ; year = 1991 $
CREATE        ; educ_fem = educ*female ; agesq = age*age $
CREATE        ; loginc = Log(hhninc) $
? First method
REGRESS       ; Lhs = loginc
              ; Rhs = one,age,agesq,educ,female,educ_fem $
? Second method
REGRESS       ; Lhs = Log(hhninc)
              ; Rhs = one,age,age*age,educ,female,educ*female $
```

The two methods of computing the regression give identical results save for a slight difference in labeling, as can be seen below. However, using the second method allows the **PARTIALS** command to detect that the model contains the nonlinearities and interaction terms and to compute the partial effects for you. That is, the regression program has no way to know that a variable named *agesq* is the square of one named *age* that appears elsewhere in the list of variables in the model. But, in the second specification, that relationship appears specifically.

```

---------------------------------------------------------------------
```

The results shown provide the partial effect for each variable averaged over the sample observations. Note, in particular, how b_5, the coefficient on *female* in the original regression, which equals +.045, is misleading regarding the female differential when the nonlinear effect of *educ* is taken into account.

There are many optional features and specifications available for partial effects described in Chapter R11. One possibility that shows clearly the implication of the quadratic specification in *age*, is to plot the partial effect of *age* at a range of values, as shown below.

PARTIALS ; Effects: age & age = 20(5)70 ; Plot(ci) $

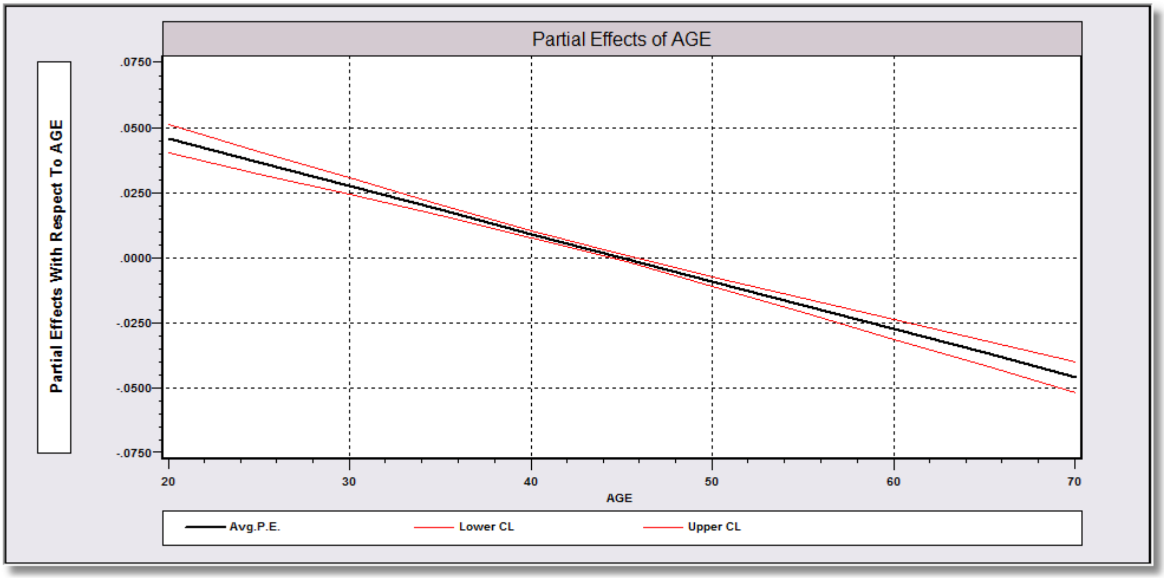

Figure E7.2 Partial Effects for Quadratic Regression Model

E7.6 Predictions and Residuals

To obtain a list of the residuals and fitted values from a linear regression model, add the specification

; List

to the command. The residuals and predicted values may be kept in your data area by using the specifications

; Res = name to retain residuals

and **; Keep = name** to retain predictions

If you are not using the full sample or all of the rows of your data matrix, some of the cells in these columns will be marked as missing. If you have data on the regressors but not the dependent variable, you can use

; Fill

to obtain predictions for the missing data. Remember, though, that the prediction is -999 (missing) for any observation for which any of the *x*s are missing. (You can use this procedure as an alternative to the multiple imputation method discussed in Chapter R20.)

The command builder dialog box for these and several other options are on the Output page of the **REGRESS** command builder, as shown below in Figure E7.3.

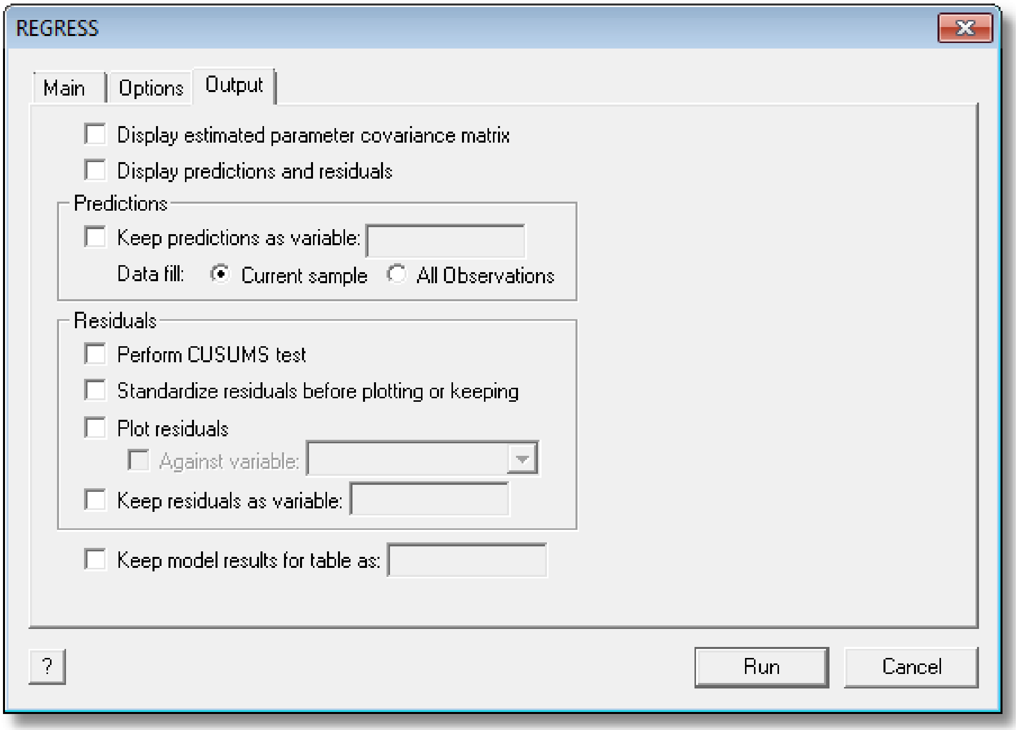

Figure E7.3 Command Builder for Regression Residuals and Predictions

The listing will also contain a 95% confidence interval for the forecast of the dependent variable. (See the example below.) The confidence limits are not kept. But, listed below are commands which can be used to obtain this result.

For the model estimated earlier with the gasoline, we now use **; List** to obtain a list of fitted values.

REGRESS ; Lhs = logg
; Rhs = one,logpnc,logpuc,logppt,logpn,logpd,logps,logpg,loginc
; List $

```

```

The following commands could be used for computing forecast standard errors. This routine uses the matrices *b* (the coefficients) and *varb* (estimated covariance matrix) kept by the regression and scalar *ssqrd* which is s-squared from the regression. The forecast standard errors are the values computed by the Sqr function in the **CREATE** command.

NAMELIST ; x = the set of regressors $
REGRESS ; Lhs = y ; Rhs = x ; Keep = yhat $
CALC ; ct = Ttb(.975,degfrdm) $
CREATE ; lowerbnd = yhat - ct * Sqr(ssqrd + Qfr(x,varb))
; upperbnd = yhat + ct * Sqr(ssqrd + Qfr(x,varb)) $

The built in simulator may also be used to obtain predictions and confidence intervals for predictions. The command

SIMULATE ; List $

immediately after the regression command produces the following results.

```
---------------------------------------------------------------------
Model Simulation Analysis for Linear Regression Function
---------------------------------------------------------------------
Simulations are computed by average over sample observations
---------------------------------------------------------------------
User Function      Function   Standard
(Delta method)      Value      Error     |t|  95% Confidence Interval
---------------------------------------------------------------------
Obs. =    1        -.74869     .02232  -33.55     -.79243     -.70495
Obs. =    2        -.74336     .01707  -43.55     -.77681     -.70990
Obs. =    3        -.67366     .01735  -38.82     -.70767     -.63965
Obs. =    4        -.61024     .01395  -43.73     -.63759     -.58289
Obs. =    5        -.62967     .01135  -55.46     -.65193     -.60742
(Rows 6 - 49 omitted)
Obs. =   50         .01242     .01582     .78     -.01859      .04342
Obs. =   51         .00351     .02025     .17     -.03618      .04319
Obs. =   52         .02561     .02342    1.09     -.02029      .07151
Avrg. Function     -.25713     .00496   51.83     -.26685     -.24741
```

Note that although the predictions are the same as those produced by the regression, the confidence intervals are narrower. The reason is that **SIMULATE** produces a confidence interval for the simulated value of the dependent variable, not a forecast interval. The forecast variance used by **REGRESS ; List…$** equals Var[*forecast*] = $s^2 + \mathbf{x}'[s^2(\mathbf{X}'\mathbf{X})^{-1}]\mathbf{x}$ while the variance for the simulated value omits the leading s^2 term. In general, the latter will be smaller than the former. No generality is possible save that the larger is R^2 the closer will be the two values.

E7.6.1 Plotting Residuals

A plot of the residuals from your regression can be requested by adding

; Plot

to the command. Residuals are plotted against observation number (i.e., simply listed). For example, the following would generate the residual plot for the preceding gasoline market example.

```
DATES       ; Undated $
SAMPLE      ; 1-52 $
REGRESS     ; Lhs = logg
            ; Rhs = one,logpg,loginc,logpnc,logpuc,logppt,logpn,logpd,logps
            ; Plot $
```

You will get a time series style plot if the data have been identified as time series data with a **DATES** command. The same plot preceded by

```
DATES       ; 1953 $
PERIOD      ; 1953-2004 $
```

appears as follows in the second panel of Figure E7.4.

If you would like to plot the residuals against another variable, change the preceding to

; Plot(variable name)

The variable can be any existing variables. It need not have been used in the regression. The residuals are sorted according to the variable you name and plotted against it. In the third panel, we used

```
REGRESS     ; Lhs = logg
            ; Rhs = one,logpnc,logpuc,logppt,logpn,logpd,logps,logpg,loginc
            ; Plot(pnc) $
```

The plot will show the residuals graphed against either the observation number, the date for time series data, or the variable you specify using the **; Plot(variable)** option described above.

- If there are outliers in the data, this may severely cramp the figure, since the vertical axis is scaled so that every observation will appear.

- The mean residual bar may not appear at zero because the residuals may not have zero mean. They will not if you do not have a constant term in your regression or if you are plotting two stage least squares residuals. Since 0.0 will generally not be the midpoint between the high and low residual, the zero bar will not be in the center of your screen even when you do have a constant term in the model.

You can plot up to 5,000 observations in the figure with this option.

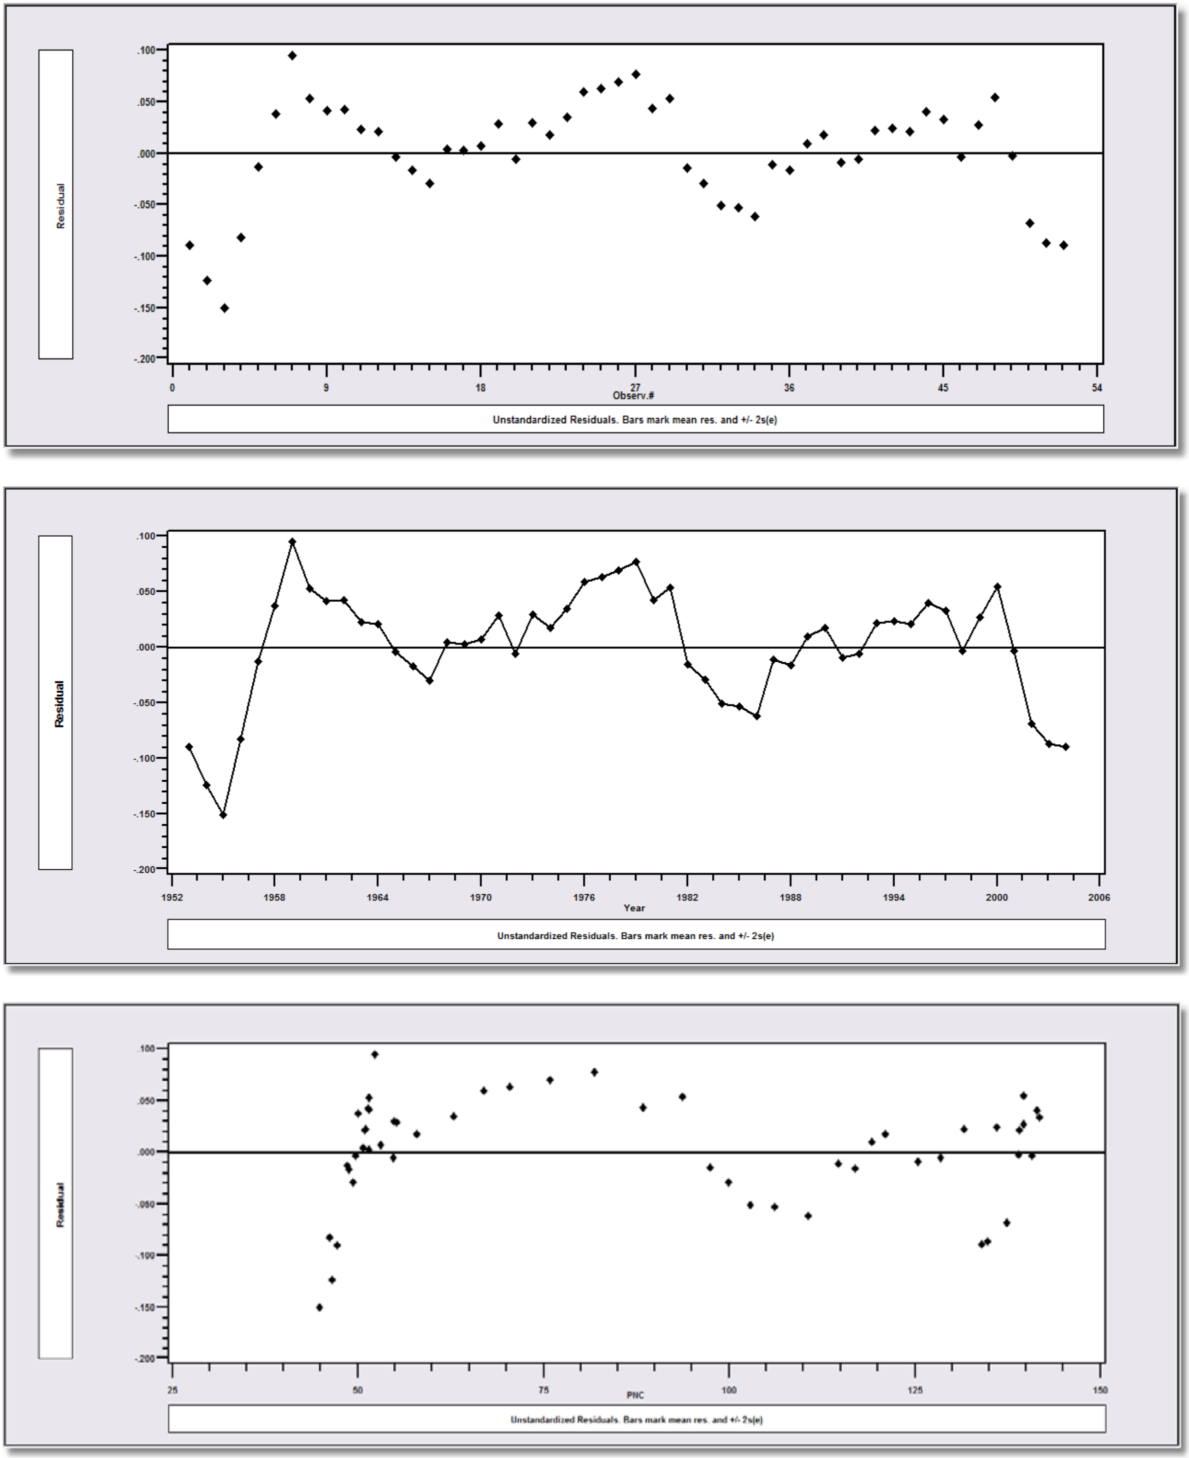

Figure E7.4 Residual Plots

E7.6.2 Standardized Residuals and Regression Diagnostics

In the linear regression model, the variance of a least squares residual is not σ^2, but

$$\text{Var}[e_i] = \sigma^2[1 - \mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i] = \sigma^2 (1 - h_{ii}).$$

Belsley, Kuh, and Welsch (1980) suggest that the standardized residuals,

$$u_i = e_i / \text{Est.Var}[e_i]^{1/2}$$

be plotted instead of the raw residuals as a more useful diagnostic tool. Values of u_i in excess of two indicate possible outliers. You can plot the standardized residuals if the regression command includes

; Plot ; Standardized

To retain the standardized residuals, just use

; Res = name ; Standardized

NOTE: These residuals have a mean and variance that will be close to 0.0 and 1.0, respectively. But, unlike the ordinary OLS residuals, they do not have a mean identically equal to 0.0 and they are only approximately orthogonal to the regressors. In fact, Est.Var[e_i] = s^2 - o(1/n), so as the sample size increases, the standardized residuals will converge to the OLS residuals.

The following is a plot of the standardized residuals. This corresponds to the center frame in Figure E7.4. Even with only 52 observations, save for the scale, the residuals are essentially the same.

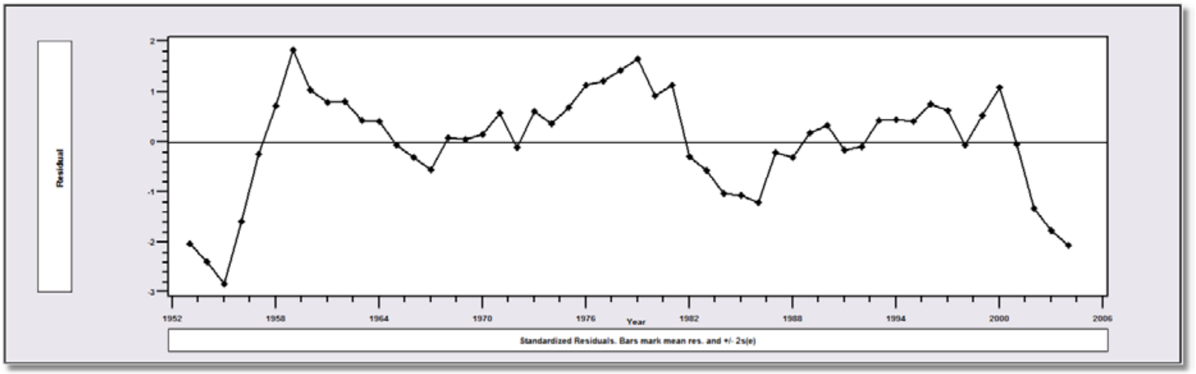

Figure E7.5 Standardized Residuals

An additional quantity of interest is the 'leverage' value,

$$h_{ii} = \mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i.$$

Note that Var[e_i] = σ^2(1 - h_{ii}). Belsley et al. suggest values of h_{ii} greater than $2K/n$ signal points worthy of attention. To obtain them, we require the 'hat matrix,' i.e., the projection matrix into the column space of $\mathbf{X}$,

$$\mathbf{H} = \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'.$$

This is an $n \times n$ matrix, which will be quite unmanageable if n is large. But, in fact, we only require the diagonal elements. To do this computation for a particular data set, you can use

```
NAMELIST    ; x = ... variables in X $
MATRIX      ; xxi = <x'x>  $
CREATE      ; hii = Qfr(x,xxi)  $
CALC        ; big = 2 * Col(x) / n $
CREATE      ; outlier = ( hii > big ) $
```

A list of the variable named *outlier* will flag the important observations with values of one. (Other observations get a zero.) When we apply this to the regression immediately above, the diagnostic identifies three years, 1978-1980, as outliers.

As a further refinement, Belsley et al. suggest that for each residual, the coefficient vector, **b**, and the residual variance, s^2, be reestimated without that observation. In principle, this requires that the regression be recomputed for each observation. But, there are some shortcuts which make the computation quite simple. To describe this procedure, we require some regression algebra. Let **X** be the $n \times K$ matrix of regressors. The least squares estimator is $\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}$. The standardized residuals were computed above

$$u_i = e_i / [s^2(1 - h_{ii})]^{1/2}.$$

This does not recompute s^2 without the ith observation. Adding in Belsley et al.'s refinement takes a bit more work. First, they show that if the regression is recomputed without observation 'i,' that the resulting slope estimator is

$$\mathbf{b}(i) = \mathbf{b} - (\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i'e_i / (1 - h_{ii}).$$

Therefore, the residual vector from this regression (where, for the moment, we include the ith observation in the residual vector) is

$$\begin{aligned}\mathbf{e}(i) &= \mathbf{y} - \mathbf{X}\mathbf{b}(i)\\ &= \mathbf{e} + \mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i'e_i / (1 - h_{ii}).\end{aligned}$$

Multiplying it out, and remembering that $\mathbf{X}'\mathbf{e} = \mathbf{0}$, we get the sum of squared residuals for the full sample based on $\mathbf{b}(i)$,

$$\mathbf{e}(i)'\mathbf{e}(i) = \mathbf{e}'\mathbf{e} + e_i^2 h_{ii} / (1 - h_{ii})^2.$$

Now, we have to subtract out the square of the ith residual. This is

$$\begin{aligned}y_i - \mathbf{x}_i'\mathbf{b}(i) &= e_i[1 + h_{ii}/(1 - h_{ii})]\\ &= e_i / (1 - h_{ii}).\end{aligned}$$

Subtracting the square of this from $\mathbf{e}(i)'\mathbf{e}(i)$ produces

$$\mathbf{e}_*(i)'\mathbf{e}_*(i) = \mathbf{e}'\mathbf{e} - e_i^2/(1 - h_{ii}).$$

This shows the 'shortcut.' The regression need not be recomputed. Finally, the estimator of σ^2 is

$$s^2(i) = \mathbf{e}_*(i)'\mathbf{e}_*(i) / (n - K - 1).$$

Combining terms, we obtain the desired standardized residual

$$u(i)_i = [e_i/(1-h_{ii})] / [(\mathbf{e}'\mathbf{e} - e_i^2/(1-h_{ii}))/(n-K-1)]^{1/2}$$

A related computation is Belsley et al.'s '*dfit*' which is an observation specific measure which attempts to capture the influence, or leverage effect as well as the effect of the residual, itself. The calculation is

$$dfit_i = u(i)_i \times \sqrt{h_{ii}}\ .$$

The following commands will obtain these standardized residuals. (The algebra is far more complicated than the actual computation.)

```
NAMELIST   ; ... define x  $
CREATE     ; ... define y $
REGRESS    ; Lhs  = y ; Rhs = x ; Res = ei $
MATRIX     ; xxi   =  <x'x> $
CREATE     ; mii  = (1 - Qfr(x,xxi))
           ; uii    = ei/mii / Sqr((sumsqdev - ei*ei/mii) / (degfrdm - 1))
           ; dfiti = uii * Sqr(1 - mii) $
```

E7.7 Multicollinearity

If there is a linear combination of the independent variables which produces a column of zeros – i.e., at least one column of **X** can be represented as a linear combination of other columns of **X** – then the least squares regression coefficient cannot be computed by inverting the moment matrix. In this case, the minimizer of the sum of squared residuals is not unique. As a general rule, *LIMDEP* does not proceed any further if it detects that your data are collinear. (Some other programs will successively drop variables from the equation until a noncollinear set remains, as if to report that your desired model was inestimable, so the program found some other model that was. While users differ in their preference for this kind of program driven specification, *LIMDEP* adheres to a strict rule of always waiting for the user to specify the model to be estimated.)

In the case of linear regression, sometimes multicollinearity cannot be detected even when it is present. Recall that in most cases, *LIMDEP* is not using **X′X** to compute the regression, so the presence of multicollinearity may not be obvious. (Even when the moment matrix is being used, the assessment of multicollinearity is only to within some tolerance.) Because the presence of internal rounding error may leave some variation in the representation of the raw data, data may be multicollinear in theory, but only approximately so and, therefore, not, internally. The *QR* method can then become unstable, and report coefficients which appear nonsensical. In some extreme cases, *LIMDEP* will report the condition number for **X'X** with a warning that the data are highly collinear.

NOTE: The condition number is the square root of the ratio of the largest to the smallest characteristic root of $(1/n)\mathbf{X}^{0\prime}\mathbf{X}^0$ in which the first column of $\mathbf{X}^0$ is a column of ones and the remaining columns are the original data not including the constant, in deviations from their means.

For example, the Filippelli data and example discussed in Section E7.11 are a notoriously collinear test data set. Although estimation can still proceed, the following warning is produced by the least squares estimator for this problem:

```
REGRESS      ; Lhs = y ; Rhs = one,x1,x2,x3,x4,x5,x6,x7,x8,x9,x10 $
WARNING: Badly conditioned X. Condition value =    .2999482D+10
```

E7.8 Variance Inflation Factors

Authors sometimes analyze multicollinearity in terms of the effect of the intercorrelation of the regressors on the variances of the least squares coefficient estimators. The *variance inflation factor* is a measure of this effect;

$$VIF_k = \frac{1}{1 - R_{k.}^2}$$

where $R_{k.}^2$ is the R^2 obtained when the kth regressor is regressed on the remaining variables. The optimal value for this statistic is 1.0, which occurs when the R^2 is zero, or this variable is orthogonal to the other variables. Some fairly straightforward algebra reveals that, if the model contains a constant term – that is, one of the columns of **X** is a column of ones – then,

$$VIF_k = \left(\sum_{i=1}^{n} \left(x_{ik} - \overline{x}_k\right)^2\right) \times (\mathbf{X}'\mathbf{X})^{kk}$$

where $(\mathbf{X}'\mathbf{X})^{kk}$ is the kth diagonal element of $(\mathbf{X}'\mathbf{X})^{-1}$. Thus, these auxiliary regressions need not be computed to obtain these factors. The vector of variance inflation factors for the entire coefficient vector can be computed and displayed with the following matrix command:

```
NAMELIST   ; x = ... the list of variables $
MATRIX     ; List ; xm0x = {n-1}*Xvcm(x)
           ; vif = Diag(<x'x>) * Vecd(xm0x) $
```

There is no consensus on what values of the variance inflation factor merit attention, or on what one should do with the results. Some authors (Chatterjee and Price (1991)) suggest that values in excess of 10 are problematic. Others suggest 30 or 40 as a benchmark value. In any event, it is less than obvious what one should do upon finding a large value (or some other indicator of a ‘multicollinearity problem’). As noted earlier, *LIMDEP* leaves this up to the user.

The example below applies the preceding to gasoline data used in the preceding example in which **X** = [*one,logpnc,logpuc,logppt,logpn,logpd,logps,logpg,loginc*]

```
     VIF|             1
--------+--------------
       1|       .000000
       2|       658.212
       3|       189.992
       4|       795.683
       5|       313.746
       6|       1593.98
       7|       5152.04
       8|       72.0155
       9|       220.726
```

Though the diagnostics seem to suggest a high degree of multicollinearity, the regression seems completely routine.

E7.9 Specification Analysis

Several devices are used to assess the adequacy of the model specification. Four that are automated are the tests for heteroscedasticity, functional form, omitted variables and autocorrelation. Others can be programmed with the command language, mainly **CREATE**, **CALC** and **MATRIX**.

E7.9.1 Breusch and Pagan Test for Heteroscedasticity

The Breusch and Pagan (B-P) test for heteroscedasticity is narrowly defined for the hypothesis of homoscedasticity in linear regression with normally distributed disturbances. The full setup for the test is $y_i = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i$ where $\varepsilon_i \sim N[0, g(\sigma^2 + \boldsymbol{\alpha}'\mathbf{z}_i)]$, so that the hypothesis of homoscedasticity is equivalent to $\boldsymbol{\alpha} = \mathbf{0}$. The variables in **z** may be the **x** in the original regression, or other variables that might appear in the model. The test statistic, which has a limiting chi squared distribution with degrees of freedom equal to the number of elements in **z**, is computed as one half the regression sum of squares in the linear regression of $w_i = [e_i^2/(\mathbf{e}'\mathbf{e}/n) - 1]$ on $[\mathbf{z},1]$. Let $\mathbf{Z}$ be the $n \times P$ matrix that has ith row $[\mathbf{z}_i',1]$. Then, the statistic is, $BP = \frac{1}{2}\, \mathbf{w}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{w}$. Several decades of research have suggested that the test has power to detect heteroscedasticity if the normality assumption is weakened.

Request this test by adding

; BPT

or **; BPT = list of variables in z**.

If the list is omitted, then the test is carried out assuming that **z** = **x** not including the constant term. The result of the test will be displayed with the regression results, as shown in the example below.

```

E7.9.2 RESET Specification Test

The regression specification error test (RESET) (Ramsey, 1969) is a general specification test of the adequacy of the linear functional form in the model

$$y_i = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i.$$

The test is carried out in various ways in the literature, all asymptotically equivalent to a linear regression of the regression residuals, e_i on powers of the regression predictions, $(\mathbf{b}'\mathbf{x}_i)^2$, $(\mathbf{b}'\mathbf{x}_i)^3$, etc. The logic of the test is that if the regression is adequately specified by the linear functional form, then addition of the powers of $\mathbf{b}'\mathbf{x}_i$ should not provide additional explanatory power. The test is carried out in a second step after the regression is computed by regressing the least squares residuals on a constant term and the second, third and fourth powers of the predicted values. The test statistic is a Wald statistic based on the three coefficients in this second regression.

The RESET test is requested by adding

; RESET

to the **REGRESS** command. Results of the test will appear in the diagnostic header for the regression model, as shown in the example below.

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=LOGG     Mean                    =      -.25713
             Standard deviation      =       .23849
             No. of observations     =           52  Degrees of freedom
Regression   Sum of Squares          =      2.84577          8
Residual     Sum of Squares          =   .550250E-01        43
Total        Sum of Squares          =      2.90080         51
             Standard error of e     =       .03577
Fit          R-squared               =       .98103  R-bar squared =   .97750
Model test   F[  8,    43]           =    277.98326  Prob F > F*   =   .00000
Diagnostic   Log likelihood          =    104.34671  Akaike I.C.   = -6.50506

             Chi squared [  8]       =    206.17758  Prob C2 > C2* =   .00000
RESET test   Chi squared [  3]       =      2.69733  Prob C2 > C2* =   .44068
-----------------------------------------------------------------------------
(Regression results omitted)
-----------------------------------------------------------------------------
```

E7.9.3 Omitted Variables

A common application is examining the effect of including an additional variable in a regression after the regression is estimated without that variable. You may provide an additional set of variables with the following specification:

; Rh2 = other variable(s).

The usual regression is computed for '*y*' on the regressors. Then, for each variable in the Rh2 list, the following are computed for that variable, if it *alone* were added to the regression:

- What its coefficient would be
- What the new R^2 would be
- How much R^2 would increase
- Partial R^2 (squared correlation of *y* with this *x*, net of the effects of the other variables)
- Partial F statistic

The partial F statistic is the F ratio for the regression of *y* on this *x*, net of the included variables. This is the square of what would be the t ratio if this variable were included. Do note, this is not a means of carrying out a joint test of whether the group of variables would contribute significantly to the fit of the model. In order to carry out this test, you would use one of the procedures described in Section E8.2.

The following illustrates this analysis applied to the six price indexes used in the preceding examples:

```
REGRESS    ; Lhs = logg
           ; Rhs = one,logpg,loginc
           ; Rh2 = logpnc,logpuc,logppt,logpn,logpd,logps $
```

```
-----------------------------------------------------------------------------

--------+--------------------------------------------------------------------
Constant|   -8.99007***     .58201   -15.45  .0000   -10.13078   -7.84936
   LOGPG|    -.17124***     .03789    -4.52  .0000     -.24550    -.09698
  LOGINC|     .96865***     .07376    13.13  .0000      .82408    1.11322
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

Note that the six Rh2 variables are collinear with the constant, so the full regression cannot be computed. But, the dummies could be added one at a time with no problem, as the results indicate.

E7.9.4 The CUSUM Test of Model Stability

Brown, Durbin, and Evans' (1972) CUSUM and CUSUM of squares tests are procedures for testing the stability of a model over time. The procedure is requested in *LIMDEP* by adding

; Cusum

to the **REGRESS** command. The procedure is based on the following: Let

$$e_t = y_t - \mathbf{x_t}'\mathbf{b}_{(t\text{-}1)}$$

where $\mathbf{b}_{(t\text{-}1)}$ is the least squares coefficient vector computed using all observations up to *but not including* $[y_t,\mathbf{x}_t]$. The set of scaled residuals

$$w_r = e_r / [1 + \mathbf{x}_r'(\mathbf{X}_{(r\text{-}1)}'\mathbf{X}_{(r\text{-}1)})^{-1}\mathbf{x}_r]^{1/2}$$

are independent and, assuming normality of the original disturbances, normally distributed with mean zero and variance

$$\sigma_{fr}^2 = \sigma^2[1 + \mathbf{x}_r'(\mathbf{X}_{(r\text{-}1)}'\mathbf{X}_{(r\text{-}1)})^{-1}\mathbf{x}_r].$$

The CUSUM test is based on the cumulated sum of residuals

$$W_t = \sum_{r=K+1}^{r=t} w_r \,/\, \hat{\sigma}$$

where
$$\hat{\sigma}^2 = \tfrac{1}{T-K-1}\sum_{r=K+1}^{r=T}(w_r - \overline{w})^2,$$

and
$$\overline{w} = \tfrac{1}{T-K}\sum_{r=K+1}^{r=T} w_r.$$

The series of values are plotted against time. Upper and lower confidence bounds are the lines connecting the points

$$\textit{Upper}:\ K + a(T\text{-}K)^{1/2} \text{ to } K + 3a(T\text{-}K)^{1/2}$$
$$\textit{Lower}:\ K - a(T\text{-}K)^{1/2} \text{ to } K - 3a(T\text{-}K)^{1/2}.$$

The values of '*a*' that correspond to various significance levels are given by the authors. Those for 95% and 99% significance are .948 and 1.143, respectively. *LIMDEP* uses the 95% significance point. The plot is obtained by plotting against

$$m = t\text{-}K = 1,\ldots,M = T\text{-}K$$

the three series W_m, *Upper* = .948 + 1.896*m*, and *Lower* = -*Upper*.

The CUSUM of squares test is based on

$$S_t = \frac{\sum_{r=K+1}^{r=t} w_r^2}{\sum_{r=K+1}^{r=T} w_r^2}$$

The expected value of S_t is approximately $(t\text{-}K)/(T\text{-}K)$. The series of values are also plotted against time. Upper and lower confidence limits are obtained by comparing S_t to $E[S_t] \pm c_0$, where c_0 is a function of both $(T\text{-}K)$ and the significance level. We use an approximation to obtain c_0:

$$c_0 \approx .31 \ \text{ if } L < 10$$
$$c_0 \approx .594017 - .142897\log(L) + .00560574\log^2(L) + .000616272\log^3(L)$$
$$c_0 \approx .11 \ \text{ if } L > 100$$

where $L = (T\text{-}K)/2 - 1$. This produces an R^2 exceeding .9999 for the table of values provided by Harvey (1988).

The following example is the result of computing the CUSUM and CUSUM of squares tests as part of the basic regression computed above for the gasoline market data. The usual regression results are given first, followed by a listing of the CUSUM and CUSUM of squares values. Those outside the confidence limits are marked with an asterisk in the output.

E7.10 Robust Covariance Matrix Estimation

REGRESS will compute robust estimators for the covariance matrix of the least squares estimator for both heteroscedastic and autocorrelated disturbances. Although OLS is generally quite robust, some researchers have advocated other estimators for finite sample purposes. **REGRESS** can also be used to compute the least absolute deviations estimator.

Robust covariance matrix estimators are specified in the command line or selected from the Options page of the command builder, as shown below.

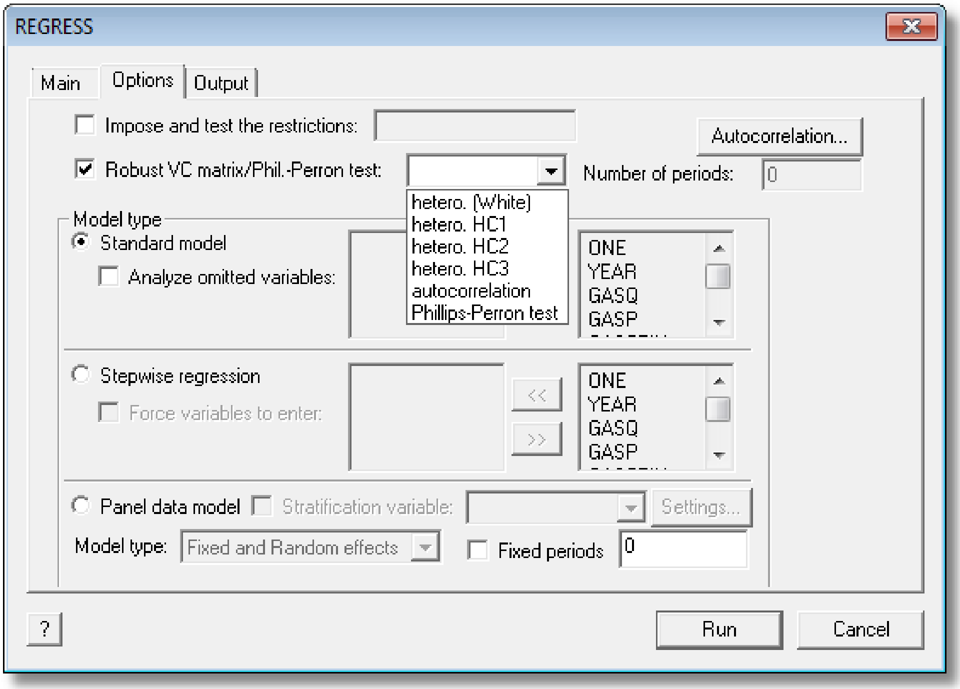

Figure E7.7 Command Builder for Robust Regression

E7.10.1 Heteroscedasticity – The White Estimator

For the heteroscedasticity corrected (White) estimator, use

; Heteroscedasticity

in the **REGRESS** command. The White estimator is

$$\text{Est.Var}[\mathbf{b}] \;=\; (\mathbf{X'X})^{-1} \times \sum_{i=1}^{n} e_i^2 \mathbf{x}_i \mathbf{x}_i{}' \times (\mathbf{X'X})^{-1}$$

Davidson and MacKinnon (1993) have recommended three alternative forms of the estimator which appear to perform well in small to moderate sized samples. Use

; Het ; Hc1 to change e_i^2 to $ne_i^2/(n\text{-}K)$

; Het ; Hc2 to change e_i^2 to e_i^2 / $[1 - \mathbf{x}_i'(\mathbf{X'X})^{-1}\,\mathbf{x}_i]$

; Het ; Hc3 to change e_i^2 to e_i^2 / $[1 - \mathbf{x}_i'\,(\mathbf{X'X})^{-1}\,\mathbf{x}_i]^2$

To illustrate, we will use the first five firms in the widely used Grunfeld data set. (There are ten firms in the whole data set.) We will use these data in several examples to follow. (These data are also found in http://pages.stern.nyu.edu/~wgreene/Text/Edition7/TableF10-4.txt – Table F10-4 in the website for Greene (2011).) The following results based on the Grunfeld data show the results of ordinary least squares and the four different heteroscedasticity robust covariance matrix estimators.

E7.10.2 Autocorrelation – The Newey-West Estimator

The Newey-West robust estimator for the covariance matrix of the least squares estimator in the presence of autocorrelation is

$$\text{Est.Var}[\mathbf{b}] = (\mathbf{X}'\mathbf{X})^{-1} \times \sum\nolimits_{t=1}^{T} e_t^2 \mathbf{x}_t \mathbf{x}_t' \times (\mathbf{X}'\mathbf{X})^{-1}$$
$$+ (\mathbf{X}'\mathbf{X})^{-1} \times \left\{ \frac{1}{T} \sum\nolimits_{j=1}^{L} \sum\nolimits_{t=j+1}^{T} \left(1 - \frac{j}{L+1}\right) e_t e_{t-j} \left[\mathbf{x}_t \mathbf{x}_{t-j}' + \mathbf{x}_{t-j} \mathbf{x}_t'\right] \right\} \times (\mathbf{X}'\mathbf{X})^{-1}$$

You (the analyst) must provide the value of L, the number of lags for which the estimator is computed. Then, request this estimator by adding

; Pds = ... the value for *L*

to the **REGRESS** command. No finite sample improvement for this estimator has been devised, so there is no counterpart to the Davidson and MacKinnon variants for the heteroscedasticity estimator.

An application based on the preceding example for the gasoline market follows.

```
REGRESS   ; Lhs = logg
          ; Rhs = one,logpg,logy,logpnc,logpuc,logppt,logpn,logpd,logps
          ; Pds = 10 $
```

The uncorrected least squares results are shown below those based on the robust estimator.

E7.10.3 Clustering

An estimator which has become popular for data which are 'clustered' (loosely like a panel), and which accommodates some kinds of correlation within groups of observations is the cluster robust estimator,

$$\text{Est.Asy.Var}\left[\mathbf{b}\right] = s^2 \ (\mathbf{X'X})^{-1} \times \frac{C}{C-1}\sum\nolimits_{c=1}^{C} \mathbf{g}_c\mathbf{g}_c{}' \times s^2 \ (\mathbf{X'X})^{-1}$$

where C is the number of clusters, n_c is the number of observations in a particular cluster, 'ic' indicates observation i in cluster c, and

$$\mathbf{g}_c = \sum\nolimits_{i=1}^{n_c} \frac{e_{ic}}{s^2}\mathbf{x}_{ic}$$

Note that $\mathbf{g}_c$ is a derivative from the normal likelihood function. (If there is one observation in each group, then this is the $(n/(n\text{-}1))$ times the White estimator.) This is requested with

; Cluster = specification.

The specification is either the fixed group size, or the name of a variable which gives the group a particular identifier – i.e., a stratification variable, such as a group number, firm number, country identifier, etc. The following applies to the Grunfeld data used earlier.

```
REGRESS    ; Lhs = i
           ; Rhs = one,f,c
           ; Cluster = firm $
```

```
+---------------------------------------------------------------------+

----------------------------------------------------------------------------
```

An extension of this robust covariance matrix estimator allows for two level, stratified and clustered data sets. Use

; Stratum = the specification

The specification provides either the fixed number of observations in a stratum or a variable that provides the identifier for strata in the data. Specifics on the use of **; Stratum** for complex survey data appear in Section R10.3.

E7.11 Accuracy in Linear Regression – NIST Benchmarks

Continuing the analysis in Chapter E2, we now examine the accuracy of the linear regression routine in *LIMDEP*. The NIST/StRD benchmarks are a suite of eleven data sets and linear regression problems designed to test the accuracy of linear regression programs. McCullough (1998) has analyzed various algorithms and programs with these data sets, and tabulated the highest accuracy he could achieve with three algorithms, Cholesky inversion, *QR* decomposition, and singular value decomposition (SVD). *QR*, the method used in *LIMDEP* is the most accurate in nine of eleven runs. The following displays full results for a few of the NIST linear regression benchmarks. The first, the Norris data, is a low level, fairly simple test. The Longley set is a moderately difficult test, but is a de facto benchmark which no respectable commercial package should fail. The Wampler (5) test is known to be one of the most difficult of the standard benchmarks. The Filippelli data are the most difficult data; this regression is not computable with many packages, and, for example, does not solve at all, if one is using Cholesky or any other direct inversion method. As shown below, *LIMDEP* achieves high accuracy on all of these problems, including the Filippelli problem.

The data sets are primarily structured to test two features of the solver, its ability to solve a problem when the data are highly collinear and its ability to handle a data set with widely differing orders of magnitude. The Filippelli data are the most difficult of the first of these. The Wampler data sets test the second. Note that in spite of the huge condition numbers reported for some of these data matrices, the solutions all agree closely with the benchmarks.

Many of the NIST datasets and test programs are included with the *LIMDEP* program, and can be found in the C:\LIMDEP10\Command Files folder created with program installation and also in the NIST Benchmarks book of the Help file. (The initial statement of each problem is the verbatim text of the NIST/StRD posting on their website.)

E8: Linear Regression – Hypothesis Tests and Restrictions

E8.1 Introduction

This chapter will detail hypothesis testing and restricted estimation in the single equation, linear regression model

$$y_i = x_{i1}\beta_1 + x_{i2}\beta_2 + \ldots + x_{iK}\beta_K + \varepsilon_i$$
$$= \mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i,\ i = 1,\ldots,n.$$

The full set of observations is denoted for present purposes as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon}.$$

The initial stochastic assumptions are the most restrictive for the linear model:

$$E[\varepsilon_i | \mathbf{X}] = 0 = E[\varepsilon_i]\ \forall\ i \quad \text{(zero mean)}$$
$$\text{Var}[\varepsilon_i | \mathbf{X}] = \text{Var}[\varepsilon_i] = \sigma^{2,}\ \forall\ i \quad \text{(homoscedastic)}$$
$$\text{Cov}[\varepsilon_i, \varepsilon_j | \mathbf{X}] = \text{Cov}[\varepsilon_i, \varepsilon_j] = 0\ \forall\ i,j \quad \text{(nonautocorrelation).}$$

Estimation of β and σ^2 and computation of appropriate standard errors were detailed in Chapter E7. This chapter will present methods of testing hypotheses about coefficients and how to estimate the regression model subject to restrictions on the coefficients.

E8.2 Hypothesis Tests in the Linear Regression Model

There are several built in procedures for inference. In addition, the **REGRESS** and **MATRIX** commands can be used to test a variety of hypotheses. For purposes of a running example, we will use the Christensen and Greene (1976) electricity data, which are in Table F4-4 in Greene (2011) – http://pages.stern.nyu.edu/~wgreene/Text/Edition7/TableF4-4.txt. The data are set up with

```
IMPORT $
id   year   cost    q     pl        sl      pk       sk      pf        sf
1    1970   .2130   8.0   6869.470  .3291   64.945   .4197   18.0000   .2512
157 additional observations.  Only the first 123 are used in the study.
SAMPLE      ; 1-123 $
CREATE      ; lnpk = Log(pk) ; lnpl = Log(pl) ; lnpf = Log(pf) $
CREATE      ; lncost = Log(cost) ; lnq = Log(q) ; lnqsq = lnq*lnq $
CREATE      ; lnpk_pf = Log(pk/pf) ; lnlp_pf = Log(pl/pf) ; lncostpf = Log(cost/pf)$
```

E8.2.1 Testing Significance of Individual Coefficients

The standard regression results contain the results of hypothesis tests that individual coefficients are equal to zero. The following results illustrate.

REGRESS ; Lhs = lncost ; Rhs = one,lnpk,lnpl,lnpf,lnq $

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=LNCOST   Mean                    =       3.00917
             Standard deviation      =       1.56241
             No. of observations     =           123  Degrees of freedom
Regression   Sum of Squares          =       292.338           4
Residual     Sum of Squares          =       5.47915         118
Total        Sum of Squares          =       297.817         122

    LNPL|     .12860         .13233      .97  .3331     -.13076    .38796
    LNPF|     .70487***      .07506     9.39  .0000      .55776    .85197
     LNQ|     .83024***      .01095    75.85  .0000      .80879    .85169
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

The statistical significance (10%, 5%, 1%) is indicated in the table. The test is based on the t statistic, the P value or whether the confidence interval contains zero. All produce the same conclusion. A test of whether a coefficient equals some particular nonzero value can, in principle, be carried out using the procedure in the next section. However, the same significance test results just by assessing whether the confidence interval contains the indicated value. For example, based on the results below, they hypothesis that β_3 (the coefficient on *lnpl*) equals 0.5 would be rejected because the interval (-0.13076,0.38796) does not contain 0.5. By the same construction, the hypothesis that β_5 (the coefficient on *lnq*) equals 0.84 would not be rejected, as 0.84 is contained in (0.80879,0.85169).

E8.2.2 Linear Function of Coefficients

A test of a hypothesis based on a linear function of the coefficients is requested by adding

; Test: value * name ± value * name ± … = value

to the **REGRESS** command. When value equals one it (and the *) may be omitted. 'Name' is the name of a variable in the equation. For example, a restriction on the model parameters that is normally imposed as part of the cost function model is that the log price coefficients sum to one. We can test that as a hypothesis here with

REGRESS ; Lhs = lncost ; Rhs = one,lnpk,lnpl,lnpf,lnq
; Test: lnpk + lnpl + lnpf = 1 $

This produces the results below

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=LNCOST   Mean                    =       3.00917
             Standard deviation      =       1.56241
             No. of observations     =           123  Degrees of freedom
Regression   Sum of Squares          =       292.338           4
Residual     Sum of Squares          =       5.47915         118

             Chi squared [  4]       =     491.45003  Prob C2 > C2* =   .00000
Wald Test:   Chi-squared [  1]       =        .00061  Prob C2 > C2* =   .98025
F Test:      F ratio [ 1, 118]       =        .00061  Prof F  > F*  =   .98030
--------+--------------------------------------------------------------------
```

(The estimates are the same.) The test statistic is reported in the diagnostic results above the estimates. When the model is fit by least squares with no modifications to accommodate nonnormality or other violations of the standard assumptions (such as a robust covariance matrix), then two versions of the statistic are presented. The standard F statistic for testing the J restrictions,

$$H_0: \mathbf{R}\boldsymbol{\beta} = \mathbf{q}$$

is

$$F[J,n-K] = [\mathbf{Rb} - \mathbf{q}]'[s^2\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}']^{-1}[\mathbf{Rb} - \mathbf{q}]/J$$
$$= [(\mathbf{e}_*'\mathbf{e}_* - \mathbf{e}'\mathbf{e})/J] \,/\, [\mathbf{e}'\mathbf{e}/(n-K)]$$

Under the assumption of normality of disturbances, this is distributed as $F[J,n-K]$ under the null hypothesis. The critical value is taken from the standard F table. When the denominator degrees of freedom are larger than 10,000, this critical value will be indistinguishable from 1/J times the counterpart from the chi squared, so in this case, only the Wald statistic is reported. For a linear regression the Wald chi squared statistic is exactly $J \times F$. The critical value for the Wald statistic is based on large sample results whereas that for the F statistic is based on the actual sample size (degrees of freedom). The result is that the P value for the Wald test will always be lower than that for the F value – the F statistic is more conservative.

NOTE: This syntax for testing restrictions is new with Version 10 of *LIMDEP*. Earlier versions would use **; Test: value * b(index) ± … ± value * b(index) = value**. The example above would be b(2) + b(3) + b(4) = 1. The older syntax is still usable (and even necessary on occasion, as shown in the next section). The syntax based on variable names rather than index positions will be more convenient, as the terms in the restriction are independent of the order or position of variables in the model specification.

E8.2.3 Linear Function with Interaction Terms and Nonlinearities

A slight change in the command is needed if the model contains interaction terms or nonlinear functions of the variables. For example, the model

REGRESS ; Lhs = lncost ; Rhs = one,lnpk,lnpl,lnpf,lnq,lnq*lnq $

contains a quadratic term in log output. To test a hypothesis about terms such as this, it is necessary to revert to the earlier form of restrictions. For example, to test the hypothesis that the coefficient on *lnq***lnq* equals zero, the syntax

; Test: lnq*lnq = 0

will not work; *lnq***lnq* is not the name of a variable, and *lnq***lnq* looks deceptively like, say, 2**lnq* to the program. The solution is to use the earlier format. For this simple hypothesis, we must use

; Test: b(6) = 0.

It is permissible to mix the two forms. For example, to test the two previous hypotheses at the same time, we would use

; Test: lnpk + lnpl + lnpf = 1, b(6) = 0

which produces

```
-----------------------------------------------------------------------------
... (Results omitted)

Wald Test:   Chi-squared [  2]    =      145.56748  Prob C2 > C2* =   .00000
F Test:      F ratio [ 2, 117]    =       72.78374  Prof F  > F*  =   .00000
--------+--------------------------------------------------------------------
```

E8.2.4 More Than One Linear Restriction

As shown in the example immediately above, when you have more than one restriction to test at the same time, you separate the restrictions with commas. To carry out separate tests, each of which can involve more than one restriction, separate the hypotheses with a '|' character. For example, to test the two restrictions above as separate hypotheses, rather than as one joint hypothesis, we would use

; Test: lnpk + lnpl + lnpf = 1 | b(6) = 0.

The results would be as follows:

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=LNCOST   Mean                 =       3.00917

E8.2.5 Testing Nonlinear Restrictions

Chapter R14 describes how to use the **WALD** command for testing and analyzing nonlinear restrictions and nonlinear functions of parameters. The procedure described there applies to the linear regression model as well as the others, so we need not add new details here. We demonstrate the use of the feature with a simple example.

Consider the equation based, once again, on the gasoline market data:

$$logg = \beta_1 + \beta_2 logpg + \beta_3 logy + \beta_4 logpnc + \beta_5 logpuc + \beta_6 logppt + \varepsilon.$$

Consider the nonlinear hypothesis

$$H_0: \beta_2/\beta_4 + \beta_2/\beta_5 = 0.$$

The following could be used to test this (admittedly meaningless) hypothesis:

NAMELIST ; x = one,logpg,logy,logpnc,logpuc,logppt $
REGRESS ; Lhs = logg ; Rhs = x $
WALD ; Fn1 = b_logpg / b_logpnc + b_logpg / b_logpuc $

Note that the restriction is implicitly **; Fn1 = … = 0**. The '**= 0**' may be omitted. Of course, if some other constant is needed, it must be included in the form **; Fn1 = … - value**. For example,

; Fn1 = b_K + b_L + b_F - 1

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=LOGG     Mean                 =       -.25713
             Standard deviation   =        .23849
             No. of observations  =            52  Degrees of freedom
Regression   Sum of Squares       =       2.79379           5
Residual     Sum of Squares       =       .107004          46
Total        Sum of Squares       =       2.90080          51
             Standard error of e  =        .04823

  LOGINC|    1.31597***     .14198      9.27  .0000      1.03769   1.59425
  LOGPNC|    -.11964        .20384      -.59  .5601      -.51916    .27989
  LOGPUC|     .03754        .09814       .38  .7038      -.15481    .22990
  LOGPPT|    -.21514*       .11656     -1.85  .0714      -.44359    .01331
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

The chi squared statistic for carrying out the test is given in the information at the top of the results, as shown below.

```
-----------------------------------------------------------------------------
WALD procedure. Estimates and standard errors
for nonlinear functions and joint test of
nonlinear restrictions.
Wald Statistic              =      .08431
Prob. from Chi-squared[ 1] =      .77154
Functions are computed at means of variables
--------+--------------------------------------------------------------------
        |                  Standard            Prob.      95% Confidence
WaldFcns|  Coefficient       Error       z     |z|>Z*         Interval
--------+--------------------------------------------------------------------
 Fncn(1)|    -.62840       2.16422     -.29  .7715    -4.87019   3.61338
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

Although the difference is large, the standard error is extremely large, and the Wald test fails to reject the hypothesis.

When necessary, you can use the more general form of the **WALD** command to provide the parameters, covariance matrix and labels for the test. The preceding could also be obtained with

```
WALD      ; Parameters = b
          ; Covariance = varb
          ; Labels = 6_b
          ; Fn1 = b2/b4 + b2/b5 $
```

If more than one nonlinear function is specified in the **WALD** command, the overall chi squared given is used to test whether all of the functions equal to zero at the same time. The individual results given in the table can be used to test whether the individual functions equal zero. The following example proposes three 'hypotheses'

```
WALD      ; Parameters = b
          ; Covariance = varb
          ; Labels = 6_b
          ; Fn1 = b2/b4 + b2/b5
          ; Fn2 = b3
          ; Fn3 = b6 $
```

```
-----------------------------------------------------------------------------
WALD procedure. Estimates and standard errors
for nonlinear functions and joint test of
nonlinear restrictions.
Wald Statistic              =   327.46324
Prob. from Chi-squared[ 3] =      .00000
Functions are computed at means of variables
--------+--------------------------------------------------------------------
        |                  Standard            Prob.      95% Confidence
WaldFcns|  Coefficient       Error       z     |z|>Z*         Interval
--------+--------------------------------------------------------------------
 Fncn(1)|    -.62840       2.16422     -.29  .7715    -4.87019   3.61338
 Fncn(2)|    1.31597***     .14198     9.27  .0000     1.03769   1.59425
 Fncn(3)|    -.21514*       .11656    -1.85  .0649     -.44359    .01331
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

The overall chi squared tests all three hypotheses at the same time. The individual results would be used to test the restrictions individually.

TIP: If you are testing a hypothesis that a function equals something other than zero, just subtract that value from the function specification. For example, **; Fn1 = b1 + b2 + b3 - 1** might be appropriate.

E8.2.6 Tests of Structural Change

We consider again the regression of gasoline consumption on price, income and three related price indexes. We are interested in testing the hypothesis that there is a structural break in 1974. The following does the standard Chow test. The **CALC** command then does a likelihood ratio test of the same hypothesis. Finally, we use a Wald test. The Wald test differs from the Chow test in that it allows for the disturbance variance to change across the periods.

```
DATES      ; 1953 $
PERIOD     ; 1953 - 2004 $
CREATE     ; d = Ind(1974,2004) ; dp = d*logpg
           ; dy = d*logy ; dpnc = d*logpnc
           ; dpuc = d*logpuc ; dppt = d*logppt $
NAMELIST   ; x = one,logpg,logy,logpnc,logpuc,logppt
           ; xd = d,dp,dy,dpnc,dpuc,dppt $
REGRESS    ; Lhs = logg ; Rhs = x,xd
           ; Test: d = 0, dp = 0, dy = 0, dpnc = 0, dpuc = 0, dppt = 0 $
CALC       ; List ; c = 2* (Lik(x,xd,logg) - Lik(x,logg))
           ; lrtest = 1 - Chi(c,(Col(xd))) $
```

The following shows the unconstrained and constrained regressions. (A few lines are omitted from the results.) Both the F and likelihood ratio statistics reject the null hypothesis of no structural change. The world did change in 1973-1974.

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=LOGG     Mean                 =      -.25713

This command set carries out the Wald test. The last line lists the critical value for the chi squared distribution. The table value is about 12 while the statistic is over 582, so again, the hypothesis is rejected. Note that the earlier F statistic was 92.9. The number of restrictions times F, 6×92.9 = 557.4 should roughly equal the chi squared value (582.46), which it does.

```
REGRESS    ; If[year < 1974]   ; Quietly ; Lhs = logg ; Rhs = x $

--------+--------------
       1|       582.461
 [CALC] *Result*=     12.5915872
```

There is a convenient, automated method of carrying out the Chow test when the hypothesis involves dividing the sample into two subsamples. The following carries out the same Wald test as shown above. *Post*1973 is a dummy variable that partitions the sample. (You might do this in a cross section, for example, to compare men and women, or two countries.) The **REGRESS** command begins with a loop that computes the regression (or any model) three times, with the full sample and with the two subsamples. The **DECOMPOSE** command then produces several results, including the chi squared statistic.

```
CREATE     ; Post1973 = year > 1973 $
REGRESS    ; For [Post1973 = *,0,1] ; Quietly ; Lhs = logg ; Rhs = x $
DECOMPOSE $
```

The following output results. (If **; Quietly** is omitted from the **REGRESS** command, then a full set of results is displayed for each of the three iterations.)

```
-----------------------------------------------------
Setting up an iteration over the values of POST1973
The model command will be executed for     2 values
of this variable.  In the current sample of      52
observations, the following counts were found:
Subsample   Observations    Subsample  Observations
POST1973 =   0         21    POST1973=   1         31

E8.2.7 Homogeneity Test

The following command set can be used to test for homogeneity of a set of *NG* subsamples of the sample. The initial **NAMELIST** command defines the variables in the regression equation. The **CREATE** command defines the dependent variable and the index variable that is used to partition the sample into *NG* groups. The rest of the command set is generic and need not be changed. The only displayed output is the test statistic and the critical value from the F table.

```
? Define the set of Rhs variables in the regression model
NAMELIST    ; x = the relevant x vector $
CREATE      ; y = the dependent variable ; Group = the index 1,2,… $
? Lines below here are generic and do not need to be changed.
SAMPLE      ; All $
CALC        ; ng = max(group) ; sspool = Ess(x,y) ; sssum = 0 ; nt = n $
PROC $
INCLUDE     ; New ; Group = i $
CALC        ; sssum = sssum + Ess(x,y) $
ENDPROC $
EXEC        ; i = 1,ng $
CALC        ; List ; f = ((sspool-sssum)/(kreg*(ng-1))) / (sssum/(nt-ng*kreg)) $
CALC        ; List ; Ftb(.95, (kreg*(ng-1)), (nt-ng*kreg)) $
```

Using the regression defined in the previous example, we defined the group variable by three periods,

```
CREATE      ; Group = 1 + year > 1073 + year > 1985 $
```

The result of the test for this partitioning of the period 1953 to 2004 is

```
[CALC] F       =     72.7744898
[CALC] *Result*=      2.0500398
```

Since the sample F statistic is greater than the critical value, the homogeneity hypothesis is rejected.

E8.2.8 J Tests for Nonnested Hypotheses

We suppose that the dependent variable is **y** and there are two competing sets of regressors, **X** and **Z**, which are nonnested. Which is the right one? Davidson and MacKinnon propose a simple method of testing the hypothesis in the linear case. We regress **y** on **X** and compute the fitted values, then regress **y** on **Z** and these fitted values. If **Z** is the correct regressor vector, the coefficient on the fitted values should be close to zero by a conventional t test. We then reverse the roles of **X** and **Z** and repeat (and hope the results are consistent). The commands are:

```
NAMELIST    ; z = ...  $
NAMELIST    ; x = ...  $
REGRESS     ; Lhs = y ; Rhs = x ; Keep = yfx $
```

In this regression, we examine the coefficient on *yfx*.

```
REGRESS     ; Lhs = y ; Rhs = z, yfz $
REGRESS     ; Lhs = y ; Rhs = z ; Keep = yfz $
```

In this regression, we examine the coefficient on *yfz*.

```
REGRESS     ; Lhs = y ; Rhs = x, yfz $
```

E8.3 Restricted Least Squares

This section describes procedures for estimating the restricted regression model,

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$$

subject to $\mathbf{R}\boldsymbol{\beta} \geq \mathbf{q}$.

R is a $J \times K$ matrix assumed to be of full row rank. That is, we impose J linearly independent restrictions. They may be equality restrictions, inequality restrictions, or a mix of the two.

E8.3.1 Equality Restrictions

If $\mathbf{X}'\mathbf{X}$ is nonsingular, the constrained ordinary least squares estimator is

$$\mathbf{b}_c = \mathbf{b} - [\mathbf{X}'\mathbf{X}]^{-1}\mathbf{R}'[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}']^{-1}\ [\mathbf{Rb}\text{-}\mathbf{q}]$$

where $\mathbf{b} = [\mathbf{X}'\mathbf{X}]^{-1}\mathbf{X}'\mathbf{y}$

is the unrestricted least squares estimator. The estimator of the variance of the constrained estimator is

$$\text{Est.Var}[\mathbf{b}_c] = s^2[\mathbf{X}'\mathbf{X}]^{-1} - s^2[\mathbf{X}'\mathbf{X}]^{-1}\mathbf{R}'[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}']^{-1}\mathbf{R}[\mathbf{X}'\mathbf{X}]^{-1}.$$

where $s^2 = (\mathbf{y} - \mathbf{X}\,\mathbf{b}_c)'\,(\mathbf{y} - \mathbf{X}\,\mathbf{b}_c)/(n\text{-}K\text{+}J)$.

The syntax for imposing linear restrictions is the same as that for testing linear restrictions described in the previous section. As before, there are two general forms available, depending on whether the regression involves only linear terms or explicit terms such as interactions, quadratics, or logs. You may impose as many restrictions as you wish with this estimator; simply separate the restrictions with commas.

To continue the earlier example, consider the hybrid cost function in Section E8.2.3,

$$\text{Logcost} = \beta_1 + \beta_2\text{logPk} + \beta_3\text{logPl} + \beta_4\text{logPf} + \gamma_1\text{logq} + \gamma_2(\text{logq})^2 + \varepsilon.$$

Linear homogeneity in the input prices requires $\beta_2 + \beta_3 + \beta_4 = 1$. The Cobb-Douglas cost function results if the restriction γ_2 equals zero is imposed in addition to the linear homogeneity restriction. The restricted regression is obtained with

```
REGRESS  ; Lhs = lncost
         ; Rhs = one,lnpk,lnpl,lnpf,lnq,lnqsq
         ; CLS: lnpk + lnpl + lnpf = 1, lnqsq = 0 $
```

In this case, both unrestricted and restricted regressions are reported. In the second, the F statistic (or Wald statistic if a robust covariance matrix is used) for testing the restrictions is also reported.

```

E8.3.2 Equality Restrictions and Singularity

LIMDEP does not use precisely the preceding formulation internally. The unrestricted estimator may not exist – $\mathbf{X}'\mathbf{X}$ may be singular. It may still be possible to obtain the restricted estimates, however. The general result is that while the unrestricted model may involve too many parameters to estimate, the restrictions may eliminate enough parameters to leave an estimable model. Instead of the formulas above, we solve the constrained first order conditions for least squares using the Lagrangean multiplier method. That is,

$$\text{Minimize}(\boldsymbol{\beta},\boldsymbol{\lambda})\text{: } ½(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) + \boldsymbol{\lambda}'(\mathbf{R}\boldsymbol{\beta} - \mathbf{r}).$$

The first order conditions are

$$\begin{bmatrix} \mathbf{X}'\mathbf{X} & \mathbf{R}' \\ \mathbf{R} & \mathbf{0} \end{bmatrix} \begin{bmatrix} \boldsymbol{\beta} \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \mathbf{X}'\mathbf{y} \\ \mathbf{q} \end{bmatrix}.$$

When $\mathbf{X}'\mathbf{X}$ is nonsingular, this produces the formulas above. (See Greene and Seaks (1991).) But, even if $\mathbf{X}'\mathbf{X}$ is singular, this equation system may have a solution. The constrained least squares estimator, if it exists, is the solution to the preceding. If $\mathbf{X}'\mathbf{X}$ does have full rank, this equation system produces the usual constrained estimator. If not, *LIMDEP* just proceeds to this solution. If it exists, no warning is given about the unconstrained estimator – presumably it was of no interest anyway; *LIMDEP* simply produces the constrained estimator.

To illustrate how this works, consider the following obviously badly constructed example:

```
CREATE      ; extra = lnqsq $
REGRESS     ; Lhs = lncost
            ; Rhs = one,lnpk,lnpl,lnpf,lnq,lnqsq,extra
            ; CLS: lnpk + lnpl + lnpf = 1, lnqsq = 0, extra = 0 $
```

The variable *extra* is identical to *lnqsq*, so the unrestricted regression cannot be computed. There is a textbook case of multicollinearity. However, the restrictions include ‘extra = 0,’ so if the restrictions are actually imposed, the regression is fine. The following are the results from this command. The unrestricted regression cannot be computed, but the restricted one can. In fact, it is identical to the one in Section E8.2.3.

```
-----------------------------------------------------------------------------
Restricted   least squares regression ............
LHS=LNCOST   Mean                 =       3.00917

-----------------------------------------------------------------------------
```

The usual method of avoiding the dummy variable trap is to drop one of the dummy variables. Consider, for example, the duration data used in Chapters E58-E60. We have the variables *time*, *sex*, and *married*. For present purposes, consider a linear regression of *time* on a constant, *married*, and *sex*. The dummy variable, *sex* would normally be coded 0/1, and the model would include a constant and this dummy variable. The constant term would give the overall intercept, and the coefficient on sex would give the deviation of the group with *sex* = 1 (male in this case) from this constant. Suppose, instead, we were to attempt to fit the regression

$$time = \beta_1 + \beta_2 male + \beta_3 female + \beta_4 married + \varepsilon.$$

This regression suffers from perfect multicollinearity; the second and third variables sum to the constant term. Therefore, the unrestricted coefficient vector for this model cannot be estimated. We add the constraint

$$\beta_2 + \beta_3 = 0.$$

This is just like the usual model, except that with this restriction, there is an average constant, and the two coefficients will give the difference of each of the two groups from the mean (in this case, a mean of only two items). The following shows the result of estimating this model with *LIMDEP*. The unrestricted regression cannot be computed, but the restricted one can. Notice that *LIMDEP* reports zero for the F test. This is not a substantive restriction. With the restriction, the model becomes just estimable.

The commands are:

READ ; Nobs = 22
; Nvar = 4
; Names = time,status,sex,married
; By Variables $

LIMDEP uses this method to fit the two way fixed effects model – see Section E17.3. The regression model is

$$y_{it} = \mu + \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}., \; i = 1,\ldots,n, \; t = 1,\ldots,T_i.$$

In order to compute the coefficients in this model, it is necessary to impose two restrictions, because both the individual effects and the time effects sum to one, the constant term. To estimate this model, *LIMDEP* drops one of the time constants and imposes that the individual constants sum to zero. (Because the number of periods can vary, it is necessary to create the time dummy variables and insert them into a one way fixed effects model. The template method of using deviations from time means does not give the correct answer when the number of periods varies with *i*.)

E8.3.3 Inequality Restricted Least Squares

You may also impose inequality restrictions. The model is specified as before, with the restrictions now specified as weak inequalities. That is,

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{e}$$

subject to $R_{11}\,\beta_1 + R_{12}\,\beta_2 + ... \geq q_1$ (When $R_{jk} = 1$, it may be omitted. Also, the $\geq$ may be $\leq$.)

$R_{21}\,\beta_1 + R_{22}\,\beta_2 + ... \geq q_2$

...

$R_{J1}\,\beta_1 + R_{J2}\,\beta_2 + ... \geq q_J$

This estimation is formulated as a classical quadratic programming problem. That is, we

Minimize (wrt $\boldsymbol{\beta}$) $\mathbf{y}'\mathbf{y} - (2\mathbf{y}'\mathbf{X})\boldsymbol{\beta} + \boldsymbol{\beta}'(\mathbf{X}'\mathbf{X})\boldsymbol{\beta} = \mathbf{a} + \mathbf{c}'\boldsymbol{\beta} + \boldsymbol{\beta}'\mathbf{H}\boldsymbol{\beta}$
Subject to the equality and inequality constraints.

In order to specify estimation of a model subject to inequality constraints, you use the exact same formulation as if they were equality constraints, save for '<=' for less than or equal to and '>=' for greater than or equal to. Also, you may have any mixture of equality constraints, >= and <= constraints in any model. As in the case of the LAD estimator, there is no well defined result for the asymptotic covariance matrix of the inequality constrained estimator. As before, we suggest using bootstrapping as a method of approximating the appropriate matrix. Use

; Nbt = ... number of bootstrap replications

To illustrate, we continue the sampling experiment computed at the beginning of this section. The following creates data generated by a log quadratic production function

$$\log y = \beta_1 + \beta_2 \log l + \beta_3 \log k + \beta_4 \log^2 l + \beta_5 \log^2 k + \beta_6 \log k \log l + \varepsilon$$

The regression model is fit subject to two constraints: $\beta_2 + \beta_3 = 1$ and $\beta_4 + \beta_5 + \beta_6 \leq 0$. The second constraint is actually binding in our results, as the final results have both constraints imposed as equalities. Standard errors are estimated using 20 bootstrap replications.

E9: Non- and Semiparametric Regression Models

E9.1 Introduction

This chapter will detail estimation of a single equation, linear regression model

$$y_i = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ i = 1,...,n.$$

The initial stochastic assumptions of the classical regression model depart from

$$E[y_i|\ \mathbf{x}_i\ ] = \boldsymbol{\beta}'\mathbf{x}_i.$$

This chapter considers models that relax this assumption. The least restrictive version is the nonparametric regression model,

$$y_i = m(x_i) + \varepsilon_i \text{ where } E[\varepsilon_i \mid x_i] = 0$$

for a single variable x_i. This makes minimal assumptions about the relationship between y_i and x_i. The LOWESS method described in Section E9.5 is a graphical technique that is based on this principle.

A convenient extension of the nonparametric regression approach is the index function model

$$E[y|\boldsymbol{\beta}'\mathbf{x} = z] = F_{\boldsymbol{\beta}}(z).$$

Finally, we describe a semiparametric approach. The median regression is

$$\text{Med}[\ y_i \mid \mathbf{x}_i\ ] = \boldsymbol{\beta}'\mathbf{x}_i.$$

This is the least absolute deviations estimator. The median is the 50^{th} percentile. Section E9.4 describes an estimator in which any specified quantile may be analyzed – and all may differ;

$$p^{th} \text{ quantile } [\ y_i \mid \mathbf{x}_i\ ] = \boldsymbol{\beta}'\mathbf{x}_i.$$

Since the regression may differ at different quantiles, this draws the model closer to the nonparametric regression.

E9.2 Nonparametric (Kernel Density) Regression Estimation

The basic command for the nonparametric regression estimator is

NPREG ; Lhs = dependent variable
; Rhs = regressor $

NPREG is used to fit a nonparametric regression function. This estimator estimates a smooth, regression function,

$$E[y|x] = F(x)$$

using the method of kernels. A straightforward extension detailed in Section E9.2.2 is to a single index model,

$$E[y|\boldsymbol{\beta}'\mathbf{x} = z] = F_{\beta}(z),$$

for any parameter vector $\boldsymbol{\beta}$ (assumed known or at least given). With an appropriate choice of $\mathbf{x}$ and $\boldsymbol{\beta}$, and by rescaling the response, **NPREG** can estimate any sufficiently smooth univariate regression function with known bounded range. **NPREG** takes as input sample data consisting of n observations $(y_i,\mathbf{x}_i)$ where $\mathbf{x}_i$ is a K-vector of regressors, and y_i is the dependent variable, and a parameter vector $\boldsymbol{\beta}$. ($\boldsymbol{\beta}$ is omitted for the simple univariate model.) **NPREG** also requires a smoothing parameter, h, also called the bandwidth parameter. The simplest nonparametric regression model between a y variable and a single x variable is obtained simply by specifying $\mathbf{x}_i$ = that variable and $\boldsymbol{\beta} = 1$. We consider this case first, then turn to the index function model.

E9.2.1 Nonparametric Regression on a Single Variable

To estimate the regression function

$$E[y|x] = F(x)$$

for a single variable, x, use

NPREG ; Lhs = y variable
; Rhs = x variable $

All aspects of the specification will be taken care of internally. Output consists of a text description of the data followed by the plot of the estimated regression function.

To illustrate, we will use the gasoline market data employed in several previous examples. The first plot showing the nonparametric regression of *logg* on *logpg* shows the model at work, but also demonstrates that the problem of omitted variables impacts the nonparametric regression as well. It is not robust to omitted variables.

NPREG ; Lhs = logg ; Rhs = logpg $

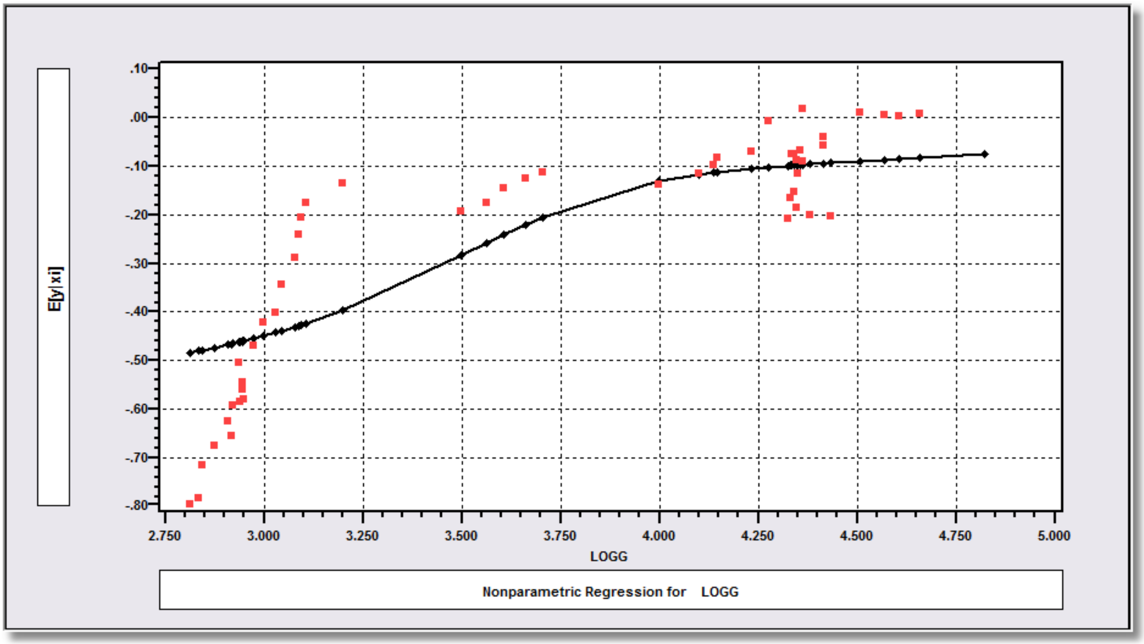

Figure E9.1 Nonparametric Regression

E9.2.2 Estimating a Nonparametric Single Index Regression Function

To analyze a regression function of the form

$$E[y|\boldsymbol{\beta}'\mathbf{x}] = F_{\beta}(\boldsymbol{\beta}'\mathbf{x}),$$

you must provide the values of the parameters as well as the data. Note that the estimator is not estimating the parameters, it is analyzing the regression function based on the index function. You may, of course, provide any parameters you wish. One possibility might be to analyze your linear regression model to see if it is really linear. Keep in mind, the results are only suggestive, as the parameters you would provide are already based on an assumption of linearity.

We first compute $z_i = \boldsymbol{\beta}'\mathbf{x}_i$ for each observation. The sample standard deviation of the observations, s, is computed next. Then, h, s, z_i, and the kernel function, $K[\cdot]$ are used to define a weighting function

$$w_i(z_j) = \frac{1}{h}K\left[\frac{z_i - z_j}{h}\right],$$

then, the regression function is

$$F(z_j) = \frac{\sum_{i=1}^{N} w_i(z_j)y_i}{\sum_{i=1}^{N} w_i(z_j)}.$$

The default kernel function used is the density for the standardized logistic. Several alternatives are available. These are discussed below.

The command for **NPREG** for an index function model is

```
(Commands to obtain the parameter vector)
NPREG          ; Lhs = y variable
               ; Rhs = ... regressors that correspond to the parameters
               ; Parameters = parameter values $
```

(In earlier versions of *LIMDEP*, **; Start = …** would replace **; Parameters = …** You may still use this syntax.) Since the command does no estimation of its own, you must provide the parameter values if you are plotting a regression function with more than one independent variable. Output from this estimator consists of a summary table and a plot of $F(z_j)$ against z_j.

To illustrate the computations, we continue the analysis above, by analyzing

$$logg = \beta_1 + \beta_2 logpg + \beta_3 logincome + \varepsilon$$

The command sequence is

```
REGRESS        ; Lhs = logg ; Rhs = one,logpg,logy $
NPREG          ; Lhs = logg ; Rhs = one,logpg,logy
               ; Parameters = b $
```

(The least squares regression results are omitted.)

```

+---------------------------------------+
```

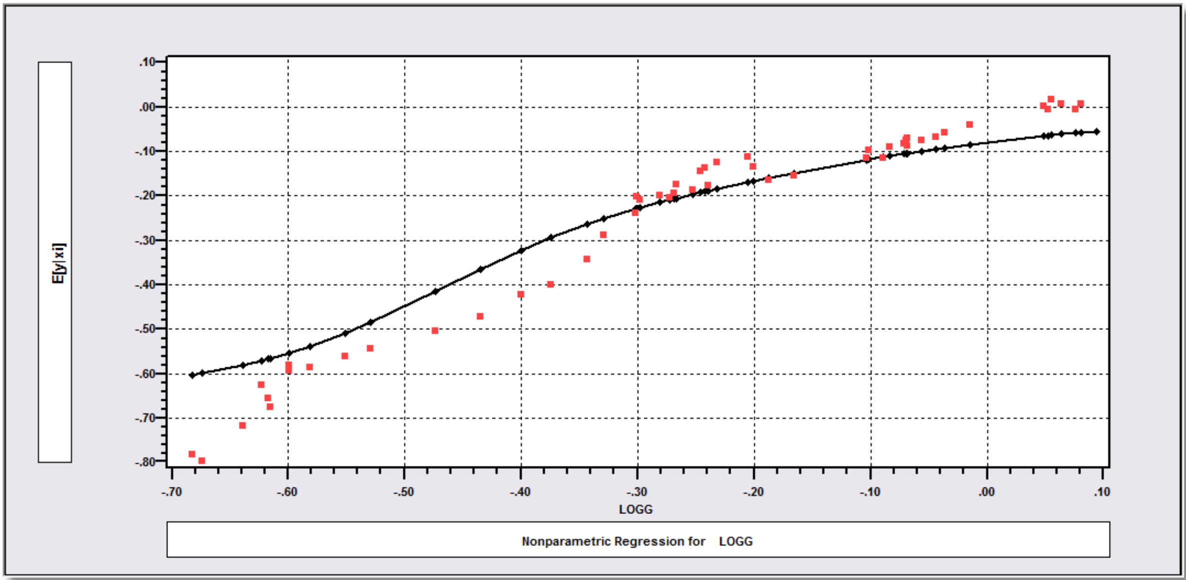

Figure E9.2 Nonparametric Regression for Gasoline Consumption

E9.2.3 Options for NPREG

Kernel Functions

The primary component of the computation is the kernel function, K[.]. Eight alternatives are provided:

1. Epanechnikov:	$K[z]$	=	$.75(1 - .2z^2)$ / Sqr(5) if $|z|$ <= 5, 0 else,
2. Normal:	$K[z]$	=	$\phi(z)$ (normal density),
3. Logit:	$K[z]$	=	$\Lambda(z)[1-\Lambda(z)]$ (default),
4. Uniform:	$K[z]$	=	.5 if $|z| \leq 1$, 0 1 else,
5. Beta:	$K[z]$	=	$(1-z)(1+z)/24$ if $|z| \leq 1$, 0 1 else,
6. Cosine:	$K[z]$	=	$1 + \cos(2\pi z)$ if $|z| < .5$, 0 else,
7. Triangle:	$K[z]$	=	$1 - |z|$, if $|z| \leq 1$, 0 else,
8. Parzen:	$K[z]$	=	$4/3 - 8z^2 + 8|z|^3$ if $|z| \leq .5$, $8(1-|z|)^3$ else.

You may specify the kernel function to be used with

; Kernel = one of the eight types of kernels listed above,

e.g., **; Kernel = normal**

The logit kernel function is used if you do not specify one. Epanechnikov is a popular alternative.

Bandwidth Parameter

The default value for the smoothing parameter,

$$h = .9Q/n^{0.2}$$

where $$Q = \min(\text{std.dev of } \mathbf{b}'\mathbf{x}_i., \text{ data range}/1.5)$$

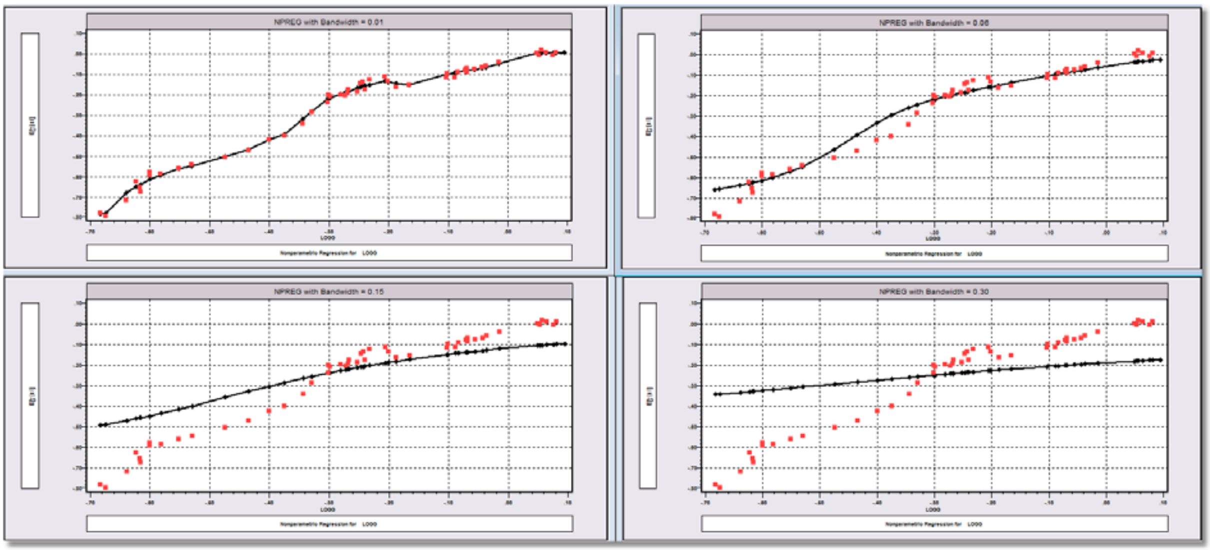
An alternative value is provided with

; Smooth = value

There is no definitive theory for choosing the right smoothing parameter, h. Large values will cause the estimated function to flatten at the average value of y_i. Values close to zero will cause the function to pass through the points z_i,y_i and to become computationally unstable elsewhere. Higher values will smooth the function, but will, in the process, degrade the fit of the function to the data.

The bandwidth parameter is a crucial element of the analysis. For example, note that in the preceding example, the bandwidth parameter is about .094 Figure E9.3 shows the estimated regression functions for four values, .01, .06, .15 and .30. The differences in the estimated function are clearly visible.

Bandwidth = 0.01 **Bandwidth = 0.06**



Bandwidth = 0.15 **Bandwidth = 0.30**

Figure E9.3 Effect of Bandwidth on Kernel Regression

Number of Points to Plot

The default number of points to be plotted is M = 100, or the sample size, n, if $n \leq 5000$ and you do not specify M or the range. Use

; Pts = M

to compute the function at M equally spaced points in the range defined as below by the sample values. **; Limits** and **; Pts** may be given together to specify a grid in a particular range. **; Pts** may be any number up to the number of rows in the data area. If the value you give exceeds the limit of rows, an error will occur and computation will cease.

Range of Estimation

The next set of specifications dictates the points at which the regression function should be computed. The default is to compute the function at the data points, of which there are n. An alternative is

; Limits = lower,upper

to compute the function at M equally spaced points in the range [lower,upper]. The default is n equally spaced points with lower = the sample minimum of $\boldsymbol{\beta}'\mathbf{x}_i - h$ and upper = the maximum + h.

Cross Validation Mean Square Prediction Error

The cross validation mean squared prediction error (*CVMSPE*) is a goodness of fit measure. Each observation, '*i*' is excluded in turn from the sample. Using the reduced sample, the regression function is reestimated at the point z_i in order to provide a point prediction for y_i. The average squared prediction error defines the *CVMSPE*. The calculation is defined by the point predictions,

$$F^*(\boldsymbol{\beta}'\mathbf{x}_i) = \frac{\sum_{j\neq i} y_j K\left[(y_j - \boldsymbol{\beta}'\mathbf{x}_i)/h\right]}{\sum_{j\neq i} K\left[(y_j - \boldsymbol{\beta}'\mathbf{x}_i)/h\right]}.$$

Then, $$CVMSPE = \frac{1}{n}\sum_{i=1}^{n}\left(y_i - F^*(\boldsymbol{\beta}'\mathbf{x}_i)\right)^2 .$$

The *CVMSPE* is more or less a counterpart to the sum of squares in regression, which suggests that one could compute a fit measure by using

```
CALC      ; List ; npregfit = 1 - cvmspe/((n-1)*Var(y)) $
```

The usual warning about fit measures in nonlinear regressions applies, however. This number need not be positive.

E9.2.4 Output from NPREG

Results from **NPREG** consist of

- The table shown in the earlier examples,
- An $M \times 2$ matrix named *kernel*, whose first column is the sorted values of $\boldsymbol{\beta}'\mathbf{x}_i$, and the second column is the estimated values from the regression function,
- A scalar named *cvmspe* (described below),
- The plot of the estimated function.

Note that since M may not equal n, there is no necessary correspondence between the observations and the values in the matrix. In addition to the stored result, a plot of the regression function, as shown earlier, is part of the usual output for this estimator as well. You can request a listing of the ordinate values, z_i, and the estimated values of the regression function by including

; List

in the command. A more compact listing in a scrollable window can be obtained by double clicking the matrix *kernel* in the project window. (See Figure E9.4.)

You may provide a title for the figure with

; Title = ... <the title for the figure> ...

If your sample size is 5000 or less and you have not specified the number of points to plot or the range in which to plot, then **NPREG** will have used the actual data to generate the abscissas for the function. In this case, the fitted function will correspond to the actual data, and you can keep the function values as predictions for the corresponding values of the Lhs variable. Use

; Keep = name to retain function values as predictions
; Res = name to retain (actual – function value) as a set of residuals

The full set of results from **NPREG** would appear like the following:

```
+----------------------------------------+
| Nonparametric Regression for LOGG      |

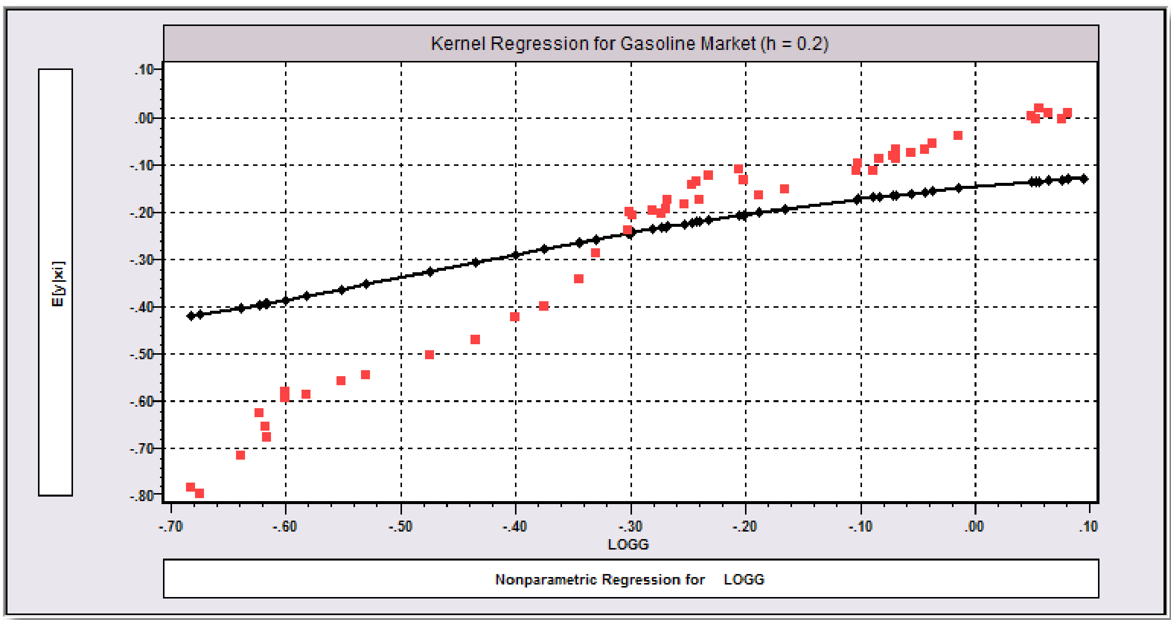

Figure E9.5 Kernel Regression

E9.3 The Least Absolute Deviations Estimator

The basic command for the least absolute deviations estimator is

REGRESS ; Lhs = dependent variable ; Rhs = list of regressors
; Alg = LAD $

The least squares estimator is robust to many variations in the specification. For consistency, it requires only that the data be 'well behaved' and that the conditional mean function, $E[y|\mathbf{x}]$ be linear in $\mathbf{x}$, $\boldsymbol{\beta}'\mathbf{x}$. Still, some researchers have criticized the estimator for the fact that it may be unduly influenced by outlying observations in small samples. The least absolute deviations (LAD) estimator has been advocated (see, e.g., Koenker and Bassett (1982) for discussion) as a preferable alternative. (LAD is a special case of the quantile regression estimator discussed in the next section. The LAD estimator corresponds to the median regression estimator.)

The LAD estimator can be obtained by specifying the regression as usual, and adding

; Alg = LAD

to the **REGRESS** command. The estimator is computed by solving the linear programming problem,

$$\text{Min (wrt } \boldsymbol{\beta}) \ \sum_{i=1}^{n} \left| y_i - \boldsymbol{\beta}'\mathrm{x}_i \right|$$

There is no definitive result for the asymptotic covariance matrix for the LAD estimator. Koenker and Bassett (1982) provide a candidate which may or may not prove useful. Their estimator is

$$\text{Asy.Var}[\mathbf{b}_{LAD}] = (\mathbf{X}'\mathbf{X})^{-1}\, \mathbf{X}'\mathbf{W}^2\mathbf{X}\, (\mathbf{X}'\mathbf{X})^{-1}$$

where $\mathbf{W}$ = Diag[.5 / $f(0)$] and $f(0)$ is the true density of the disturbances evaluated at zero. This requires knowledge of the true density, which is unspecified here. However, one could use the kernel estimator described above to estimate it. Once the set of residuals is in hand, one could use the estimator

$$\hat{f}(0) = \frac{1}{n}\sum_{i=1}^{n} \frac{1}{h} K\left[\frac{(y_i - \mathbf{x}_i'\mathbf{b}_{LAD})}{h}\right] = \frac{1}{n}\sum_{i=1}^{n} \frac{1}{h} K\left[\frac{e_{i,LAD})}{h}\right]$$

One useful special case would be that of the normal distribution. If the disturbances are distributed normally with zero mean and constant variance σ^2, then the result specializes to

$$\text{Asy.Var}[\mathbf{b}_{LAD}|\text{normal}] = \frac{\pi}{2}\sigma^2(\mathbf{X}'\mathbf{X})^{-1},$$

which is a simple multiple of the result for least squares. It would also be simple to compute. (Of course, if the disturbances are known to be normal, we should be using least squares.) We might consider two approaches in this case,

$$\text{Est.Asy.Var}[\mathbf{b}_{LAD}|\text{normal}] = \frac{\pi}{2}\frac{\mathbf{e}'\mathbf{e}}{n}(\mathbf{X}'\mathbf{X})^{-1}$$

or, allowing for possible heteroscedasticity and using White's robust estimator,

$$\text{Est.Asy.Var}[\mathbf{b}_{LAD}|\text{normal}] \;=\; \frac{\pi}{2}\;(\mathbf{X}'\mathbf{X})^{-1} \times \sum\nolimits_{t=1}^{T} e_t^2 \mathbf{x}_t \mathbf{x}_t{}' \times (\mathbf{X}'\mathbf{X})^{-1.}$$

Both of these are based on the normal distribution, which rather defeats the purpose, since one intent of the estimator is to relax distributional assumptions. An alternative approach which moves in this direction is to use a bootstrap estimator. The estimator would be

$$\text{Est.Asy.Var}[\mathbf{b}_{LAD}] \;=\; \frac{1}{R}\sum\nolimits_{r=1}^{R}\left(\mathbf{b}_{LAD,r} - \mathbf{b}_{LAD}\right)\left(\mathbf{b}_{LAD,r} - \mathbf{b}_{LAD}\right)'$$

where R is the number of repetitions, $\mathbf{b}_{LAD,r}$ is the LAD estimator obtained at the rth repetition, and $\mathbf{b}_{LAD}$ is the original LAD estimate. Each repetition is computed using a random sample of n observations, drawn with replacement, from the original sample. To obtain this estimator, add

; Nbt = ... value for *R* ...

to the **REGRESS** command.

If you do not specify bootstrap samples, no estimate of the asymptotic covariance matrix is computed. As shown below, the estimators based on the normal distribution are very simple to compute. The following data limitations are imposed on the LAD estimator:

- Number of observations up to 5,000
- Number of coefficients including the constant term, up to 15

(Both of these restrictions can be relaxed by using the **QREG** command described in the next section.)

In the following application, the LAD estimator is computed with 50 bootstrap replications using the gasoline market data. The three estimators of the asymptotic covariance matrix are computed. At the end of the results, the ordinary least squares estimator is computed, and its sum of absolute deviations is computed to compare to the LAD estimator. (Some of the output is omitted, including the initial table of statistics for the OLS estimator.)

To define the data matrix, use

```
NAMELIST    ; x = one,logpg,loginc,logpnc,logpuc,logppt $
```

This is the LAD estimator with bootstraps:

```
REGRESS     ; Lhs = logg ; Rhs = x
            ; Res = e
            ; Alg = LAD
            ; Nbt = 50 $
```

The covariance matrices are based on the normal distribution. V2 is the White estimator.

```
CREATE      ; abslad = Abs(e) $
MATRIX      ; v1 = {pi/2 * e’e/n} * <x’x>
            ; v2 = {pi/2} * <x’x> * Bhhh(x,e) * <x’x>
            ; Stat(b,v1,x)
            ; Stat(b,v2,x) $
```

Compare the sums of absolute deviations and sum of squares to OLS.

```
CALC        ; sumlad = Sum(abslad)
            ; sumlad2 = e'e $
```

Compute the ordinary least squares regression.

```
REGRESS     ; Lhs = logg ; Rhs = x
            ; Res = e $
CREATE      ; absols = Abs(e) $
```

Compare the residual sums and sums of squares for the two estimators.

```
CALC        ; List
            ; sumols = Sum(absols)
            ; sumlad
            ; sumsqdev
            ; sumlad2 $
```

```

E9.4 Quantile Regressions

The command for the quantile regression estimator is

QREG ; Lhs = dependent variable ; Rhs = list of regressors
; Qnt = desired quantile (0.0+ to 1.0-) $

The quantile regression estimator fits a model of the form

$$Q(y_i|\mathbf{x}_i,\theta) = \boldsymbol{\beta}'\mathbf{x}_i,\ 0 < \theta < 1,$$

where $Q(y_i|\mathbf{x}_i,\theta)$ is the θth quantile of the distribution of $y_i|\mathbf{x}_i$. The default value is $\theta = .5$, which implies the median (and will replicate the LAD estimator of the previous section). The estimator is the linear programming method – a discussion may be found in the various papers on Roger Koenker's (University of Illinois) home page.

$$\arg\min_{\beta} \sum_i \rho_\theta\left(y_i - \sum\nolimits_k \beta_k x_{ik}\right)$$

$$\rho_\theta(u) = \begin{cases} u\theta & u \geq 0 \\ u(1-\theta) & \text{else} \end{cases}$$

Further discussion of the estimation method used here and useful computer code (which was modified for our implementation) may be found in Koenker and D'Orey (1987).

The command for requesting the quantile regression estimator is

QREQ ; Lhs = dependent variable
; Rhs = independent variables $

With no other specifications, this sets $\theta = .5$, and estimates the model by median regression, which is least absolute deviations. (The usual limits on model size – about 150 parameters – millions of observations, apply. But, if you have a huge sample, chances are this is not the estimator you should be using.) You can set a specific quantile with

; Quantile = the desired value of θ

(In previous versions of *LIMDEP*, **; Quantile** would be replaced with **; Qnt**. You may still use the earlier syntax.) You may specify several quantile regressions in the same command with

; Quantile = the set of values.

In the example below, we use **; Quantile = .3,.5,.7**. Standard errors are computed using bootstrapping as described in the previous section. You may request the number of bootstrap replications with

; Nbt = desired number

Other standard options for the linear model are available, including **; Res = name** to keep the residuals, **; Keep = name** for fitted values, and so on. Hypothesis testing about the coefficients must be done with Wald statistics using matrices *b* and *varb* after estimation.

In the example below, we continue our examination of the U.S. gasoline market from 1953 to 2004. The model specification is the same as that in the previous section. The quantile regression is fit for the .3, .5, .7 quantiles – this is a typical form of application.

```

PLOT ; Lhs = loginc ; Rhs = loggf2,loggf5,loggf8 ; Fill ; Grid
; Title = Predictions from Quantile Regressions
; Vaxis = Predicted Log Consumption $

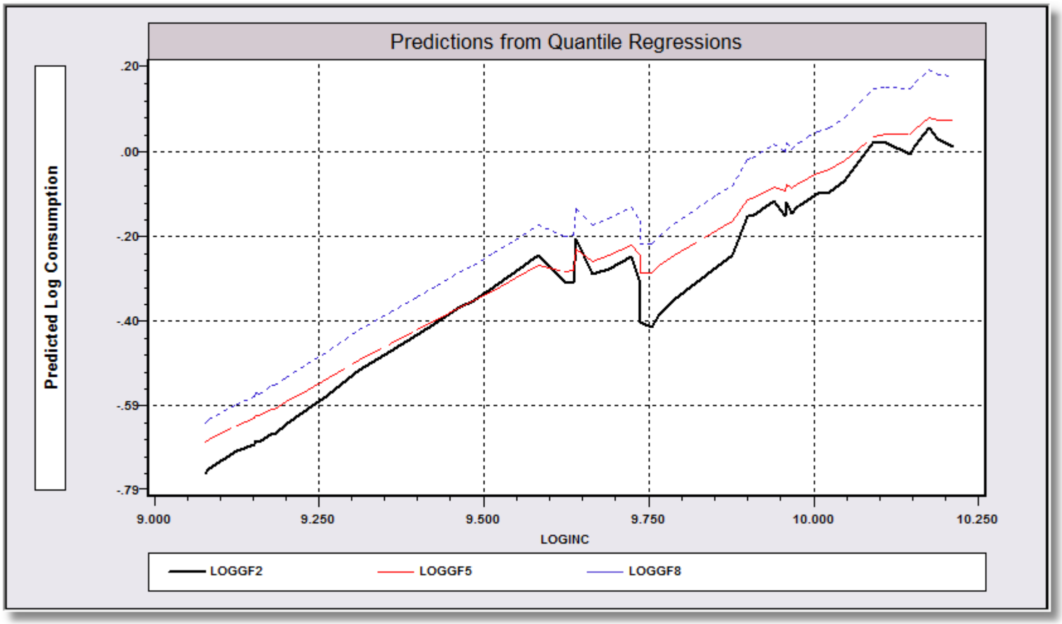

Figure E9.6 Quantile Regressions

E9.5 LOWESS

LOWESS (Locally Weighted Regression and Scatterplot Smoothing) is a nonparametric smoothing technique for examining the relationship between two variables graphically. For the LOWESS regression of a *y* on a single *x*, the technique provides a graphical device for examining the relationship. For example, continuing the gasoline market application, the following is the default results for LOWESS regression of log of consumption on log of income:

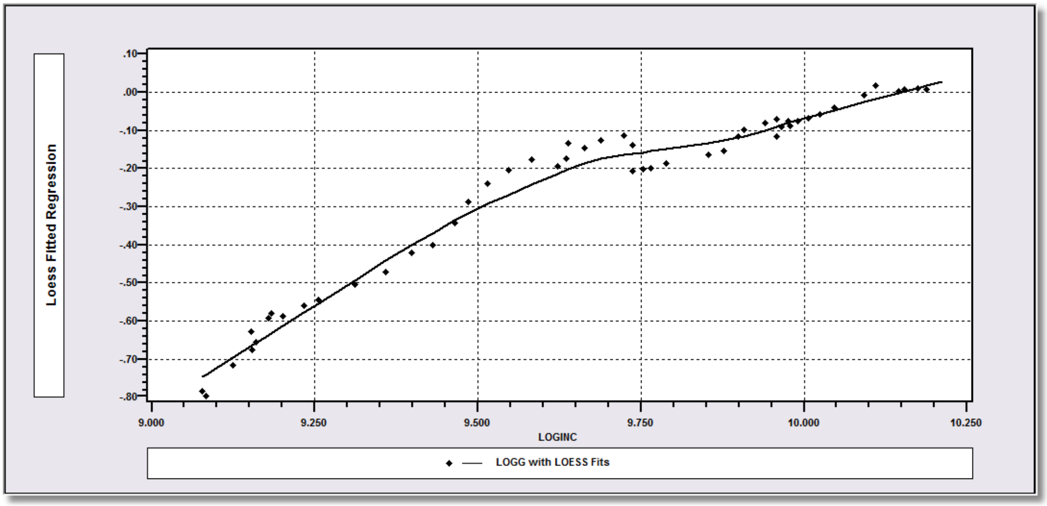

Figure E9.7 LOWESS Smoothed Fit

The technique is also used for a multiple regression, in which case, it produces a 'local' estimate of the parameter vector at each observation, using kernel methods. For the regression of *logg* on (*one*,*logpg*,*loginc*), least squares produces the following:

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=LOGG     Mean                    =        -.25713
             Standard deviation      =         .23849
             No. of observations     =             52  Degrees of freedom
Regression   Sum of Squares          =        2.72390            2
Residual     Sum of Squares          =        .176898           49
Total        Sum of Squares          =        2.90080           51
             Standard error of e     =         .06008

Figure E9.8 Matrix Result from LOWESS

E9.5.1 Graphical Smoothing with LOWESS

The command for describing a single variable is

LOWESS ; Lhs = dependent variable
; Rhs = independent variable $

The optional specifications are

; Alg = linear, quadratic or cubic

(see the technical details below),

; Bandwidth = the value

and **; Keep = name** to retain predictions
; Res = name to retain residuals

The bandwidth is used to compute the kernel based estimator. You can analyze up to five variables simultaneously by including them as a set of Lhs variables. Figure E9.9 shows the relationship of three transport related price indices to the price of gasoline

LOWESS ; Lhs = pnc,puc,ppt ; Rhs = gasp $

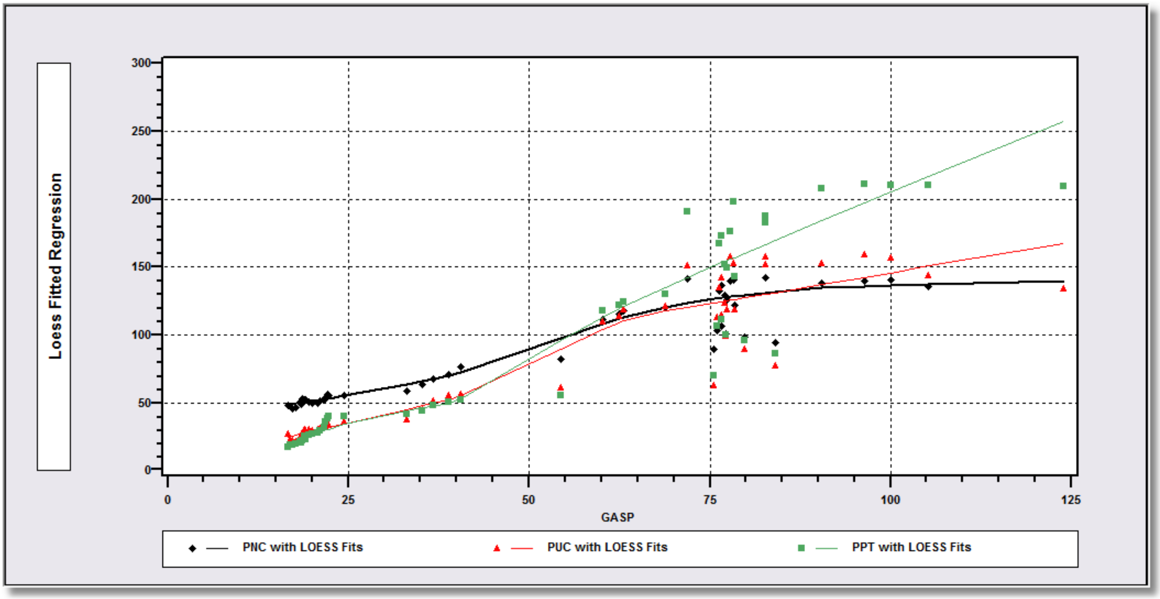

Figure E9.9 LOWESS Fits

The predictions and residuals are not computed when there is more than one Lhs variable.

The bandwidth can be specified as a single value or as a sequence of values using

; Bandwidth = lowest (increment) highest

For example, the analysis below searches for the best fit using the nine values in .1(.1).9. The best fit is found with the lowest value. (That is to be expected). A lower bandwidth, all else equal, will force the kernel estimator to track the data better.)

```
Grid search over bandwidth for lowest sum of squares
Bandwidth =  .10000, LOWESS sum of squares =   .102748E-01
Bandwidth =  .20000, LOWESS sum of squares =   .156447E-01
Bandwidth =  .30000, LOWESS sum of squares =   .309022E-01
Bandwidth =  .40000, LOWESS sum of squares =   .441540E-01
Bandwidth =  .50000, LOWESS sum of squares =   .542459E-01
Bandwidth =  .60000, LOWESS sum of squares =   .615275E-01
Bandwidth =  .70000, LOWESS sum of squares =   .747685E-01
Bandwidth =  .80000, LOWESS sum of squares =   .916489E-01
Bandwidth =  .90000, LOWESS sum of squares =   .125457
```

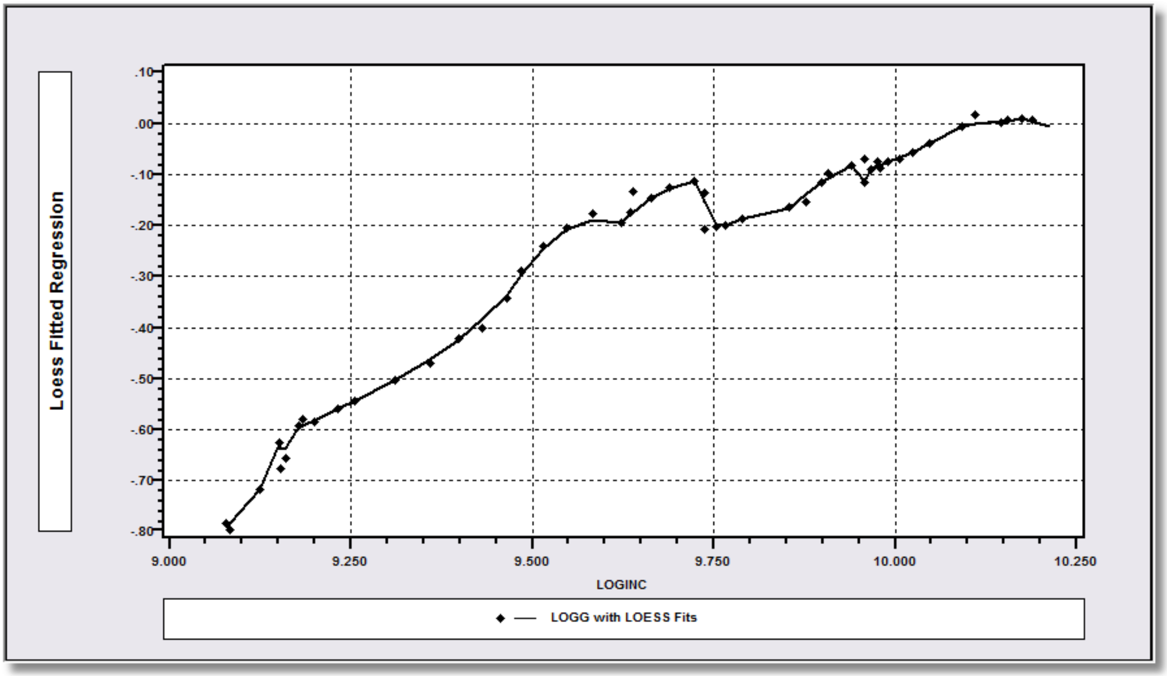

Figure E9.10 Best LOWESS Fit

E9.5.2 Local Multiple Regression

The command for local multiple regression is

LOWESS ; Lhs = dependent variable
; Rhs = list of more than one independent variables $

The options for this procedure are

; Bandwidth = value or lowest (increment) highest

and **; Keep = name** to retain predictions
; Res = name to retain residuals

No graphical output is produced. Results consist of the brief tabular summary of the computation and the matrix *loclbeta* which contains the $n \times K$ matrix of local derivatives of the function relating the dependent variable to the regressors.

We continue (conclude) the gasoline market application with

LOWESS ; Lhs = logg
; Rhs = one,loginc,logpg,logpnc,logpuc,logppt
; Bandwidth=.1(.1).9 $

```
Grid search over bandwidth for lowest sum of squares

E9.5.3 Technical Details for LOWESS Computations

The calculations for LOWESS are presented in Cleveland (1979). The computations differ slightly for the single variable case in Section E9.5.1 (Case 1) and the multiple regressor case in Section E9.5.2 (Case 2). The flow of computations is as follows:

1. For each Lhs variable, the following iterations are computed:

   A. A set of weights, Δ_i is initialized at 1.0

   For each observation i, the following are assembled:
   For each observation j, $D(j|i)$ = the distance between x_i and x_j.
   This is either $D(j|i) = |x_i - x_j|$ for case 1 or $[(\mathbf{x}_i - \mathbf{x}_j)'(\mathbf{x}_i - \mathbf{x}_j)]^{1/2}$ for case 2.

   h_i = the distance to the nearest neighbor to $\mathbf{x}_i$.
   The bandwidth is used to define the width of the interval for this nearest neighbor calculation.
   For each observation j, $U(j|i) = D(j|i)/h_i$.
   Tricube weights $W(j|i) = [1 - |U(j|i)|^3]^3 \times \Delta_i$.

   B. We now compute the weighted regression of y on either $(1,x,x^2,x^3)$ in Case 1, or on $\mathbf{x}$ in Case 2, with weights $W(j|i)$. The cubic regression is the default in Case 1. You may specify the linear or quadratic regression with **; Alg = linear** or **; Alg = quadratic**. This produces coefficients $\mathbf{b}(i)$. We store the prediction, $\hat{y}_i$ and residual $e_i = y_i - \hat{y}_i$. For case 2, we store $\mathbf{b}(i)$ in row i of *loclbeta*.

   C. Update Δ_i. Let $v_i = |y_i - \hat{y}_i|$. M_v = the median value of v_i then $U_i = e_i/(6M_v)$. Δ_i is replaced with zero or $(1 - U_i^2)^2$ if $|U_i| < 1$. We return to Step A with the updated Δ_i. Cleveland recommends iterating between Steps (A,B) and C. We do a single iteration, then collect the results.

2. For case 1, the result of the computations is a plot of each $\hat{y}_i$ and y_i against x_i. For multiple Lhs variables, the plots are produced in the same figure.

When more than one bandwidth is specified, the entire procedure is computed (silently) for each value, then the results are presented for the bandwidth that results in the lowest sum of squared LOWESS residuals.

E10: Heteroscedasticity and GARCH Models

E10.1 Introduction

This chapter will detail the methods of testing for and estimating with heteroscedasticity in the linear regression model. The underlying model is

$$y_i = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,$$

$$E[\varepsilon_i \mid \mathbf{x}_i] = 0,$$

$$\text{Var}[\varepsilon_i \mid \mathbf{x}_i] = \sigma^2\omega_i,\ i = 1,\ldots,n.$$

E10.2 Correcting the OLS Covariance Matrix

Heteroscedasticity in linear regression is modeled with different forms of

```
REGRESS    ; Lhs = dependent variable
           ; Rhs = independent variables
           ; Heteroscedasticity ; other specifications
           ; Wts = weighting variable $
```

Under the assumptions above, the ordinary least squares (OLS) estimator of $\boldsymbol{\beta}$,

$$\mathbf{b} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}$$

is consistent, and has covariance matrix

$$\text{Var}[\mathbf{b}] = \sigma^2(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{\Omega}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1} = \boldsymbol{\Sigma}.$$

where $\boldsymbol{\Omega} = \text{diag}[\omega_1,\ldots,\omega_n]$. The usual estimator,

$$\mathbf{V} = s^2(\mathbf{X}'\mathbf{X})^{-1}$$

may not be consistent if the variables in $\mathbf{x}\otimes\mathbf{x}$ are correlated with the observation specific variances, ω_i. (See Greene (2011).) White's (1980) consistent estimator of $\boldsymbol{\Sigma}$ is

$$\mathbf{S}_{\text{WHITE}} = \text{Est.Var}[\mathbf{b}] = (\mathbf{X}'\mathbf{X})^{-1} \times \sum_{i=1}^{n} e_i^2 \mathbf{x}_i\mathbf{x}_i' \times (\mathbf{X}'\mathbf{X})^{-1}.$$

For the underlying theory of this estimator, see White (1980) or Greene (2011). *LIMDEP* will produce this estimator as part of the **REGRESS** procedure if the command includes

; Heteroscedasticity (or, just **; Het**)

The usual set of OLS results is given, but with the revised, robust covariance matrix. (Note, this does not change the coefficient estimates. Also, it does not necessarily lead to larger (or smaller) estimated standard errors.)

Davidson and MacKinnon (1993) and Horn, Horn and Duncan (1975) have recommended three alternative forms of the White estimator which appear to perform well in small to moderate sized samples. Use

; Het ; Hc1 to use $\text{Est.Var}[\mathbf{b}] = (\mathbf{X}'\mathbf{X})^{-1} \times \dfrac{n}{n-K} \sum_{i=1}^{n} e_i^2 \mathbf{x}_i \mathbf{x}_i' \times (\mathbf{X}'\mathbf{X})^{-1}$

; Het ; Hc2 to use $\text{Est.Var}[\mathbf{b}] = (\mathbf{X}'\mathbf{X})^{-1} \times \sum_{i=1}^{n} \dfrac{e_i^2}{\left(1-\mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i\right)} \mathbf{x}_i \mathbf{x}_i' \times (\mathbf{X}'\mathbf{X})^{-1}$

; Het ; Hc3 to use $\text{Est.Var}[\mathbf{b}] = (\mathbf{X}'\mathbf{X})^{-1} \times \sum_{i=1}^{n} \dfrac{e_i^2}{\left(1-\mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i\right)^2} \mathbf{x}_i \mathbf{x}_i' \times (\mathbf{X}'\mathbf{X})^{-1}$

(They recommend HC3 as their preferred estimator.)

MacKinnon and White (1985) have recommended a modification of HC3. Define

$$\mathbf{x}_i^* = \frac{e_i}{\left(1-\mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i\right)} \times \mathbf{x}_i \quad \text{and} \quad \overline{\mathbf{x}}^* = \frac{1}{n}\sum_{i=1}^{n} \mathbf{x}_i^*$$

Thus, each row (observation) of **X** is multiplied by e_i / [1 - $\mathbf{x}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_i$]. The estimator is

$$\text{Est.Var}[\mathbf{b}] = (\mathbf{X}'\mathbf{X})^{-1} \times \frac{n-1}{n}\left[\mathbf{X}^{*\prime}\mathbf{X}^* - n\overline{\mathbf{x}}^*\overline{\mathbf{x}}^{*\prime}\right] \times (\mathbf{X}'\mathbf{X})^{-1}$$

This estimator is not built in, but it can be computed as follows:

```
NAMELIST   ; x = ... the list of variables, including one $
REGRESS    ; Lhs = ... ; Rhs = x ; Res = e $
MAXRIX     ; xxi = <x'x> $
CREATE     ; u = e / (1 - Qfr(x,xxi)) $
MATRIX     ; v = Bhhh(x,u) - 1/n * x'u * u'x
           ; v = {(n-1)/n} * xxi * v * xxi ; Stat(b,v,x) $
```

All results saved by these procedures are the same as usual with **REGRESS** (see Section E7.2) except:

- v*arb* is the revised estimate,
- The log likelihood function, *logl* should be ignored.

The following data are from an exercise on page 349 of Gujarati (1988). The original source is *The Economic Report of the President*, 1985. Observations pertain to the manufacturing sector of the U.S. economy.

Year	Inventory	Sales	Year	Inventory	Sales
1950	31.1	18.6	1967	84.7	46.5
1951	39.3	21.7	1968	90.6	50.2
1952	41.1	22.5	1969	98.2	53.5
1953	43.9	24.8	1970	101.6	52.8
1954	41.6	23.3	1971	102.6	55.9
1955	45.1	16.5	1972	108.2	63.0
1956	50.6	27.7	1973	124.6	72.9
1957	51.9	28.7	1974	157.8	84.8
1958	50.2	27.2	1975	159.9	86.4
1959	52.9	30.3	1976	175.2	98.8
1960	53.8	30.9	1977	189.2	113.2
1961	54.9	30.9	1978	210.4	126.9
1962	58.2	33.4	1979	240.9	143.9
1963	60.0	35.0	1980	264.1	154.4
1964	63.4	37.3	1981	282.1	168.1
1965	68.2	41.0	1982	264.6	159.2
1966	78.0	44.9	1983	260.4	170.6

Shown below are the results of applying the procedures listed above to the model

$$Inventory = \beta_1 + \beta_2 Sales + \beta_3 Sales^2 + \varepsilon.$$

The consistently larger diagonal elements of the robust estimators suggest that the OLS computations might be somewhat optimistic.

E10.3 Estimating Models with Heteroscedasticity

There are many procedures for estimating heteroscedastic regression models. We consider two that use weighted least squares here, then more elaborate models in the next two sections.

E10.3.1 Weighted Least Squares

For the model in which ω_i is either known or has been estimated already, the weighted least squares estimator is requested with

REGRESS ; Lhs = ... ; Rhs = ... ; Wts = weighting variable $

In computing weighted estimators, we use the formulas:

n	=	the current sample size, after skipping any missing observations,
w_i	=	$(n/\Sigma_i W_i)W_i \quad = \quad Scale \times W_i$ (note that $\Sigma_i w_i = n$),
$\mathbf{b}_w$	=	$[\Sigma_i w_i \mathbf{x}_i \mathbf{x}_i']^{-1}[\Sigma_i w_i \mathbf{x}_i y_i]$,
s_w^2	=	$\Sigma_i w_i(y_i - \mathbf{x}_i'\mathbf{b}_w)^2$,
Est.Var.$[\mathbf{b}_w]$	=	$[s_w^2/(n\text{-}K)][\Sigma_i w_i \mathbf{x}_i \mathbf{x}_i']^{-1}$,

where W_i is your weighting variable. Your original weighting variable is not modified (scaled) during this computation. The scale factor is computed separately and carried through the computations.

NOTE: Apart from the scaling, your weighting variable is the reciprocal of the *individual specific variance*, not the standard deviation, and not the reciprocal of the standard deviation. This construction is used to maintain consistency with the other models in *LIMDEP*.

For example, consider the common case, $\text{Var}[\varepsilon_i] = \sigma^2 z_i^2$. For this case, you would use

```
CREATE      ; wt = 1 / z ^ 2 $
REGRESS     ; Lhs = ... ; Rhs = ... ; Wts = wt $
```

Weighted least squares is requested on the Main page of the regression command builder as shown in Figure E10.1.

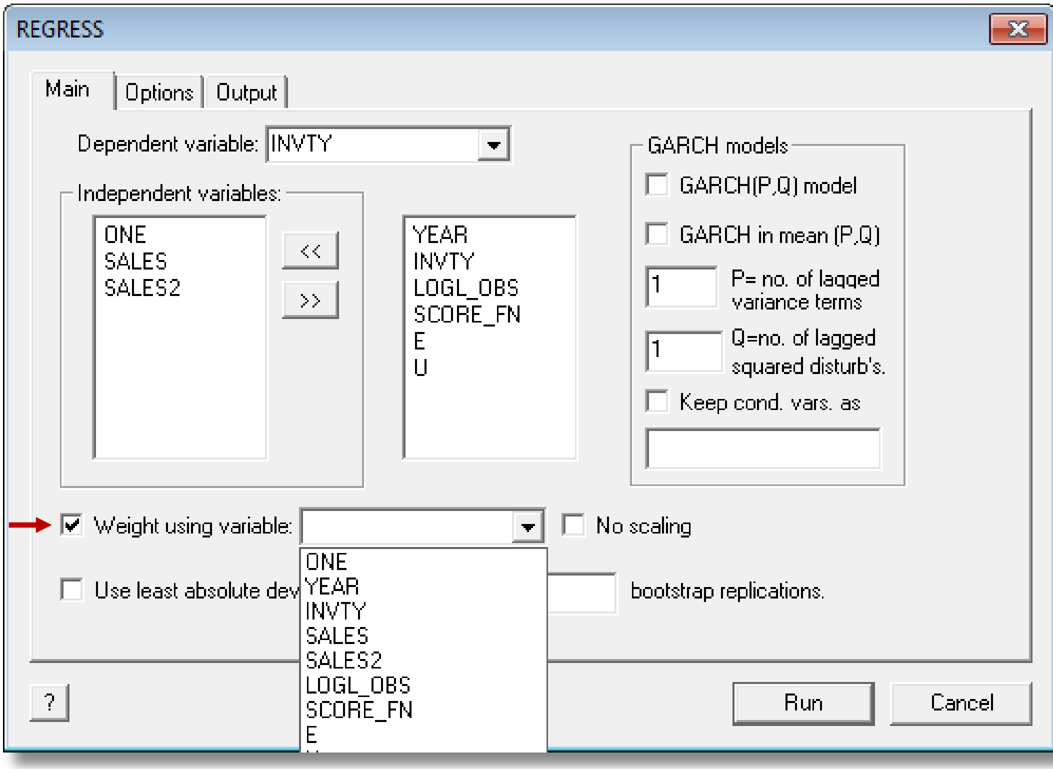

Figure E10.1 Command Builder for Weighted Least Squares

E10.3.2 Variance Proportional to the Square of the Mean

The case in which the variance is proportional to the square of the mean is simple to handle with linear regression. The model is

$$y_i = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, \ \mathrm{Var}[\varepsilon_i] = \sigma^2[\boldsymbol{\beta}'\mathbf{x}_i]^2.$$

This can be estimated iteratively as a weighted regression as follows:

```
REGRESS     ; Lhs = y ; Rhs = x ; Keep = bx $
CREATE      ; w = 1 / bx ^ 2 $
REGRESS     ; Lhs = y ; Rhs = x ; Wts = w ; Keep = bx $
```

The second and third steps can be repeated until satisfactory convergence is achieved. A convenient approach would be to put the three lines in a procedure, then use

```
EXECUTE     ; Query $
```

E10.3.3 Testing for Heteroscedasticity

There are several different tests for heteroscedasticity that one might use. The tests due to Glejser (1965) involve regressions of squares, logs of squares or absolute values, or the absolute values themselves, of least squares residuals on a set of regressors. For present purposes, this calls for no new techniques. The special aspect of the procedure concerns using the appropriate covariance matrix to calculate the statistic. Consider some examples:

1. variance linear in **z** $\quad \text{Var}[\varepsilon_i] = \sigma^2[1 + \boldsymbol{\alpha}'\mathbf{z}_i]$,
2. standard deviation linear in **z** $\quad \text{Var}[\varepsilon_i] = \sigma^2[1 + \boldsymbol{\alpha}'\mathbf{z}_i]^2$,
3. log of variance linear in **z** $\quad \text{Var}[\varepsilon_i] = \sigma^2\exp[\boldsymbol{\alpha}'\mathbf{z}_i]$.

For these three cases, we would carry out the test by regression of the squares, absolute values, and logs of absolute values of the residuals on $\mathbf{z}_i$. A joint test of the significance of the coefficients constitutes a test of homoscedasticity. The second step regression is necessarily heteroscedastic, so we use the White estimator to compute the asymptotic covariance matrix. The following can be used: The first step is to obtain the coefficients that are in the variance functions.

```
NAMELIST   ; x = ...
           ; z = one, ... $
REGRESS    ; Lhs = y ; Rhs = x ; Res = e $
```

Use **f = e^2**, **f = abs(e)** and **f = log(e^2)** for the three functions above.

```
CREATE     ; f = ... the appropriate function of e $
REGRESS    ; Lhs = f ; Rhs = z,one ; Het $
```

Now, in each case, carry out a test of the joint hypothesis that the coefficient vector not including the constant term is zero.

```
CALC       ; m = Col(z) $
MATRIX     ; a = b(1:m) ; va = varb(1:m,1:m) ; wald = a’ <va>a $
CALC       ; Ctb(wald,m) ; 1 - Chi(wald,m) $
```

The Goldfeld-Quandt test is simple to carry out when the heteroscedasticity can be identified as a monotonic function of a single variable, z. If

$$\text{Var}[\varepsilon_i] = \sigma^2[1 + f(z_i)],$$

then, the test statistic is

$$F[\, n_1\text{-}K \,,\, n_2\text{-}K \,] = [\mathbf{e}_1'\mathbf{e}_1/(n_1\text{-}K)] \;/\; [\mathbf{e}_2'\mathbf{e}_2/(n_2\text{-}K)],$$

where group '1' is associated with high values of z_i and group '2' is associated with low values of z_i. The optimal way to split the sample, including how many observations to discard in the middle is unclear. (See Greene (2011).) With normally distributed disturbances, the statistic has an F distribution with n_1-K and n_2-K degrees of freedom. If the calculated value comes out less than one, for convenience in using the tables, we can take the reciprocal and reverse the degrees of freedom.

To carry out the test, one need only decide what values to use for the cutoffs for z_i, then

```
NAMELIST   ; x = ... $
REGRESS    ; Lhs = ... ; Rhs = x ; Res = e $
CREATE     ; d1 = zi < lower value ; e1 = d1*e
           ; d2 = zi > upper value ; e2 = d2*e $
CALC       ; df1 = d1'd1-kreg ; dfn = df1
           ; df2 = d2'd2-kreg ; dfd = df2
           ; f = (e1'e1/df1) / (e2'e2/df2)
           ; If[f < 1] ; f = 1/f ; dfn = df2 ; dfd = df1 $
CALC       ; List ; f ; 1 - Fds(f,dfn,dfd)
           ; Ftb(.95,df1,df2) $
```

For the data used in the earlier example, we used *sales* as *z* and split the sample at *sales* = 50. (The upper and lower values are 50 in the preceding routine.) The results are shown below:

```
CREATE     ; zi = sales $
REGRESS    ; Lhs = inventor ; Rhs = x ; Res = e $
...
CALC       ; List ; f ; 1 - Fds(f,dfn,dfd)
           ; Ftb(.95,df1,df2) $
```

```
F       =  .23324659539519980D+01
Result  =  .59576135098001640D-01
Result  =  .25331099831399990D+01
```

Since the sample statistic, 2.33, is less than the critical value, 2.53, the hypothesis of homoscedasticity based on the high and low values of *sales* is not rejected.

The Breusch and Pagan (1980) Lagrange multiplier test is also a simple calculation. The model is assumed to be of the form:

$$\text{Var}[\varepsilon_i] = \sigma^2 h(1 + \boldsymbol{\alpha}'\mathbf{z}_i).$$

Different normalizations involving the explicit σ^2 parameter produce the identical result. The extra parameter is actually superfluous since if $\boldsymbol{\alpha} = \mathbf{0}$, then $h(1)$ is the constant variance. As stated above, we would be assuming that $h(1) = 1$. The LM statistic is then simply one half the explained sum of squares in the regression of

$$u_i = e_i /(\mathbf{e}'\mathbf{e}/n) - 1$$

on $\mathbf{z}_i$. This statistic is always reported for the *x*s in the regression when you use the **; Het** option on the **REGRESS** command. It is also reported for the specified *z* vector when you use the **HREG** command described below. The second regression in Section E10.2 above produces

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=INVTY    Mean                    =     111.74412
             Standard deviation      =      78.44813
             Number of observs.      =            34
Model size   Parameters              =             3
             Degrees of freedom      =            31
Residuals    Sum of squares          =       1080.51
             Standard error of e     =       5.90383
Fit          R-squared               =        .99468
             Adjusted R-squared      =        .99434
Model test   F[  2,    31] (prob) =  2897.8(.0000)
White heteroscedasticity robust covariance matrix.
Br./Pagan LM Chi-sq [  2]  (prob) =  15.30 (.0005)
--------+--------------------------------------------------------------------
        |                Standard            Prob.      95% Confidence

Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

For the more general case, the built in procedure is

REGRESS ; … ; BPT = list of variables $

For example, if we replace **; Het** with **; BPT** = sales in the preceding regression, we obtain

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=INVTY    Mean                    =     111.74412
             Standard deviation      =      78.44813
             No. of observations     =            34  Degrees of freedom
Regression   Sum of Squares          =       202005.             2
Residual     Sum of Squares          =       1080.51            31
Total        Sum of Squares          =       203086.            33
             Standard error of e     =       5.90383
Fit          R-squared               =        .99468  R-bar squared =   .99434
Model test   F[  2,    31]           =    2897.77082  Prob F > F*   =   .00000
Diagnostic   Log likelihood          =    -107.04403  Akaike I.C.   =  3.63530
             Restricted (b=0)        =    -196.05929  Bayes  I.C.   =  3.76998
             Chi squared [  2]       =     178.03052  Prob C2 > C2* =   .00000
B-P test     Chi squared [  1]       =       2.86393  Prob C2 > C2* =   .09059
--------+--------------------------------------------------------------------
```

(The regression coefficients are the same. The standard errors differ because this second command uses the original estimator, $s^2(\mathbf{X}'\mathbf{X})^{-1}$ while the first one uses the White estimator. Using **; BPT** disables the **; Het** option.)

You can replicate the computations for the Breusch and Pagan test using the programming language. For the general test, use

```
NAMELIST    ; z = ... definition -- include one $
REGRESS     ; Lhs = y ; Rhs = ... ; Res = e $
CREATE      ; u = e*e / (sumsqdev/n) - 1 $
CALC        ; List ; lmbp =  .5 * Xss(z,u)     ? LM statistic
            ; 1 - Chi(lmbp, (Col(z)))          ? p value
            ; Ctb(.95, (Col(z)))               $ critical value from table
```

A variant due to Koenker and Bassett (1982) which allows for nonnormality is even simpler. Their 'studentized' version produces the LM statistic as nR^2 in the regression of the squared residuals on z and a constant term. Thus, this statistic is obtained with

```
REGRESS     ; Lhs  = y ; Rhs = ... ; Res = e $
CREATE      ; u = e*e  $
CALC        ; List ; lmkb =  n * Rsq(z,one,u)
            ; 1 - Chi(lmbp, (Col(z)))
            ; Ctb(.95, (Col(z))) $
```

E10.4 Multiplicative Heteroscedasticity

In this section, we modify the regression model for a specific type of heteroscedasticity,

$$\text{Var}[\varepsilon_i] = \exp(\gamma_0 + \boldsymbol{\gamma}_1'\mathbf{z}_{i1}) = \exp(\boldsymbol{\gamma}'\mathbf{z}_i).$$

(This model is developed in Harvey (1976).) We assume that the set of variables specified as $\mathbf{z}_i$ contains a constant term, so that the variance can be written in the first form when necessary. This is just for convenience. The implication is that

$$\text{Var}[\varepsilon_i] = \sigma^2\exp(\boldsymbol{\gamma}_1'\mathbf{w}_{i1}) \quad \text{and} \quad \gamma_0 = \log\sigma^2.$$

This is a general model which accommodates several kinds of heteroscedasticity. For example, the model

$$\text{Var}[\varepsilon_i] = \sigma^2 z_i^{\gamma}$$

is obtained by defining $\mathbf{z}_i$ to be [1,logz_i]. A model of groupwise heteroscedasticity for a panel of data with G groups, $\text{Var}[\varepsilon_{ig}] = \sigma_i^2$, can be produced by defining $\mathbf{z}_i$ to be a constant term and a set (minus the last one) of group specific dummy variables. By this definition,

$$\sigma_G^2 = \exp(\gamma_0),\ \sigma_i^2 = \exp(\gamma_g),\ g = 1,...,G\text{-}1.$$

The command for estimating a linear regression with this form of heteroscedasticity is

```
HREG        ; Lhs = dependent variable
            ; Rhs = independent variables
            ; Rh2 = variables in z – do not include one in this list  $
```

It is not necessary to include a constant term in *z* since one is included automatically. Results which are saved for later use are:

Matrices:	*b*	=	estimate of $\boldsymbol{\beta}$
	varb	=	estimate of the asymptotic covariance matrix
	gamma	=	estimate of $\boldsymbol{\gamma} = [\sigma,\boldsymbol{\gamma}_1]$, (note, σ, not γ_0; $\sigma = \exp(\gamma_0/2)$)
Scalars:	*ssqrd*	=	$\exp(\gamma_0)$ = estimate of σ^2
	s	=	estimate of σ
	ybar	=	mean of Lhs variable
	sy	=	standard deviation of Lhs variable
	kreg	=	number of *x*s
	nreg	=	number of observations used
	log	=	log likelihood function

Last Model: *b_x...*
b_x... c_sigma c_z... if the command includes **; Par**

Last Function: Conditional mean = $\mathbf{b}'\mathbf{x}$

The full asymptotic covariance matrix for the estimate of $[\boldsymbol{\beta},\boldsymbol{\gamma}]$ is given below. This is a $(K+M)\times(K+M)$ block diagonal matrix. If you include

; Parameters

in the **HREG** command, *b* and *varb* include both parts of the full parameter vector.

NOTE: The first element of the '**C**' part of the saved parameter vector is $\hat{\sigma}$, not $\hat{\gamma}_0$.

The predictions for this model are the same as those for the linear regression model. But, in order to construct the confidence interval for the prediction, *LIMDEP* uses the sample mean of the **z**s, rather than the individual values, when it computes the 'σ^2' part of the forecast variance, which is $\sigma^2 + \mathbf{x}_i'\mathbf{VARB}\mathbf{x}_i$.

The method of scoring is always used for the iterations. This model does not allow you to supply starting values or to control the convergence rules for the iterations. The starting values used are **b** (OLS) for $\boldsymbol{\beta}$, $\exp(1.2704)\times s^2$ for γ_0, and **0** for $\boldsymbol{\gamma}_1$. You can specify the number of iterations with

; Maxit = maximum

NOTE: There is no need to use **; Maxit = 0** to carry out an LM test of $\boldsymbol{\gamma}_1 = \mathbf{0}$. The LM statistic is presented with the standard output in the OLS results.

The convergence rule used is given below with the technical details.

WARNING: This estimator can become unstable particularly with badly scaled data. For example, it blows up in our example below if the full sample is used. It will abort if this occurs.

E10.4.1 Results

HREG produces two sets of estimates. Starting values for the slopes are obtained by ordinary least squares. Consistent starting values for the variance parameters are obtained by regressing the logs of the squares of the least squares residuals on the variables in *z*. A consistent estimate of the unconditional variance is obtained multiplying the constant term in this regression by 1.2704. These OLS estimates of $\boldsymbol{\beta}$ and the starting values for γ_0 and $\boldsymbol{\gamma}_1$ are presented with appropriate covariance matrices. Two statistics for testing the hypothesis of homoscedasticity, Lagrange multiplier and Wald, are also presented with the initial results. Finally, the full set of maximum likelihood results is presented in the standard format.

Further details on this set of computations are given in Section E10.4.5. Two applications are presented below.

E10.4.2 Application 1 – Heteroscedastic Regression

To continue our example, we specify the multiplicative model for our inventory-sales data. One model is

$$\text{Var}[\varepsilon_i] = \sigma^2 Sales^{\gamma}$$

so $$\mathbf{z} = [one, \log(Sales)].$$

As noted earlier, the estimator diverges when the full sample is used. This may be because the variance of the disturbance appears to grow dramatically at the end of the sample.

HREG ; Lhs = invty ; Rhs = one,sales,sales2 ; Rh2 = Log(sales) $

```
HREG:Estimates diverging. Variances vanishing or exploding.
```

With this failure, we respecify the variance function as

$$\text{Var}[\varepsilon_i] = \sigma^2 \exp(\gamma\, Sales)$$

The maximum likelihood estimates are given below after the initial OLS estimates.

```
-----------------------------------------------------------------------------
Ordinary     least squares regression ............
LHS=INVTY    Mean                    =     111.74412

E10.4.3 Application 2 – Groupwise Heteroscedasticity

The Grunfeld data used in several earlier examples lend themselves well to this estimator. (These are Table F10.4 in Greene (2011).The model is

$$I_{it} = \beta_1 + \beta_2 F_{it} + \beta_3 C_{it} + \varepsilon_{it},\ \ \varepsilon_{it} \sim \text{N}[0, \sigma^2\exp(\gamma_i)],\ \gamma_1 = 0.$$

The variance function is constructed by defining four firm specific dummy variables for the last four firms – the first is omitted. Then, the command for the model is

```
IMPORT      ; File = "C:/…/Grunfeld.dat" $
CREATE      ; Expand(firm) = d1,d2,d3,d4,d5,d6,d7,d8,d9,d10 $
NAMELIST    ; firms = d2,d3,d4,d5,d6,d7,d8,d9,d10 $
HREG        ; Lhs = i ; Rhs = one,f,c ; Rh2 = firms $
```

```

The chi squared test in the final results rejects the hypothesis of homoscedasticity. We can extract the firm specific variances from the saved results. Recall, the retained estimates are

Matrix: *gamma* = $[\sigma = \exp(\gamma_0),\ \gamma_1,\ldots,\gamma_M]$

Scalar: *s* = σ

Therefore, to extract the parts, we can use the following:

```
CALC      ; v1 = s*s $
MATRIX    ; gamma1 = gamma(2:10)  ? You would use different subscripts
          ; v = v1*Expn(gamma1)
          ; List ;  v = [v1/v]         $ Stacks variances in a vector

E10.4.4 Restrictions

The **HREG** estimation program does not use *LIMDEP*'s built-in function optimization routines. Therefore, restrictions on the regression parameters ($\boldsymbol{\beta}$) can be tested using the **; Test:...** specification as usual, but not imposed, by using the **; CML:...** specification as with other maximum likelihood estimators. You can estimate this model subject to linear restrictions, however, as follows: For either group of parameters, linear restrictions can be built directly into the index function. For example, to impose $\beta_2+\beta_3=1$, or $\beta_3 = 1 - \beta_2$, create $y - x_3$ to use as the Lhs variable and replace (x_2,x_3) with x_2-x_3 (one variable) on the Rhs. Similar constructions could be used to constrain the elements of $\boldsymbol{\gamma}_1$. (You should not restrict σ^2.) It is also possible to impose fixed value restrictions on $\boldsymbol{\gamma}_1$, but the method of doing so is a bit indirect. Suppose that the variance can be written as

$$\text{Var}[\varepsilon_i] = \sigma^2 \exp(c_0 f_i + \boldsymbol{\gamma}_1{}'\mathbf{w}_i) = \sigma^2 \exp(c_0 f_i) \exp(\boldsymbol{\gamma}_1{}'\mathbf{w}_i)$$

where c_0 is a fixed, known coefficient and f_i is a variable. You can fit the model in this form by treating $1/\exp(c_0 f_i)$ as if it were a weight and this were just a problem in weighted least squares. That is,

```
CREATE    ; wt  =  1 / Exp(c0 * fi)  $
HREG      ; Lhs = ... ; Rhs = ... ; Rh2 = ... ; Wts = wt $
```

The model estimation routine will sort this out internally and treat the variables in the two parts of the variance properly. (Note that this would allow you to impose nonhomogeneous restrictions on the variance parameters. For example, to impose $\gamma_2+\gamma_3=1$, the variance becomes

$$\text{Var}[\varepsilon_i] = \sigma^2 e^{\gamma_2 w_2 + (1-\gamma_2) w_3} = \sigma^2 e^{w_3} e^{\gamma_2 (w_2 - w_3)}$$

so, you would use **wt** = $1/\exp(w_3)$ in the procedure described above.)

E10.4.5 Technical Details on Computation of the HREG Model

The computations for this model are derived in Harvey's (1976) paper. The interested reader is referred to that source for background. Additional analysis appears in Greene (2011). We will sketch the computations here.

Starting values for the slopes are obtained by OLS,

$$\mathbf{b}_0 = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y}.$$

Since Var[ε_i] equals exp($\boldsymbol{\gamma}'\mathbf{z}_i$), an estimate of $\boldsymbol{\gamma}$ is obtained by regressing the logs of the squared residuals on $\mathbf{Z}$:

$$\mathbf{c}_0 = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{u}$$

where $u_i = \log(e_i^2)$.

The constant term in this regression is inconsistent. To make it consistent, it is necessary to add 1.2704. These results are presented in the initial output of least squares results. The corrected covariance estimator,

$$\mathbf{V} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{S}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

is used for the OLS slopes. This is computed using the consistent second round estimates of the variance parameters. The estimate of $\boldsymbol{\gamma}$ is asymptotically uncorrelated with $\mathbf{b}_0$, and its asymptotic covariance matrix is

$$\mathbf{Q} = 4.9348(\mathbf{Z}'\mathbf{Z})^{-1}.$$

This is also presented with the OLS results.

We enter iteration k with $\mathbf{c}_{k-1}$ and $\mathbf{b}_{k-1}$ in hand. Compute weights and residuals

$$v_i = \exp(-\mathbf{c}_{k-1}'\mathbf{z}_i)$$

$$e_i = y_i - \mathbf{b}_{k-1}'\mathbf{x}_i.$$

Then, we regress $f_i = (e_i^2 v_i - 1)$ on $\mathbf{Z}$ (v_i is the estimate of ω_i)

to obtain $\mathbf{d} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{f}$.

Convergence is based on $\mathbf{d}'\mathbf{d}$. If $\mathbf{d}'\mathbf{d} < 10^{-9}$, exit the iteration. If not,

$$\mathbf{b}_k = [\Sigma_i v_i \mathbf{x}_i \mathbf{x}_i']^{-1}[\Sigma_i v_i \mathbf{x}_i y_i] \quad \text{(this is GLS)}$$

and $\mathbf{c}_k = \mathbf{c}_{k-1} + \mathbf{d}$.

At convergence, the asymptotic covariance matrix of $\mathbf{b}_k$ is the inverse matrix above while the asymptotic covariance matrix of $\mathbf{c}_k$ is

$$\text{Asy.Var.}[\mathbf{c}_k] = 2(\mathbf{Z}'\mathbf{Z})^{-1}.$$

The asymptotic covariance matrix of $\mathbf{c}_k$ and $\mathbf{b}_k$ is zero, so the full matrix is block diagonal.

A Program for the Multiplicative Heteroscedasticity Model

The preceding presents a straightforward application of the method of scoring. For the interested reader, we present a *LIMDEP* program which does the same iterations. The routine is specialized for the application above, but only the definitions of **x**, *y*, and **z** need be changed for a different application.

E10.5 ARCH(m) and GARCH(m) Models

Engle's (1982) original model of autoregressive conditional heteroscedasticity, ARCH(1),

$$y_t = \boldsymbol{\beta}'\mathbf{x}_t + \varepsilon_t$$

$$\varepsilon_t = v_t[\sigma_0 + \alpha_1\varepsilon_{t-1}^2]^{1/2}$$

$$v_t \sim N[0,1],$$

has provided a foundation in the literature on volatility in financial markets. The model has since been generalized in many directions. The most straightforward extension is the ARCH(q) model,

$$\text{Var}[\varepsilon_t \mid \varepsilon_{t-1}, ..., \varepsilon_{t-q}] = \sigma_0^2 + \sum_{q=1}^{Q} \alpha_q \varepsilon_{t-q}^2 .$$

An important variation on the ARCH theme is the generalized ARCH model, or GARCH(p,q) model,

$$\text{Var}[\varepsilon_t \mid \varepsilon_{t-1}, ..., \varepsilon_{t-q}] = \sigma_t^2 = \sigma_0^2 + \sum_{s=1}^{q} \alpha_s \varepsilon_{t-s}^2 + \sum_{r=1}^{p} \delta_r \sigma_{t-r}^2$$

The command for estimating a linear regression with ARCH or GARCH disturbances is

```
REGRESS     ; Lhs = dependent variable
            ; Rhs = independent variables
            ; Model = GARCH(p,q)  $
```

Estimation of these models can be done by two step (or iterated) weighted least squares or by (approximate) maximum likelihood. (With this variance specification, the model could not be based on the normal distribution save for some special cases, so the analysis is viewed as approximate. See Bollerslev (1986) and Greene (2011) for discussion.) Maximum likelihood has become the standard approach in recent years. (See Fiorentini, Calzolari, and Panattoni (1996) and McCullough and Renfro (1999) for discussion and analysis.) Finally, an interesting innovation by Engle, Lilien, and Robins (1987) is the ARCH(*m*), which we generalize here to the 'GARCH in mean,' or GARCH(*m*) model in which the variance appears in the conditional mean function:

$$y_t = \boldsymbol{\beta}'\mathbf{x}_t + \lambda\sigma_t^2 + \varepsilon_t$$

$$\mathrm{Var}[\varepsilon_t \mid \varepsilon_{t-1}, \ldots, \varepsilon_{t-q}] = \sigma_t^2 = \sigma_0^2 + \sum_{s=1}^{q} \alpha_s \varepsilon_{t-s}^2 + \sum_{r=1}^{p} \delta_r \sigma_{t-r}^2$$

The ARCH and GARCH models are discussed in Sections E10.5.1 and E10.5.2. The GARCH(*m*) model is discussed in Section E10.5.3. Finally, technical details on estimation are presented in Section E10.5.4.

The GARCH(*p*,*q*) model may be fit by maximum likelihood for any *p* and *q* by using

REGRESS	**; Lhs = ... dependent variable**	
	; Rhs = ... independent variables	(May be just the constant term, *one*)
	; Model = GARCH (p,q) $	(You provide *p* and *q*)

The ARCH model is specified by providing a value of 0 for *p*.

The command builder for this model appears on the Main page for the linear regression model: Model:Linear Models/Regression.

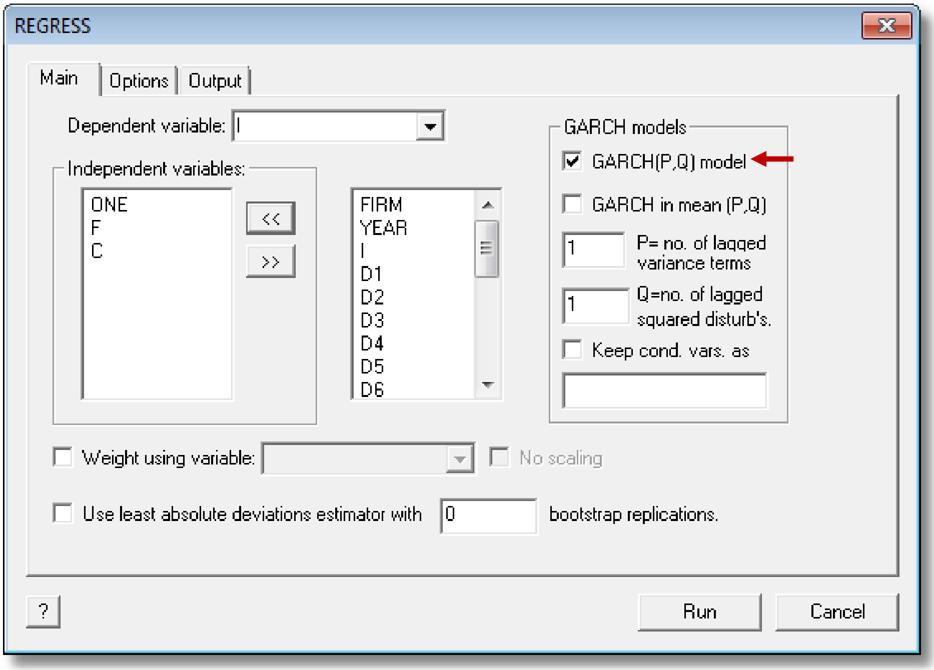

Figure E10.2 Command Builder for ARCH and GARCH Models

Output for this estimator consists of the ordinary least squares regression used to obtain the starting values for the slope parameters followed by the maximum likelihood estimators of the models parameters. Two additional statistics are included in the results:

Equilibrium variance $= \bar{\sigma}^2 = \sigma_0^2 / (1 - \alpha_1 - ... - \alpha_q - \delta_1 - ... - \delta_p)$

Wald statistic for the hypothesis of GARCH(0,0) $= \mathbf{c}'\{\text{Est.Asy.Var}[\mathbf{c}]\}^{-1}\mathbf{c}$
where **c** is the vector of estimates of the GARCH parameters.

Standard results available for later analysis include:

Matrices:

b	=	estimates of $\boldsymbol{\beta}$
varb	=	estimated asymptotic covariance matrix (includes the variance parameters if you include **; Parameters** in the command)
variance	=	estimates, in order, σ_0^2, δ_1, ... δ_P, α_1, ..., α_Q, $\bar{\sigma}^2$

Scalars:

ssqrd	=	$\mathbf{e}'\mathbf{e}/T$
rsqrd	=	$1 - \mathbf{e}'\mathbf{e} / \sum_{t=1}^{T}(y_t - \bar{y})^2$ (do not use this!)
s	=	$\sqrt{ssqrd}$
rho	=	0.0
degfrdm	=	T - number of parameters in $\boldsymbol{\beta}$
sy	=	standard deviation of *y*
ybar	=	mean of *y*
kreg	=	number of *x* variables
nreg	=	total number of observations
logl	=	log likelihood
exitcode	=	the usual

Last Function: None

Fitted values and residuals are based on the regression part of the model, not the GARCH part. As such, the confidence limits listed are conditional, and are based only on the equilibrium variance. They will be somewhat narrower than would be strictly appropriate if a full accounting of all estimated parameters were included. Thus, use

; Keep = variable name to retain the regression values as predictions
; Res = variable name to retain residuals, as usual.

You may also obtain estimates of the conditional variances,

$$\sigma_t^2 = \sigma_0^2 + \sum_{q=1}^{Q}\alpha_q\varepsilon_{t-q}^2 + \sum_{p=1}^{P}\delta_p\sigma_{t-p}^2$$

Use

; Cvar = variable name to retain estimates of conditional variances.

E10.5.1 Example: ARCH(0,1) Model for Expected Inflation

We examine a model for expected inflation of the form

$$P_t^e = P_{t-1}^e + \lambda_1(P_t - P_{t-1}^e) + \lambda_2(P_{t-1} - P_{t-2}^e) + \varepsilon_t.$$

We examine the model in the context of the ARCH models. The data are from the UK, so this more or less coincides with Engle's analysis. To simplify matters, we compute the lagged values initially, discard the incomplete observations, and treat the remainder as the full sample.

E10.5.2 A Benchmark GARCH(1,1) Model for Exchange Rates

The Bollerslev and Ghysels (1986) model for the daily percentage nominal returns for the Deutschemark/Pound exchange rate (BG data) have become a de facto benchmark for calibrating software for estimating GARCH models They analyzed 1974 observations, and fit a GARCH (1,1) model,

$$y_t = \mu + \varepsilon_t,\ \mathrm{Var}[\varepsilon_t] = \sigma_t^2 = \sigma_0^2 + \alpha_1\varepsilon_{t-1}^2 + \delta_1\sigma_{t-1}^2.$$

McCullough and Renfro (1999) provide the following benchmark values:

$$\mu = -0.00619041$$
$$\sigma_0^2 = 0.0107613$$
$$\alpha_1 = 0.153134$$
$$\delta_1 = 0.805974$$

They also discuss algorithms and the computation of asymptotic standard errors, which we turn to in the next section.

LIMDEP's estimates based on the BG data are as follows:

REGRESS ; Lhs = y ; Rhs = one ; Model = GARCH(1,1) $

The benchmarks are matched to all reported digits for the (1,1) model. The literature provides virtually no guidance on model formulation. For better or worse, specification searches appear to be largely ad hoc. In fact, the log likelihood function for the GARCH model is extremely complicated, and iterations will often break down. The second set of results given below show an example, where we attempt to fit a GARCH(2,2) model to the same BG data.

Evidently, the GARCH(2,2) model is overparameterized. The iterations have terminated abnormally. The log likelihood function for the (2,2) model is only slightly larger than for the (1,1) model in spite of the fact that the additional parameters are a fairly substantial expansion of the model.

E10.5.3 The GARCH in Mean Model

Engle, et al. (1987) found that it would be useful to relax the independence of the mean and the variance in the GARCH model. The ‘GARCH in mean’ model, or GARCH(m) model is

$$y_t = \boldsymbol{\beta}'\mathbf{x}_t + \lambda\sigma_t^2 + \varepsilon_t$$

$$\text{Var}[\varepsilon_t \,|\, \varepsilon_{t-1}, ..., \varepsilon_{t-q}] = \sigma_t^2 = \sigma_0^2 + \sum\nolimits_{s=1}^{q}\alpha_s\varepsilon_{t-s}^2 + \sum\nolimits_{r=1}^{p}\delta_r\sigma_{t-r}^2$$

$$\varepsilon_t \,|\, \Psi_t \sim N[0,\sigma_t^2].$$

This model is requested with

REGRESS ; Lhs = ... ; Rhs = ...
; Model = GARCH(p,q,1)
; ... any other optional specifications $

In particular, the addition of the '1' to the GARCH(p,q) specification triggers this specification. (It is possible to extend this model to additional lags in the variance, and to nonlinear functions in the variance term in the regression. Whether or not this provides substantial value added to the specification remains to be verified. *LIMDEP* is limited to this simple specification, however.) Save for this change in the specification, the model is otherwise the same as the GARCH model.

The results below show the outcome of extending the BG model to a GARCH(1,1,1) model. The predicted values shown for the (1,1) and (1,1,1) models suggest that a somewhat better fit is obtained with the extension. The GARCH(1,1) model is shown above. The GARCH(m) (1,1,1) model is shown below. The iterations for the GARCH(m) model did not actually reach a 'clean' convergence. The likelihood function has become flat at the point reported, and no further improvement could be produced. Nonetheless, it does improve somewhat on the GARCH(1,1) model; the log likelihood function has improved. The prediction from the GARCH model is simply the mean, as there are no covariates. So, for the GARCH model with no mean term, the predicted value equals the estimated mean, -.00619041. The mean value of the Lhs variable is -.016427. For the GARCH in mean model, we use the estimated unconditional variance to form the forecasted value, so for this model,

$$
\begin{aligned}
\hat{y}_t &= \hat{\mu} + \hat{\lambda}\hat{\bar{\sigma}}^2 \\
&= .0057666 - .077164\left(\frac{.0109532}{1-.803872-.1545375}\right) \\
&= -.00145552
\end{aligned}
$$

which is a bit of an improvement. The log likelihood function has improved somewhat as well.

```
Line search at iteration 13 does not improve fn. Exiting optimization.

E10.5.4 Technical Details on Estimation of the GARCH(*m*) Model

With normally distributed disturbances, the log likelihood function for the GARCH(*m*) model is

$$\log L = \frac{-1}{2}\left[\sum_{t=1}^{T}\left(\log\sigma_t^2 + \frac{\varepsilon_t^2}{\sigma_t^2}\right)\right] - \frac{T\log(2\pi)}{2}$$

where $\varepsilon_t = y_t - \boldsymbol{\beta}'\mathbf{x}_t - \lambda\sigma_t^2$

and $\sigma_t^2 = \sigma_0^2 + \sum_{s=1}^{q}\alpha_s\varepsilon_{t-s}^2 + \sum_{r=1}^{p}\delta_r\sigma_{t-r}^2$.

To maximize the function, it is necessary to minimize the term in square brackets. We do this with *LIMDEP*'s general optimization package. Two aspects of this optimization make it more complicated than usual. First, the variances must be computed recursively, and, since they are a difference equation, must be initialized at values that will affect the ultimate solution. Second, as a consequence of the first factor, derivatives must be computed recursively as well. We turn to these considerations first, then discuss how standard errors are computed for the estimates.

The *t*th term in the function to be maximized is

$$\log L_t = \log\sigma_t^2 + \frac{\varepsilon_t^2}{\sigma_t^2}$$

The involved part of the computation is the computation of the variances, σ_t^2, as each depends on the previous ones. *LIMDEP* does its initializations as follows: The computation involves p+q lagged values, as the pth lag of σ_t^2 itself involves q lags of ε_t. Take first the case in which there is no 'in mean' term; $\lambda = 0$. For this case, as McCullough and Renfro (1999) note, there are various approaches to initialization. We initialize all presample values of both ε_t^2 and σ_t^2 at an estimate of the unconditional variance using the then current estimate of $\boldsymbol{\beta}$;

$$s^2 = \frac{1}{T}\sum_{t=1}^{T}\left(y_t - \hat{\boldsymbol{\beta}}'\mathbf{x}_t\right)^2 .$$

This begins the recursion and enables us to compute the function and its derivatives. The derivatives must be computed recursively as well. Extensive detail on the procedure may be found in Fiorentini, Calzolari, and Panattoni (FCP, 1996) and in Greene (2011). An issue arises with respect to the derivatives of the initial values. *LIMDEP* accounts completely for these as well – once again, details appear in FCP. (*LIMDEP* uses analytic derivatives, not numerical approximations, for all computations in the GARCH(*m*) models.)

The GARCH(*m*) model presents a substantial complication in this set of computations. In order to compute the initial estimates of the variances, we need the estimates of the disturbances. But, the disturbances involve the variances. In order to complete the loop, we extend the assumption used in the simpler case. If the variances in all sample periods had stabilized at the same value, then, assuming that the presample disturbances take their conditional means, that variance would be

$$\bar{\sigma}^2 = \sigma_0^2 / (1 - \delta_1 - ... - \delta_p - \alpha_1 - ... - \alpha_q).$$

(Of course, there seems to be a bit of an inconsistency in assuming that the initial disturbances are zero and their squares equal the initial variances – we are setting each value to its expectation, not to a forecasted value.) Therefore, for the GARCH in mean model, we initialize the variances and squared disturbances at the revised estimate

$$s^2 = \frac{1}{T}\sum_{t=1}^{T}\left(y_t - \hat{\boldsymbol{\beta}}'\mathbf{x}_t - \hat{\lambda}\hat{\bar{\sigma}}^2\right)^2 .$$

where
$$\hat{\bar{\sigma}}^2 = \frac{\hat{\sigma}_0^2}{1-\hat{\delta}_1-\ldots-\hat{\delta}_p-\hat{\alpha}_1-\ldots-\hat{\alpha}_q}$$

One complication remains. If the denominator of $\hat{\bar{\sigma}}^2$ is nonpositive, the function will be nonsensical, and problems will emerge in the function evaluation. If this occurs, we revert to an alternative estimator; we recompute $\hat{\bar{\sigma}}^2$ without the α terms. If the denominator of this revised estimate is also nonpositive, the log likelihood function will be noncomputable. Before reaching this point, the trial value of the parameter vector that produced this situation would have been rejected, and we would have reentered the iteration with another set of estimates. Note, this is the situation which produces the diagnostic

```
Warning   141: Iterations:current or start estimate of sigma is nonpositive
```

which appears before our estimates of the GARCH(2,2) model earlier.

Asymptotic standard errors for the coefficient estimators are obtained via a hybrid form of the 'sandwich' (robust) covariance matrix estimator. We compute the BHHH estimator first,

$$\mathbf{B} = \sum_{t=1}^{T}\mathbf{g}_t\mathbf{g}_t'$$

where $\mathbf{g}_t$ is the vector of derivatives of $\log L_t$ with respect to the full vector of parameters. We then compute

$$\mathbf{H} = -\mathrm{E}\left[\sum_{t=1}^{t}\mathbf{H}_t\right]$$

where $\mathbf{H}_t$ is the second derivatives matrix of $\log L_t$ with respect to the full vector of parameters. The actual derivatives are extremely complicated. However, the expectations have an extremely simple form. (See Bollerslev (1986).) Finally, the estimated asymptotic covariance matrix is computed as

$$\text{Est.Asy.Var}[\ .] = \mathbf{H}^{-1}\,\mathbf{B}\,\mathbf{H}^{-1}.$$

McCullough and Renfro label this the Bollerslev and Wooldridge (1992) estimator, and provide the following benchmark values for the standard errors for the BG GARCH(1,1) model: (.00873092, .00312364, .0273219, .0301509). *LIMDEP*'s values for these are (.0087309247, .0031236375, .027321934, .030150886), which agree with all reported digits.

After estimation of the structural parameters,

$$\bar{\sigma}^2 = \sigma_0^2 / (1 - \alpha_1 - \ldots - \alpha_Q - \delta_1 - \ldots - \delta_P)$$

is estimated. The standard error is estimated using the delta method.

E11: Autocorrelation in the Linear Model

E11.1 Introduction

This chapter will detail estimation of linear regression models with autocorrelated disturbances. The models presented here are of autoregressive disturbances:

$$y_t = \boldsymbol{\beta}'\mathbf{x}_t + \varepsilon_t,$$

$$\varepsilon_t = \rho_1\varepsilon_{t-1} + \rho_2\varepsilon_{t-2} + \ldots + \rho_p\varepsilon_{t-p} + u_t\,.$$

Moving average disturbances,

$$\varepsilon_t = u_t + \lambda_1 u_{t-1} + \lambda_2 u_{t-2} + \ldots + \lambda_q u_{t-q}\,,$$

are presented in Chapter E12 under the subject of ARIMA and ARMAX models. *LIMDEP* has a somewhat limited facility for handling mixed disturbances. For the most part, mixed models can be handled by prior modification of the data (to set up the autoregressive part) and/or use of the ARIMA/ARMAX procedure.

Autocorrelation in the linear regression is modeled with different forms of

REGRESS ; Lhs = dependent variable
; Rhs = independent variables
; AR1 and/or other specifications $

E11.2 Correcting the OLS Covariance Matrix

Section E10.2 describes how to obtain a consistent covariance matrix for the OLS estimates in the presence of heteroscedasticity (the 'White estimator'). Newey and West's (1987) counterpart is consistent in the presence of generally unspecified autocorrelation. The specification for requesting the Newey-West estimator as part of a regression is

; Pds = L

where '*L*' is the number of periods for which lags are to be computed. You can also access this on the Options page of the command builder by selecting Model:Linear Models/Regression.

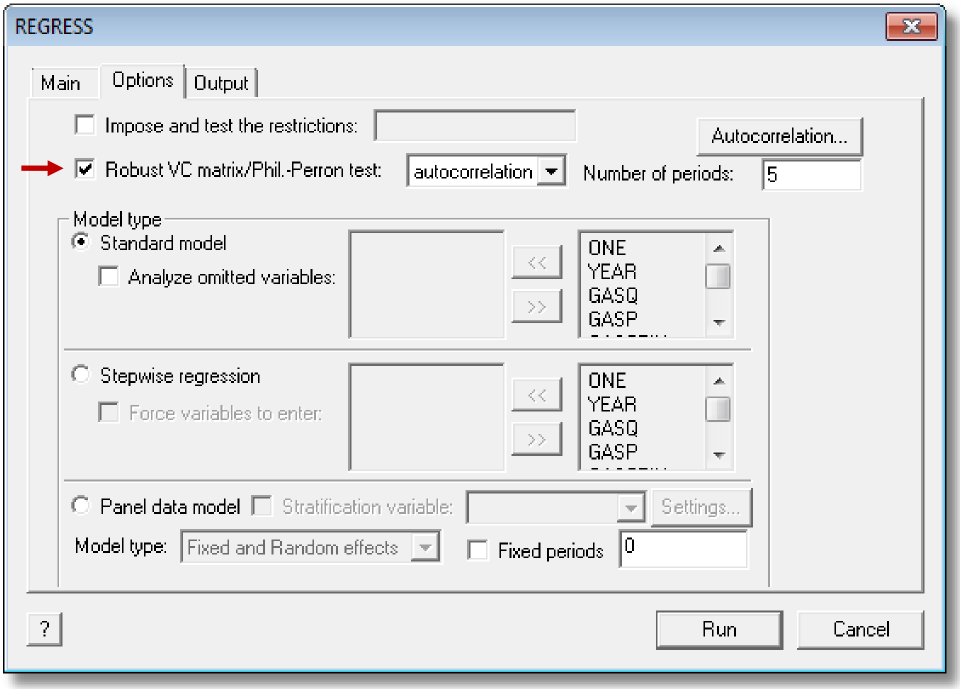

Figure E11.1 Command Builder for Linear Models with Autocorrelation

The computations are listed as follows, where **V** is the final result:

$$\mathbf{V} = \text{White estimator} + \mathbf{SRS},$$

$$\mathbf{S} = (\mathbf{X}'\mathbf{X})^{-1},$$

$$\mathbf{R} = \sum_{i=1}^{i=L} w(i,l)\mathbf{R}(i),$$

$$\mathbf{R}(i) = \sum_{t=i+1}^{t=T} [\mathbf{x}_t\mathbf{x}_{t-i}' + \mathbf{x}_{t-i}\mathbf{x}_t']e_t e_{t-i},$$

$$w(i,L) = 1 - i/(L+1) \text{ is a scalar weight,}$$

and e_t = the OLS residual for period t, t=1,...,T.

The value 'L' is the number of periods used in computing **R**. There is little theoretical guidance on the best choice of L. If the model were a moving average, L is the maximum lag. Of course, if it were known that an MA(L) model applied, this would be the wrong procedure to use in the first place. For autoregressions and mixed processes, the picture is far less clear. Readers are referred to Newey and West (1987), and for some background material, White (1981).

We will base this example and several to follow on the gasoline market data set used earlier in Chapters E7 and E8. Results of fitting a multiple regression with an autocorrelation robust covariance matrix estimator with lags of five periods are shown below. The accompanying residual plot strongly suggests the presence of autocorrelation. The rather large increase in the estimated standard errors that occurs when the Newey-West correction is applied is to be expected.

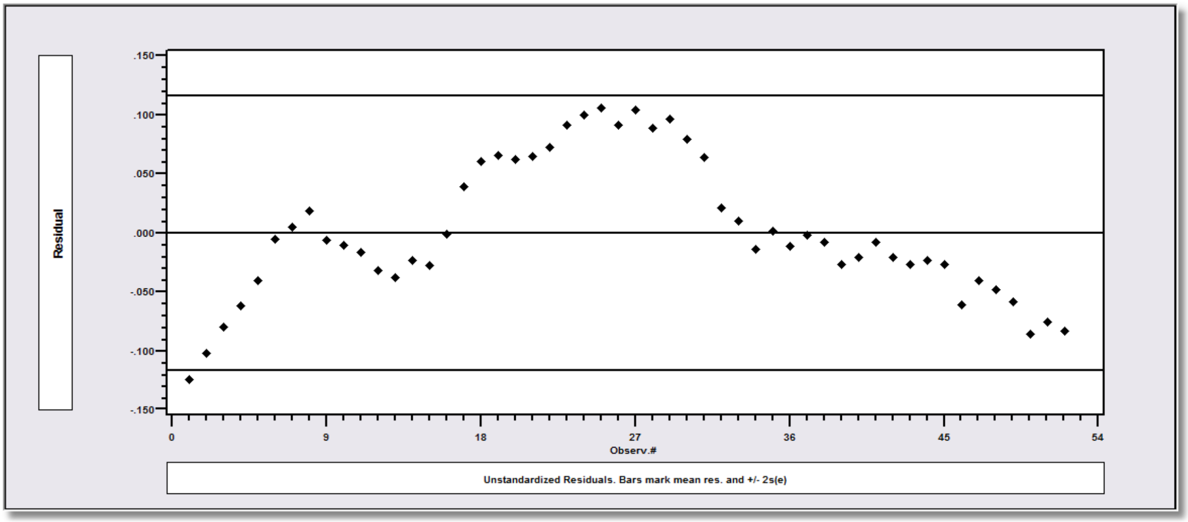

Figure E11.2 Autocorrelated Residuals

E11.3 Correcting for First Order Autocorrelation

There are numerous procedures for estimating a linear regression with first order autoregressive disturbances,

$$y_t = \boldsymbol{\beta}'\mathbf{x}_t + \varepsilon_t,$$

$$\varepsilon_t = \rho\varepsilon_{t-1} + u_t\,.$$

The simplest form of the command is

REGRESS ; Lhs = ... ; Rhs = ... ; AR1

The command builder for the linear regression model may also be used. Note in Figure E11.1 at the upper right of the dialog box, there is a button for Autocorrelation. This dialog box is shown in Figure E11.3:

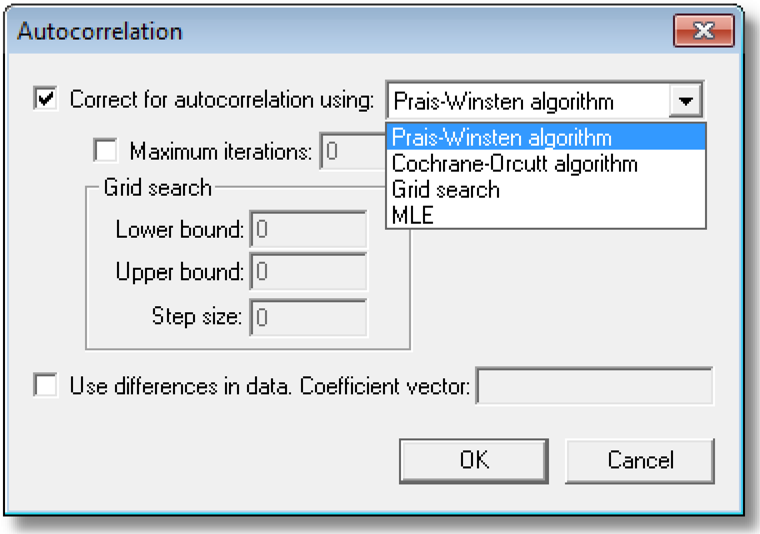

Figure E11.3 Command Builder for Specifying Autocorrelation Estimator

The default estimator is the iterative Prais-Winsten algorithm. That is, the first observation is *not* discarded; the full GLS transformation is used. This is a repeated two step estimator:

Step 1. OLS regression of **y** on **X**. Then, estimate ρ with

$$r = 1 - ½ \times \text{Durbin-Watson statistic.}$$

Step 2. OLS regression of

$$y_1{*} = (1 - r^2)^{1/2}\, y_1$$

$$y_t{*} = y_t - ry_{t-1},\ t = 2,\ldots,T$$

on the same transformation of $\mathbf{x}_t$.

After Step 2, r is recomputed based on the GLS estimator, and the regression is repeated. This iteration continues until the change in r from one iteration to the next is less than 0.0001. The covariance matrix for the slope estimators is the usual OLS estimator, $s^2(\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}$ based on the transformed data. The asymptotic variance for r is estimated by $(1 - r^2)/(T-1)$.

Results and diagnostics are presented for both transformed and untransformed models. The example below shows the specific results given.

> **NOTE:** If no other specification is given, the estimator is allowed to iterate to convergence, which usually occurs after a small number of iterations. The updated value of r at each iteration is computed from the Durbin-Watson statistic based on the most recent GLS coefficients estimates. Iterating these estimators to convergence does not produce a maximum likelihood estimator.

The ordinary least squares regression results are the same as in the previous section and are omitted.

```

Other estimation procedures are requested by adding them to the **; AR1** request:

; AR1 ; Alg = Corc

requests the iterative Cochrane-Orcutt estimator. The first observation is skipped, and the pseudo-difference defined above is applied to the remaining observations. (We do not recommend this estimator, as it needlessly discards the information contained in the first observation, with no accompanying gain in speed, efficiency, or any statistical properties.) Alternatively,

; AR1 ; Alg = MLE

requests the maximum likelihood estimator of Beach and MacKinnon (1978). In this model, the MLE is not GLS because in addition to the generalized sum of squares, the log likelihood function contains an extra term, the Jacobian for the first observation, ½log(1 - ρ^2). This term becomes de minimis as $T\to\infty$, so in a large sample, the MLE and the other GLS estimators should not differ substantially.

TECHNICAL NOTE: The maximum likelihood estimator uses the Beach and MacKinnon method. The iteration is as shown at the beginning of this section. However, the recomputation of *r* is done differently, as follows: Let $D = (T\text{-}1)\sum_{t=2}^{T-1} e_t^2$. Then,

$$a = -\frac{(T-2)\sum_{t=2}^{T} e_t e_{t-1}}{D};\ b = \frac{(T-1)e_1^2 - T\sum_{t=1}^{T-1} e_t^2 - \sum_{t=2}^{T} e_t^2}{D};\ c = \frac{T\sum_{t=2}^{T} e_t e_{t-1}}{D}$$

Now, $p = b - a^2/3$, $q = c - ab/3 + 2a^3/27$, and $\phi = \arccos\left[\left(q\sqrt{27}\right)/\left(2p\sqrt{-p}\right)\right]$. Finally,

$\hat{\rho} = -2\sqrt{-p/3}\cos(\phi/3+\pi/3) - a/3$. Iteration of the feasible GLS procedure with this formula for *r* at each step produces the maximum likelihood estimates.

To use a grid search for the autocorrelation coefficient, use

; AR1 ; Alg = grid(lower, upper, step)

This requests a simple grid search over the indicated range with a stepsize as given. The method used for the grid search is the default Prais-Winsten estimator. To request the Cochrane-Orcutt estimator, instead, use

; AR1 ; Alg = grid(lower, upper, step, 1)

(As before, the Cochrane-Orcutt estimator is inferior to the MLE or Prais-Winsten estimator.) You can request a particular value for ρ by a simple request:

; AR1 ; Rho = specific value

When you use this form of the model command, the output will still contain an estimated standard error for the estimate of ρ, as if it had been estimated. The number of iterations allowed for the first three estimators can be controlled with the specification

; Maxit = maximum

The results saved by this estimator are the same as for the model without autocorrelation. The estimate of ρ is saved, as before, in the scalar, *rho*. Matrices *b* and *varb* contain the FGLS estimates for **β**. The **; Parameters** switch has no effect here. Residuals, predictions, and the confidence interval are the same as in the model without autocorrelation; the only adjustment is to use the GLS estimates of the residual variance and the covariance matrix of the slopes. *The set of fitted values does not contain predictions of the residuals.* Thus, if you use **; Fill** to extrapolate beyond the sample data, we do not use the BLU forecast,

$$\hat{y}_{T+1} = \mathbf{b}_{gls}'\mathbf{x}_{T+1} + \mathrm{r}e_T.$$

This can easily be constructed, if desired, with the **CREATE** command.

E11.4 Autocorrelation with a Lagged Dependent Variable

Hatanaka (1974) has derived an efficient estimator for this model which is asymptotically equivalent to maximum likelihood. The procedure is as follows: The model is

$$y_t = \boldsymbol{\beta}'\mathbf{x}_t + \gamma y_{t-1} + \varepsilon_t ,$$

$$\varepsilon_t = \rho\varepsilon_{t-1} + u_t .$$

Step 1. Use instrumental variables to estimate $[\boldsymbol{\beta},\gamma]$. Any consistent estimator will do. A suitable instrumental variable for the lagged value of y_t might be the lagged value of the prediction of y_t from a regression on $\mathbf{x}_t$ and $\mathbf{x}_{t-1}$.

Step 2. Using the consistent estimates in Step 1, estimate ρ consistently by the autocorrelation of the residuals, $e_t = y_t - \mathbf{b}_{iv}'\mathbf{x}_t - c_{iv}y_{t-1}$. That is, compute the residuals using actual values, not predictions.

Step 3. Now, use the Cochrane-Orcutt transformation to do GLS based on the original data, but add an additional regressor to the model, e_{t-1}. (The transformation is not applied to the lagged residual.)

Step 4. The efficient estimate of ρ is the original estimate plus the slope on the lagged residual in the regression at Step 3. The asymptotic covariance for this estimate is that provided for the slope in Step 3. I.e., the GLS regression in Step 3 provides the full set of covariances.

This procedure uses the **2SLS** command, not **REGRESS**. The command is

```
2SLS        ; Lhs = y  ;  Rhs = ...
            ; Inst = full set of instruments ; AR1 ;  Hatanaka $
```

Note that the set of instruments includes:

1. all exogenous variables in x on the Rhs,
2. *one* if it is included in the Rhs,
3. additional instrumental variables.

For example

```

E11.5 Differencing and Higher Order Autocorrelation

LIMDEP does not have built-in estimators for other models of autoregressive disturbances. But, the Cochrane-Orcutt method is easily generalized. Suppose the desired model is

$$\varepsilon_t = \rho_1\varepsilon_{t-1} + \rho_2\varepsilon_{t-2} + \dots \rho_p\varepsilon_{t-p} + u_t.$$

If consistent estimates of ρ_1,... are in hand, the counterpart to the Cochrane-Orcutt estimator will use least squares regression of

$$y_t - r_1 y_{t-1} - r_2 y_{t-2} - \dots r_p y_{t-p}$$

on the same transformation of the **x** vector. The initial p observations are lost.

LIMDEP does have a simple procedure for using lagged values in this fashion. The feature is available generally, but is likely to be most useful for estimating this model. Suppose you wish to regress

$$y_t^* = y_t - \rho_1 y_{t-1} - \rho_2 y_{t-2} - \dots - \rho_p y_{t-p}$$

on the same transformation of **x**. It is not necessary to compute the transformed variables. Use

REGRESS ; (as usual) ; Dfr = r1, r2, ..., rp $

The differences are used during estimation, but not retained during or after estimation. As always, you may specify the set of values any way you like, i.e., as a matrix, set of values, etc. *One* is not differenced by this procedure, so if you specify a constant term in the regression, it will remain after the differences. Of course, you might want to drop it at the outset, as

$$y_t = \alpha + \boldsymbol{\beta}'\mathbf{x}_t + \varepsilon_t$$

implies

$$y_t - y_{t-1} = \boldsymbol{\beta}'(\mathbf{x}_t - \mathbf{x}_{t-1}) + \varepsilon_t - \varepsilon_{t-1}$$

without a constant term.

For example, if you wish to do the Cochrane-Orcutt transformation for an AR(1) model yourself, you could use the following:

```
SAMPLE      ; 1 - ... $
REGRESS     ; ... (as usual) ... $   (Saves rho)
SAMPLE      ; 2 - ... $
REGRESS     ; ... (same as above) ... ; Dfr = rho $
```

Any of the coefficients in the **; Dfr** list may be 1.0. As such, you can use this procedure to estimate equations in differences. For examples, to regress y_t - y_{t-1} on $\mathbf{x}_t$ - $\mathbf{x}_{t-1}$, use

```
            ; Dfr = 1
```

To use second differences, $\Delta^2 y_t = (y_t - y_{t-1}) - (y_{t-1} - y_{t-2})$ include **; Dfr = 2,-1** in the command.

With this in hand, the following is a procedure you can use for a *p*th order autoregression model. For our example, we use a fourth order model.

```
REGRESS     ; Lhs  = ... ; Rhs = ...
            ; Res  = e $            (Get OLS residuals)
SAMPLE      ; 5 - ... $
REGRESS     ; Lhs  = e
            ; Rhs  = e[-1],e[-2],e[-3],e[-4],one $
MATRIX      ; r = b (1 : 4) $      (Strip off constant term)
REGRESS     ; ... as above...
            ; Dfr  = r $            (Does GLS instead of OLS)
```

This method could also be used to estimate a model of fourth order autocorrelation for quarterly data. That is, one for which

$$\varepsilon_t = \rho\varepsilon_{t-4} + u_t.$$

Suitable commands would be

```
REGRESS     ; Lhs  = ...
            ; Rhs  = ...
            ; Res  = e $            (Get OLS residuals)
SAMPLE      ; 5 - ... $
REGRESS     ; Lhs  = e
            ; Rhs  = e[-4], one $
REGRESS     ; ...as above...
            ; Dfr  = 0,0,0,b(1) $
```

E11.6 Testing for Autocorrelation

For testing against the hypothesis of autocorrelated disturbances, the Durbin-Watson statistic produced with the initial output provides a rough and ready test for a fairly small class of models. Godfrey (1978) has devised a more general test for the case of *p*th order autoregressive or moving average (or a mixture). The formalities of the procedure can be found in the article. In practical terms, the test statistic can be computed by regressing the least squares residuals on the original set of regressors and *p* lagged values of the residuals. (See Greene (2011).) To do this with *LIMDEP*, use the **; Res = name** option to retain the residuals from the regression. Then use **REGRESS** to compute the least squares regression, including the original regressors and the lagged residuals on the Rhs and the current residual on the Lhs *without resetting the sample*. Then,

$$\text{chi squared } (p) = TR^2$$

is a chi squared statistic with *p* degrees of freedom. The **CALC** command can be used to obtain the significance level for the test statistic. The commands would be

```
NAMELIST    ; x = one,... $
CREATE      ; e1 = 0 ;  e2 = 0 ; ... ep = 0 $
REGRESS     ; Lhs  = ... ; Rhs = x ; Res = e $
SAMPLE      ; Set sample to p+1 to T $

```

The LM test requires that the initial values of the lagged residuals be filled with zeros and that these observations be included in the regression. (An alternative computation is obtained by dropping the initial observations. Authors differ on this – Godfrey, himself changes his prescription in a later article.) The commands above which create the lagged residuals set them to zero initially because *LIMDEP* would otherwise fill the lagged values with the missing value code, -999.

Finally, the Box-Pierce *Q*-statistic may be used in a similar fashion to test for higher order autocorrelation. To obtain this statistic for the OLS residuals, keep the residuals as described above, then use

```
IDENTIFY    ; Rhs  = ... residuals ; Pds = L $
```

to obtain the autocorrelations and the associated statistics. You must supply the value for *L*.

E12: ARIMA, ARMAX and Distributed Lag Models

E12.1 Introduction

This chapter will detail some of *LIMDEP*'s time series capabilities. Although *LIMDEP* is primarily oriented to cross section and panel data analysis, many common applications in time series analysis, including autocorrelation, identification, spectral analysis, unit root tests and some distributed lag models can be handled as well. (It would be possible, with some effort, to work with other time series techniques, such as unit roots, VARs, and cointegration tests. Some of these, such as basic ADF and Phillips-Perron tests are presented in Chapter E5.) This chapter will describe two estimation programs and some procedures constructed from the matrix and regression commands. Note as well that some other time series topics have been covered in earlier chapters, in particular, spectral analysis, time series identification and unit root tests in Chapter E5, GARCH models in Chapter E10 and autocorrelation in the linear regression model in Chapter E11.

E12.2 Box-Jenkins ARIMA and ARMAX Models

The models estimated by this procedure are

$$y_t = \mu + \boldsymbol{\beta}'\mathbf{x}_t + \phi_1 y_{t-1} \ldots \phi_p y_{t-p} + \varepsilon_t + \theta_1\varepsilon_{t-1} + \theta_q\varepsilon_{t-q}, \text{ where } y_t = (1 - L)^d Y_t$$

and L is the lag operator. I.e., y_t is the original series differenced 'd' times, if this is desired. More compactly

$$\boldsymbol{\Phi}(L) \times [\delta(L)^d\, Y_t] = \mu + \boldsymbol{\beta}'\mathbf{x}_t + \boldsymbol{\Theta}(L)\varepsilon_t,$$

where $\boldsymbol{\Phi}$ and $\boldsymbol{\Theta}$ are polynomials in the lag operator and $\delta(L) = (1\text{-}L)$. The nonstochastic part, $\boldsymbol{\beta}'\mathbf{x}_t$ is optional. Without it, a pure ARIMA model results. You may also specify no differences (d = 0), which will be most of the time. If you leave out $\boldsymbol{\Phi}(L)$ as well, (p = 0), a pure moving average regression results. Do note that this estimator requires that q, the order of the moving average part, be greater than zero. If q = 0, you can just estimate the equation by least squares, so there is no need for the ARMAX estimator. In this case, a diagnostic is issued and estimation is halted.

E12.2.1 Model Command

The command for this model is

ARMAX **; Lhs = dependent variable**
; Rhs = variables (optional)
; Model = p,d,q $ (in exactly that order)

If you want to include a constant term in the model (μ), *include one in the Rhs list*. Note that if d is nonzero, a nonzero constant implies a nonstationary series. You must provide all three values for p,d,q, even if they are zero. Other options are

; Res = name	to retain residuals
; Keep = name	to retain fitted values
; List	to display predicted values and residuals
; Covariance Matrix	to display the estimated asymptotic covariance matrix, same as **; Printvc**

You can use the model to predict beyond the end of the sample by adding

; Pds = number of periods to forecast

If there are regressors (Rhs variables) in the model, you must have valid data available for the forecasts in the rows that immediately follow the last observation in the estimating sample. If the model is a pure ARIMA model (no Rhs variables), you can forecast as many post sample periods as you like. You may also plot the fitted and actual values, including any post sample predictions by including

; Plot

in the command.

You can check the adequacy of the model by using **IDENTIFY** and/or **PLOT** to examine the residuals. To do so, be sure to include **; Res = name** to retain the residuals after estimation.

For the identification step, (i.e., for determining the orders of the lag structures in the model) here is a practical hint: If you are estimating a pure ARIMA model, use **IDENTIFY** on y_t to determine the appropriate p and q. If you are estimating a pure MA model, you need first to obtain a 'clean' set of residuals for the identification step. So, use ordinary least squares to obtain an estimate of [μ, $\boldsymbol{\beta}$], and use **IDENTIFY** on the residuals from this least squares regression. Assuming that an MA model is appropriate, the PACF from this step will reveal its order. If you are estimating an ARMAX model, in order to obtain a consistent set of residuals, you can do the following: Use instrumental variables to estimate [μ,$\boldsymbol{\beta}$], and the ϕs simultaneously. The independent variables will be *one*, the *x*s, then *y*[**-**1],...,*y*[**-***p*]. The instruments will be *one*, the *x*s, then *y***[-***q***-**1**]**,...,*y***[-***q*-*p***]**. For example, to estimate an ARMAX(1,0,1) (no differencing), your IV estimator is a 2SLS regression of *y* on *one*, the *x*s, and *y*[**-**1] with instruments *one*, the *x*s, and *y*[**-**2].

The starting values for the iterations are generated internally by this estimator. (See below.) The controls for nonlinear estimation,

; Start = list
; Tlj (j=b, f, g) [=value]

are ignored by this program. Convergence is described in the technical details in Section E12.2.4. You can set the maximum number of iterations with

; Maxit = value

if you wish. The default is 25.

HINT: This estimator normally converges in a small number of iterations. If a large number of iterations is required, there is probably a problem with the model specification. One problem that can impede convergence is overfitting, that is, making q too large.

Finally, restrictions on coefficients can *only* be imposed on the elements of $\boldsymbol{\beta}$ by building them into the model. The specification

; Rst = list

is ignored. You can test restrictions on the coefficients by two methods. First,

; Test: ...

can be used for Wald tests. The coefficient vector is, in order (μ's position will correspond to *one*, in the Rhs list)

$$\gamma \ = \ \phi_1,...,\phi_p,\mu,\beta_1,...,\beta_K,\theta_1,...,\theta_q.$$

Some of these may not be present in your model. For purposes of testing hypotheses, these are b(1),...,b(M). Since this is likely to be a bit cumbersome, using the **WALD** command with the *Last Model* results is likely to be much simpler (see Section R14.4). The list of labels to use is given in the next section.

E12.2.2 Model Output

The data listed below are a some of the quarterly macroeconomic data in Greene (2011, Table F5.2). There are 204 quarterly observations, from 1950I to 2000IV. The data are quarterly observations on a number of familiar variables including real GDP, real consumption, real investment, real government spending, real disposable income, the money stock, short term interest rate, unemployment rate, population, the rate of inflation and a real interest rate. We will use these data in several examples below.

Figure E12.1 Quarterly Macroeconomic Data

The ARMAX model is an extension of the linear regression model that is completely specified by p, d, and q. *LIMDEP* will estimate the full set of parameters by nonlinear least squares procedures. Results will resemble the following:

ARMAX ; Lhs = realinvs ; Rhs = one,tbilrate
; Model = 1,0,1 $

```
-----------------------------------------------------------------------------
Model:y(t) = mu + bx + phi(1)y(t-1)...phi(p)y(t-p))
          + e(t) + theta(1)e(t-1)...theta(q)e(t-q))
      y(t) = [(1-L)^d]Y(t)  (differences))
Dependent variable                             REALINVS
Raw data were differenced d =  0 times.
Sum of squares at best estimates:         157812.826207
Estimated standard deviation of e(t):         27.881949
For diagnostic checking, use IDENTIFY with residuals.
Number of iterations completed                        6
Number of observations in the sample                204
--------+--------------------------------------------------------------------
        |                Standard            Prob.      95% Confidence
REALINVS|  Coefficient     Error        z    |z|>Z*        Interval
--------+--------------------------------------------------------------------
  Phi(1)|    1.01824***     .00506   201.09  .0000     1.00832   1.02816
      Mu|    3.39819       4.29008      .79  .4283    -5.01021  11.80659

-----------------------------------------------------------------------------
```

The parameter vector, *b* and covariance matrix, *varb* stored for later use correspond to

$$b = [\phi_1,\ldots,\phi_p,\mu,\beta_1,\ldots,\beta_K,\theta_1,\ldots,\theta_q.].$$

NOTE: If you provide *one* as one of your regressors, and it is not first in the list, the order of [μ,$\boldsymbol{\beta}$] will correspond to your command, not the preceding.

The retrievable results are:

Scalars: *sumsqdev* = $\Sigma_t\, \hat{\varepsilon}_t^2$ (the first p+q residuals are zero)

ssqrd $= \hat{\sigma}_\varepsilon^2 = \dfrac{\sum_{t=p+q+1}^{T}\hat{\varepsilon}_t^2}{T-p-q} - \left[\dfrac{\left(\sum_{t=p+q+1}^{T}\hat{\varepsilon}_t\right)}{T-p-q}\right]^2$

kreg $= K$

nreg $= T - p - q$

Last Model: *phi1,...phip,mu,b_variables...,theta1,...thetaq*, labels in order

The predictions are computed as

$$\hat{y}_t = m + f_1 y_{t-1} + \ \ldots\ + f_p y_{t-p} + \mathbf{b}'\mathbf{x}_t + \theta_1 e_{t-1} + \ldots + \theta_q e_{t-q}\,.$$

I.e., these are static forecasts which assume the current disturbance is zero. If the series has been differenced, the forecasts are integrated back to produce the forecasts of Y_t, not y_t.

E12.2.3 Examples

We will fit two models to these data, one in raw form and one in logs. In each case, we used a simple [1,0,1] specification. For the first,

```
DATES     ; 1950.1 $
PERIOD    ; 1950.1 - 1980.4 $
ARMAX     ; Lhs = realgdp ; Rhs = one,m1 ; Res = e ; Model = 1,0,1$
IDENTIFY  ; Rhs = e ; Pds = 10 $
PLOT      ; Rhs = e ; Bars = 0  $  (Note, time series plot. No Lhs.)
```

```
-----------------------------------------------------------------------------
Model:y(t) = mu + bx + phi(1)y(t-1)...phi(p)y(t-p))
          + e(t) + theta(1)e(t-1)...theta(q)e(t-q))
      y(t) = [(1-L)^d]Y(t)  (differences))
Dependent variable                            REALGDP

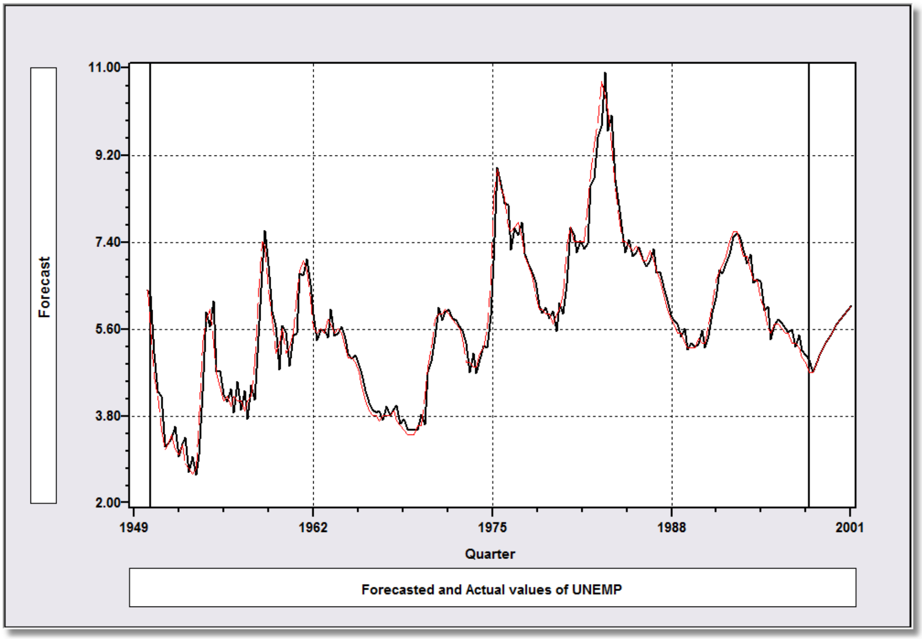

Figure E12.3 Plot of Forecasted and Actual Values of Unemployment

E12.2.4 Technical Details

Estimates are computed by nonlinear least squares. (References are Harvey (1988), Box and Jenkins (1984) and Greene (2011).) The sum of squares is

$$S(\mu,\boldsymbol{\beta},\boldsymbol{\phi},\boldsymbol{\theta}) \;=\; S(\gamma) \;=\; \Sigma_t\varepsilon_t^{\,2}.$$

The iterative process is as follows: Given estimates $\boldsymbol{\gamma}^k$ in hand at entry to the kth iteration,

$$\boldsymbol{\gamma}^{k+1} \;=\; \boldsymbol{\gamma}^k \;+\; [\mathbf{G}_k{'}\mathbf{G}_k]^{-1}\mathbf{G}_k\mathbf{e}_k \;=\; \boldsymbol{\gamma}^k \;+\; \boldsymbol{\delta}^k.$$

The $(T\text{-}p\text{-}q)\times M$ matrix of derivatives $\mathbf{G}$ is the time series of vectors of cross partials whose tth row is

$$\mathbf{g}_t{'} \;=\; \partial\varepsilon_t/\partial\boldsymbol{\gamma}',$$

and $\mathbf{e}_k$ is the vector of estimates of ε_t based on $\boldsymbol{\gamma}^k$. We exit the iterations normally when $\boldsymbol{\delta}'\boldsymbol{\delta}$ is less than 10^{-8} or abnormally either at maximum iterations, which you may set with

; Maxit = the maximum

or if the estimates (generally $\boldsymbol{\theta}$) diverge. The sum of squares is not unimodal, so on the way to convergence, a local minimum may be encountered. *LIMDEP* uses the parameter vector associated with the minimum sum of squares computed during the iterations.

Starting values are computed in two steps as follows:

Step 1. $[\mu,\boldsymbol{\beta},\boldsymbol{\phi}]$ are estimated by the instrumental variable method described in Section E12.2.1. The instruments for lagged ys are just deeper lagged ys, outside the range of the moving average part of the disturbance.

Step 2. $\boldsymbol{\theta}$ is initially estimated by a method suggested by Box and Jenkins. Beginning with $\boldsymbol{\theta} = \mathbf{0}$, we compute a vector of autocovariances, c_0 and $[c_1,...,c_q]$, for the residuals from the instrumental variable estimator above. Then, the iteration is:

a. $s^2 \;=\; c_0 \,/\, (1 + \boldsymbol{\theta}'\boldsymbol{\theta})$,

b. For $i = q,...,1$ (counting backwards) $\theta_i \;=\; c_i/s^2 \;-\; \sum_{j=1}^{q-i} \theta_j\theta_{j+\mathrm{i}}$,

c. Check for convergence based on change from the last iteration. Exit if more than 20 iterations have been taken or if $\boldsymbol{\theta}$ has exploded. Otherwise, return to Step a.

NOTE: This method of estimating the moving average parameters is not guaranteed to be stable. The estimates can diverge. For example, the following will produce the outcome:

```
SAMPLE   ; 1-125 $
CREATE   ; w = Rnn(0,1) ; v = Rnn(0,1) $
ARMAX    ; Lhs = w ; Rhs = one,v ; Model = 1,0,1$
```

```
ARMAX: Moving average terms are explosive. Exit iterations.
```

The derivatives are computed as follows:

$$\partial\varepsilon_t/\partial\mu = 1 + \theta_1\partial\varepsilon_{t-1}/\partial\mu + ... + \theta_q\partial\varepsilon_{t-q}/\partial\mu,$$

$$\partial\varepsilon_t/\partial\beta_k = x_{tk} + \theta_1\partial\varepsilon_{t-1}/\partial\beta_k + ... + \theta_q\partial\varepsilon_{t-q}/\partial\beta_k\,,$$

$$\partial\varepsilon_t/\partial\phi_r = y_{t-r} + \theta_1\partial\varepsilon_{t-1}/\partial\phi_r + ... + \theta_q\partial\varepsilon_{t-q}/\partial\phi_r\,,$$

$$\partial\varepsilon_t/\partial\theta_s = \varepsilon_{t-s} + \theta_1\partial\varepsilon_{t-1}/\partial\theta_s + ... + \theta_q\partial\varepsilon_{t-q}/\partial\theta_s\,.$$

These are difference equations which we initialize at zero for q periods. Collecting each set of derivatives in a matrix, we obtain the following convenient representation:

$$\mathbf{G}_\mu = [\partial\varepsilon_{t-s}/\partial\mu] \quad (1\times q),$$

$$\mathbf{G}_\beta = [\partial\varepsilon_{t-s}/\partial\beta_k] \quad (k\times q),$$

$$\mathbf{G}_\phi = [\partial\varepsilon_{t-s}/\partial\phi_r] \quad (p\times q),$$

$$\mathbf{G}_\theta = [\partial\varepsilon_{t-s}/\partial\theta_s] \quad (q\times q).$$

Then,

$$\partial\varepsilon_t/\partial\mu = 1 + \mathbf{G}_\mu\boldsymbol{\theta},$$

$$\partial\varepsilon_t/\partial\beta = \mathbf{x}_t + \mathbf{G}_\beta\boldsymbol{\theta},$$

$$\partial\varepsilon_t/\partial\phi = \mathbf{y}_{lags} + \mathbf{G}_\phi\boldsymbol{\theta},$$

$$\partial\varepsilon_t/\partial\theta = \boldsymbol{\varepsilon}_{lags} + \mathbf{G}_\theta\boldsymbol{\theta}.$$

As noted, the derivatives are initialized at zero for the first q observations. Thereafter, the difference equation is evaluated in seriatim, simply by right shifting the columns of the matrices and inserting the current value in the vacant first column in preparation for the next observation.

At exit from the iterations, the variance estimator $\hat{\sigma}^2$ is the mean square of the estimated residuals minus the squared mean (since they do not have mean zero),

$$\hat{\varepsilon}_t = y_t - \hat{\boldsymbol{\beta}}'\mathbf{x}_t - \hat{\boldsymbol{\phi}}'\mathbf{y}_{lags} - \hat{\theta}_1\hat{\varepsilon}_{t-1} - ... - \hat{\theta}_q\hat{\varepsilon}_{t-q}$$

with the series begun with q initial values of zero for the disturbances.

E12.3 The Geometric Lag Model

In the geometric distributed lag model, the moving average form is

$$y_t \ = \ \alpha + \beta(1\text{-}\lambda)[x_t + \lambda x_{t-1} + \lambda^2 x_{t-2} + \ldots\ ] + \varepsilon_t.$$

A nonlinear least squares estimator can be computed based on the regression

$$y_t \ \approx \ \alpha + \beta(1\text{-}\lambda)x_t{*} + \lambda^t\mu^0$$

$$y_t \ \approx \ \alpha + \beta(1\text{-}\lambda)x_t{*} + \mu^0 z_t$$

where μ^0 is the 'truncation remainder' and

$$x_t{*} \ = \ x_t + \lambda x_{t-1} + \lambda^2 x_{t-2} + \ldots + \lambda^{t-1}x_1.$$

Thus, we regress y_t on a constant, $x_t{*}$ and $z_t = \lambda^t$. (See, for example, Greene (2011).) This is a nonlinear regression because of λ. With a known value of λ, the regression is linear in parameters α, $\beta(1\text{-}\lambda)$ and μ^0. We obtain the nonlinear least squares estimates by computing the linear model for different values of λ. The one associated with the smallest sum of squares gives the nonlinear least squares estimator.

The procedure involves just setting up the artificial regressors for the value of λ, then computing the linear regression. Each regression estimates α, $k = \beta(1\text{-}\lambda)$, and μ^0 given the value of λ. We collect the values of λ and the associated sums of squares in a vector, plot them, then go back and examine in detail the one which minimizes the sum of squares. For computational purposes, the two artificial regressors can be obtained as follows:

$$x_1{*} \ = \ x_1 \qquad \text{and } z_1 \ = \ \lambda$$

then $$x_t{*} \ = \ x_t + \lambda x_{t-1} \qquad \text{and } z_t \ = \ \lambda z_{t-1},\ t = 2,\ldots,T.$$

One might compute the regression for values of λ from .01 to .99 in steps of .01. When the best value is located in this grid, we could repeat the exercise over a finer grid if more precision is desired. The following lists a basic routine for computing the regression coefficients. We then turn to computation of the asymptotic covariance matrix.

First set up initial value of the counter and estimation criterion. Then, define the procedure to estimate the regression and keep the results. We also retain the optimal value of *lambda* by using two **CALC** commands. The procedure is defined generally so that you can pass any two variables you wish to it.

The commands are:

```
PROCEDURE = GeoLag(y,x) $
MATRIX      ; ee = Init(99,1,0) ; l = ee $
CALC        ; i =  1
            ; eemin = 9999999
            ; best = 0
            ; lambda = .01 $
DO WHILE    ; 10 ; i  <  100  $
CREATE      ; If(_obsno = 1) | z = lambda ; xstar = x $
CREATE      ; If(_obsno > 1) | z = lambda * z[-1]
            ; xstar = x + lambda * xstar[-1] $
REGRESS     ; Lhs = y ; Rhs = one,z,xstar ; Quietly $
MATRIX      ; ee(i) = sumsqdev ; l(i) = lambda
            ; If[sumsqdev < eemin] best = lambda
            ; eemin = sumsqdev $
CALC        ; i = i + 1
            ; lambda = lambda + .01 $
ENDDO       ; 10 $
ENDPROCEDURE
```

Execute the procedure and display the plot to show the results.

```
EXECUTE     ; Proc = GeoLag(dep. var…, indep. var...) $
MPLOT       ; Lhs = l ; Rhs = ee
            ; Fill ; Endpoints = 0,1 $
```

Notice the use of the scalars in the **CREATE** commands and as subscripts for the matrices.

We will apply this to the GDP and M1 data. For this example, we use the first differences of the logs of GDP and M1, so an observation is lost.

```
PERIOD      ; 1950.1 - 2000.4 $
CREATE      ; loggdp = Log(realgdp) ; logm1 = Log(m1) $
CREATE      ; dlgdp = loggdp - loggdp[-1]
            ; dlm1 = logm1 - logm1[-1] $
PERIOD      ; 1950.2 - 2000.4 $
EXECUTE     ; Proc = GeoLag(dlgdp,dlm1) $
MPLOT       ; Lhs = l ; Rhs = ee
            ; Fill ; Endpoints = 0,1
            ; Grid
            ; Title = Sum of Squares for Values of Lambda $
```

The result is contained in the figure below:

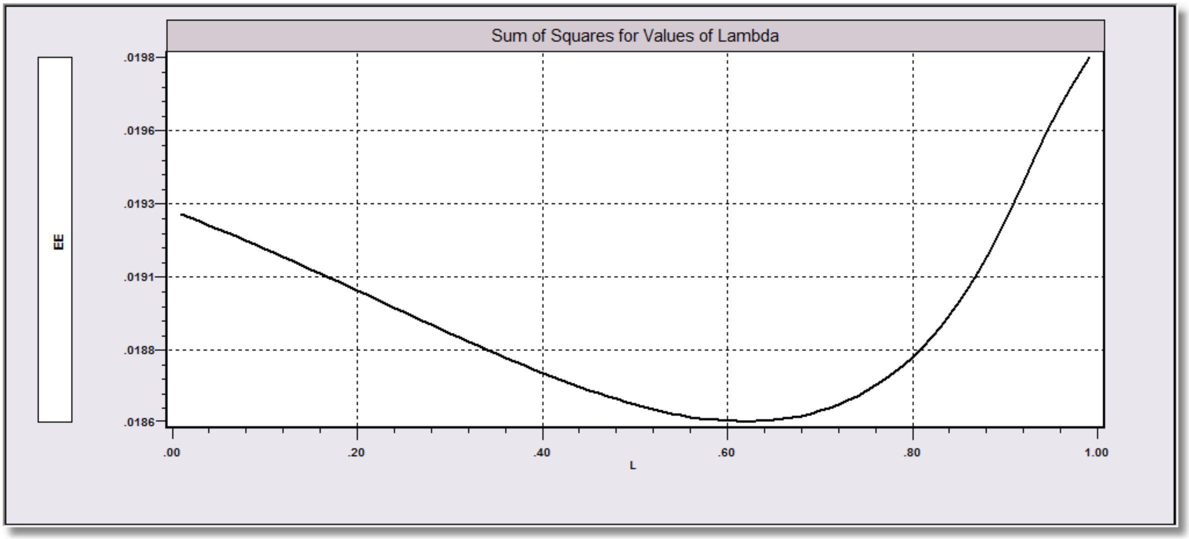

Figure E12.4 Plot of Sum of Squares

Assuming that we have found the optimal value of λ, we can now compute the appropriate asymptotic covariance matrix for the estimates. Let s^2 be the mean squared residual,

$$s^2 = (1/T)\Sigma_t e_t^2.$$

Let $\mathbf{W}(\lambda)$ be the $T\times 3$ regressor matrix used in the regression. Each row is $\mathbf{w}_t(\lambda) = [1, x_t^*, \lambda^t]$. Denoting the nonlinear least squares estimates by a, k, m^0, and l, we require the matrix

$$\text{Est.Var}[a, k, m^0, \ell] = s^2 \begin{bmatrix} \mathbf{W'W} & \mathbf{W'd} \\ \mathbf{d'W} & \mathbf{d'd} \end{bmatrix}^{-1}$$

where $\mathbf{d}$ is an extra column which accounts for the estimate of λ. Each element in $\mathbf{d}$ is

$$\begin{aligned} d_t &= \partial[a + kx_t^* + \lambda^t m^0]/\partial\lambda \\ &= t\lambda^{t-1}m^0 + k\partial x_t^*/\partial\lambda \\ &= t\lambda^{t-1}m^0 + k\delta_t. \end{aligned}$$

We can compute δ_t by using the recursion

$$\begin{aligned} \delta_1 &= 0, \\ \delta_2 &= x_1, \\ \delta_t &= x_{t-1}^* + \lambda\delta_{t-1} \text{ for } t > 2. \end{aligned}$$

(Because k is a function of β, a free parameter, we need not account for the presence of λ in k when we differentiate.) The procedure could be modified as follows:

```
PROCEDURE = GeoLag(y,x) $
```

Set up the iterations using two column vectors, a counter, and the parameter.

```
MATRIX      ; ee = Init(99,1,0) ; l = ee $
CALC        ; i = 1 ; eemin = 9999999 ; best = 0 ; lambda = .01 $
```

Execute the grid search.

```
DO WHILE    ; 10 ; i  <  100  $
CREATE      ; If(_obsno = 1) | z = lambda ; xstar = x $
CREATE      ; If(_obsno > 1) | z = lambda * z[-1]
            ; xstar = x + lambda * xstar[-1] $
REGRESS     ; Lhs = y ; Rhs = one,z,xstar ; Quietly $
MATRIX      ; ee(i) = sumsqdev ; l(i) = lambda
            ; If[sumsqdev < eemin] best = lambda
            ; eemin = sumsqdev $
CALC        ; i = i + 1 ; lambda = lambda+.01 $
ENDDO       ; 10 $
```

The grid search kept the optimal value. Now, compute the parts, run the regression, and get the covariance matrix.

```
CREATE      ; If(_obsno = 1) | z = best  ; xstar = x $
CREATE      ; If(_obsno > 1) | z = best * z[-1]
            ; xstar = x + best * xstar[-1] $
REGRESS     ; Lhs = y ; Rhs = one,z,xstar $
CREATE      ; delta = 0 $
CREATE      ; If( _obsno = 1) delta = 0 $
CREATE      ; If( _obsno = 2) delta = x $
CREATE      ; If( _obsno > 2) delta = xstar[-1] + best * delta[-1]
            ; t = Trn(1,1)
            ; d = b(2) * delta + t * b(3) * lambda^(t-1) $
NAMELIST    ; xs = one,xstar,z,d $
```

Display the full set of results.

```
MATRIX      ; var = ssqrd * <xs’xs>
            ; beta = [b/best] ;  Stat(beta,var,x) $
ENDPROC
```

We applied the preceding to the data given earlier, using the changes in the logarithms;

```
PERIOD      ; 1950.1 - 1980.4 $
CREATE      ; dlgnp = loggnp - loggnp[-1]
            ; dlm1  = logm1  - logm1[-1] $
PERIOD      ; 1950.2 - 1980.4 $
EXECUTE     ; Proc = GeoLag(dlgnp,dlm1) $
MPLOT       ; Lhs = l ; Rhs = ee ; Fill ; Endpoints = 0,1 $
```

```

HINT: In even a moderate sample, λ^t and δ_t may degenerate to sequences of zeros, and *LIMDEP* will return diagnostics about over- or underflows. The diagnostics can be ignored.

E12.4 Roots of Dynamic Equations

For the dynamic equation,

$$y_t = \gamma_1 y_{t-1} + \gamma_2 y_{t-2} + \ldots + \gamma_p y_{t-p} + \text{any other terms},$$

the characteristic equation is

$$1 - \gamma_1 z - \gamma_2 z^2 - \ldots - \gamma_p z^p = 0.$$

The difference equation is stable if all of the roots of this polynomial are outside the unit circle. (They may be complex.) The roots of the equation are the reciprocals of the characteristic roots of the matrix

$$\mathbf{A} = \begin{bmatrix} \gamma_1 & \gamma_2 & \cdots & \gamma_{p-1} & \gamma_p \\ 1 & 0 & \cdots & 0 & 0 \\ 0 & 1 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ 0 & 0 & \cdots & 1 & 0 \end{bmatrix}$$

If the root is a complex pair ($a \pm bi$), the reciprocal is ($a/M \mp b/Mi$), where $M = (a^2 + b^2)^{½}$, the modulus. In the **MATRIX** command

MATRIX ; Root(A) $

if **A** is a row or column vector, *LIMDEP* assumes that **A** is the set of lag coefficients of a difference equation. It then sets up the preceding matrix, computes the roots, and reports the reciprocals in the form of the complex pair. You can then compute the modulus of the smallest one and resolve the stability question. If **A** is not a vector, then *LIMDEP* assumes **A** is a symmetric matrix and reports the (real) characteristic roots.

For example: Is the equation $y_t = .7y_{t-1} - .5y_{t-2} + .3y_{t-3} + \varepsilon$ stable?

MATRIX ; List ; A = [.7, -.5, .3] ; Root(A) $

LIMDEP reports a 3×2 matrix,

```
       A|           1           2           3
--------+------------------------------------
       1|     .700000    -.500000     .300000
  Result|           1           2
--------+------------------------
       1|    .0586812     1.46563
       2|    .0586812    -1.46563
       3|     1.54930     .000000
```

The smallest root is greater than one, so the answer is yes.

A related computation is the stability of a dynamic system of linear equations. Greene (2011) discusses this at length. The computational aspect can be reduced to the following: The dynamic equation system, of any lag length, can be reconstructed in the form

$$\mathbf{y}_t = \mathbf{q}_t + \mathbf{R}\mathbf{y}_{t-1}.$$

Stability of the system depends on the characteristic roots of **R** being less than 1.0 in absolute value. To obtain the characteristic roots of a nonsymmetric matrix, then check the modulus of the dominant root, use

```
MATRIX    ; z  = Cxrt(r) $
CALC      ; List
          ; bigroot = z(1,1)^2  +  z(1,2)^2 $
```

The function Cxrt computes complex roots for nonsymmetric matrices. The result is a $K\times 2$ matrix whose first column is the real parts and the second column is the imaginary parts of the roots. K is the number of rows in the source matrix.

WARNING: The eigenvalue problem for nonsymmetric matrices must be solved iteratively, if it can be solved at all. It may, in fact, be impossible, to find the roots. If so, an error message is sent, instead of an answer.

Example

The data in Figure E12.5 are the classic 'Klein I' data used to build and test simultaneous equations estimators. (See Greene (2011, Chapter 10).)

Figure E12.5 Klein I Data

For Klein's Model I as estimated by two stage least squares, the relevant **R** matrix is

$$\mathbf{R} = \begin{matrix} 0.172 & -0.051 & -0.008 \\ 1.511 & 0.848 & 0.743 \\ -0.287 & -0.161 & 0.818 \end{matrix}$$

The command

MATRIX ; R = [.172, -.051, -.008 / 1.511, .848, .743 / -.287, -.161, .818]
; List ; Cxrt(r) $

produces

```
  Result|             1             2
--------+----------------------------
       1|       .769242      -.349385
       2|       .769242       .349385
       3|       .299516       .000000
```

which is the widely cited result. The modulus of the first root is .8448, so the system is, as expected, stable.

E13: The Box-Cox Regression Model

E13.1 Introduction

The Box-Cox transformation is $q^{(\gamma)} = (q^{\gamma} - 1)/\gamma$ or $\log(q)$ if $\gamma = 0$. The Box-Cox regression model is:

$$y^{(\theta)} = \boldsymbol{\beta}'\mathbf{x}^{(\lambda)} + \boldsymbol{\alpha}'\mathbf{z} + \varepsilon.$$

This model allows different transformations for the Rhs and Lhs variables. The vector **z** contains any variables to which the transformation should not be applied, for example dummy variables, etc. Four forms of the model may be estimated:

Model 1: transformation (λ) applied only to the Lhs variable, y,
Model 2: transformation (λ) applied only to the Rhs variables, x,
Model 3: same transformation (λ) for the Lhs, y, and Rhs, x, variables,
Model 4: different transformations (θ) for the Lhs and (λ) for the Rhs variables.

The estimator also allows heteroscedasticity:

$$\text{Var}(\varepsilon) = \sigma^2[w^2]^{(\lambda)}$$

where w is any variable. The same transformation that is applied to the right hand side is also applied to the weights.

The estimator is maximum likelihood. If only a single value of λ and/or θ are specified, the estimator is least squares conditioned on that (those) values. Otherwise, you may specify a grid search over values of λ with a fixed θ or a full algorithmic search over λ and θ for the fully general model.

E13.2 Model Commands

The essential command for the Box-Cox model is

BOXCOX ; Lhs = dependent variable
; Rhs = independent variables that are to be transformed
; Lambda = the value of λ $

Specifications **; Lhs**, **; Rhs**, and **; Lambda** are mandatory. This basic form requests Model 1, transformation of the Lhs variable by the value of λ that you specify. The standard errors of the estimates are estimated as if λ had been estimated by maximum likelihood.

Since the standard errors cannot be computed unless all transformed variables are strictly positive, the data are checked for this. Also, if heteroscedasticity is specified, the variable '*w*' must always be strictly greater than one, once again to prevent computing logs of negative numbers when computing standard errors and the log likelihood function.

E13.2.1 Specification of the Model

The four different variations are requested as follows:

Model 1: As above. **; Lambda = the specification of λ**

Model 1 specifies that only the Lhs variable is to be transformed. For any of the other three models, the Rhs variables are to be transformed, so the following will be very important. Add

; Rh2 = list of any variables which are not transformed

Of course, the constant term, *one*, is not transformed. You may include *one* in either Rhs or Rh2, or neither if you prefer. Note, as well that for Model 1, although you provide an Rhs list, all variables are actually of type Rh2. This is taken care of internally, and you need not worry about the distinction. For the other three forms of the model, you will use:

Model 2: **; Lambda = specification ; Model = 2**
Model 3: **; Lambda = specification ; Model = 3**
Model 4: **; Lambda = specification ; Theta = value ; Model = 4**

In Models 1-3, there are various specifications of **; Lambda**. But, in Model 4, you always provide only a single value of θ.

E13.2.2 Specification of the Estimation Method

You may specify that the model is to be estimated conditioned on the specific value(s) you specify for λ (and θ), or that a search for the optimal value(s) be undertaken. For searching, you may choose a grid search or a full algorithmic function optimization procedure. To compute estimates at a specific value for λ (and θ if Model 4), use:

; Lambda = the value [; Theta = the value for Model 4]

To specify a grid search over the range λ = lower to λ = upper, estimating the parameters at N values of λ including the endpoints use:

; Lambda = lower,upper ; Pts = number of points [; Theta = value]

θ is still fixed at the single value. The estimates are those in the specified range associated with the highest value of the log likelihood function. To do a full maximum likelihood estimation procedure for λ (and θ if Model 4), use:

; Lambda = value [; Theta = value is optional]
; MLE ; Model = 1,2,3 or 4

Note the inclusion of **; MLE**. In this case, you are providing the starting values for the transformation parameters. The starting values for the other parameters are obtained by ordinary least squares involving transformed variables. This can be used for any of the four models.

If your command specifies the MLE (**; MLE**), then you are using the general optimization program and the iteration control options are also available as listed below. You may still provide a grid of values for λ. If you do, and if the MLE happens to be in the grid you provide, **; MLE** will just fine tune the estimates. If the MLE is not in the grid, the grid search may have been a waste of time, but might still have improved the start value you provided.

E13.2.3 Starting Values

The starting values for ML iterations are obtained by ordinary least squares. If you have specified values for λ and/or θ, these are used for the transformation parameters. Either the grid search or estimation at a specific value will provide new estimates of the $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$ parameters. The transformation parameters, themselves, that you provide are the starting values for MLE. In any event, the **; Start = list of starting values** specification is not used by this estimator.

HINT: For some values of λ, the iterations will terminate with a message about a nonpositive variance. The problem is that for very high or very low powers, a variable can become just a column of zeros or simply too large. Rescaling the data may help.

E13.2.4 The Asymptotic Covariance Matrix

As noted earlier, we use the analytic second derivatives matrix to compute the estimated asymptotic covariance matrix of the estimated parameters. In the unusual case in which this is not positive definite, the Berndt, Hall, Hall, and Hausman estimator is used, instead. Although it is inadvisable, you can obtain (perhaps for comparison purposes) an estimated covariance matrix which takes λ and/or θ as fixed value(s) rather than an estimated parameter(s). The estimator is simply the conventional estimator from the least squares procedure. Request this estimator with

; Fixed

The literature varies on the method of computation of the asymptotic covariance matrix. Use of the BHHH estimator is common. Spitzer (1984) argues (incorrectly, in fact, as he neglects to account for the variation of the variance estimator) that one should not use the BHHH estimator, and that the Hessian is the appropriate choice. We use the Hessian. You may, if you wish, dictate that the variation in the transformation parameter(s) be ignored, in which case the covariance matrix of the estimates is simply what is produced by least squares.

E13.2.5 Model Specifications

This is the full list of general specifications for this nonlinear estimation program. Specific elements of the model command are detailed in Section E13.3.

Controlling Output from Model Commands

; Par keeps ancillary parameters in main results vector *b*.
; Margin displays marginal effects.
; Table = name saves model results to be combined later in output tables.

Display Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **Test: spec**.
; Maxit = 0 ; Start = the restricted values specifies the Lagrange multiplier test.

E13.3 Model Components

There are two additional specifications which modify the basic model.

E13.3.1 Heteroscedasticity

To request the heteroscedastic form of the disturbance variance, use:

; Wts = name of variable w

This model is different from other ones in *LIMDEP* in that you *do not* provide the reciprocals of the variances. The variable you give must be untransformed, since it will be transformed by this estimator. In addition, this variable must be strictly greater than 1.0 for all observations.

E13.3.2 Restrictions on Parameters

The preceding discussion shows, by implication, how to restrict λ and/or θ to specific values if you wish. Restrictions on the slope parameters $[\boldsymbol{\beta},\boldsymbol{\alpha}]$ cannot be imposed directly, except, of course, by building them into the model. For example, to force $\beta_j = \beta_k$, the *j*th and *k*th regressors need only to appear in the form of their sum to impose the restriction.

HINT: The scaling of the parameters in this model depends crucially on the transformation parameters. Thus, any nonhomogeneous restriction on the model parameters, e.g., $\beta_j+\beta_k = 1$, will be extremely problematic.

You can test restrictions, however, by the usual two methods. The

; Test: ...

specification can be used to test linear restrictions on the parameters. The parameter vector is exactly $[\boldsymbol{\beta},\boldsymbol{\alpha}]$ in the order of your **; Rhs,** then **; Rh2** lists. The other method is to use the *Last Model* formulation with the **WALD** command. The labels to use for this approach are given below with the listing of the saved results.

E13.4 Output and Saved Results

After the display of intermediate output from the minimization routine (if you use **; MLE**), this program displays the usual output for a regression model. This includes the initial table of fit measures and diagnostic statistics and the coefficient estimates, standard errors, t ratios, etc. The predicted values for this model are computed using:

$$y_i = \{\theta\,[\boldsymbol{\beta}'\mathbf{x}_i^{(\lambda)} + \boldsymbol{\alpha}'\mathbf{z}_i] + 1\}^{1/\theta}$$

Residuals are simply the difference between the actual value and the prediction. The additional variables, '*var*1' and '*var*2' usually shown in the listing are not computed for this model.

You may also display marginal effects for this model with

; Partial Effects

(In previous versions of *LIMDEP* and *NLOGIT*, the command was **; Marginal Effects**. This form is still supported, and has the same meaning in the current versions of *LIMDEP* and *NLOGIT*.)

For the Box-Cox model, the elasticities are

$$\partial \log y/\partial \log x = \beta(x^{\lambda})/(y^{\theta}),$$

so the marginal effects are

$$\partial y/\partial x = (y/x)(\partial \log y/\partial \log x) = \beta(x^{\lambda-1})/(y^{\theta-1}).$$

Values kept for later use are:

Matrices: *b* = slope coefficients
varb = estimated asymptotic covariance matrix

If you include **; Par** in the command, the additional parameters $[\lambda,\theta,\sigma^2]$ are included in *b* and *varb*.

epsilon = elasticities, $\partial \log y/\partial \log x_k$. This additional matrix contains elasticities for all of the Rhs and Rh2 variables in the model. These are computed at the sample means of all the exogenous variables according to the result above.

Scalars:

ssqrd	=	$\hat{\sigma}^2 = \mathbf{e}'\mathbf{e}/n$
s	=	$\sqrt{ssqrd}$
rsqrd	=	$1 - (\mathbf{e}'\mathbf{e}/n)/s_y^2$ (not necessarily positive)
sumsqdev	=	$\mathbf{e}'\mathbf{e}$
rho	=	0
degfrdm	=	*n*
nreg	=	*n*
sy	=	sample standard deviation of Lhs
ybar	=	sample mean of Lhs
logl	=	log likelihood function at best estimates
lmda	=	λ
theta	=	θ or 1 if Model 2 or λ if Model 1 or 3

Last Model: *b_variables* **; Rhs** and **; Rh2** are combined.

Last Function: None

Note, no function is stored for the **PARTIALS** and **SIMULATE** programs. However, partial effects and predictions are provided with the model command. You can also use **; Function = …** and provide your own specification of the Box-Cox model in either **PARTIALS** or **SIMULATE**.

E13.5 Application

To illustrate the Box-Cox model, we will use the macroeconomic data used in the application in Chapter E12. (See Section E12.2.4 for discussion.) We will fit several different forms of the Box-Cox model. We emphasize, for these data, the calculations are purely illustrative, and are not intended to provide any evidence about the interest elasticity of the demand for money. We precede estimation with:

```
DATES      ; 1950.1 $
PERIOD     ; 1950.1 - 2000.4 $
CREATE     ; lm = Log(m1) ; loggdp = Log(realgdp) $
NAMELIST   ; x = one,tbilrate,loggdp $
```

The first model specifies the log of *money* on the Lhs and transformations on the Rhs only.

```
BOXCOX     ; Lhs = lm ; Rhs = x
           ; Model = 2
           ; Lambda = -2,2
           ; Pts = 50
           ; List
           ; Partial Effects $
```

The next model specifies transformation of both sides of the equation.

```
BOXCOX     ; Lhs = m1 ; Rhs = one,tbilrate,realgdp
           ; Model = 3
           ; Lambda = -1,1
           ; Pts = 100 $
```

We now allow the estimator to find the MLE. The initial part of the search encounters some difficulties in optimizing the function, but after several iterations, the interior maximizer is found, actually near where the grid search located it in the previous command.

```
BOXCOX     ; Lhs = m1 ; Rhs = one,tbilrate,realgdp
           ; Model = 3
           ; Lambda = -1,1
           ; Pts = 100
           ; MLE $
```

Finally, we attempt a full ML estimation of Model 4. This is extremely sensitive to the starting values. The following terminates after 500 iterations. The values are similar to the estimates after 100 iterations.

```
BOXCOX     ; Lhs = m1 ; Rhs = one,tbilrate,realgdp
           ; Model = 4
           ; Lambda = 0.0
           ; Theta = .35
           ; MLE
           ; Maxit = 500 $
```

```

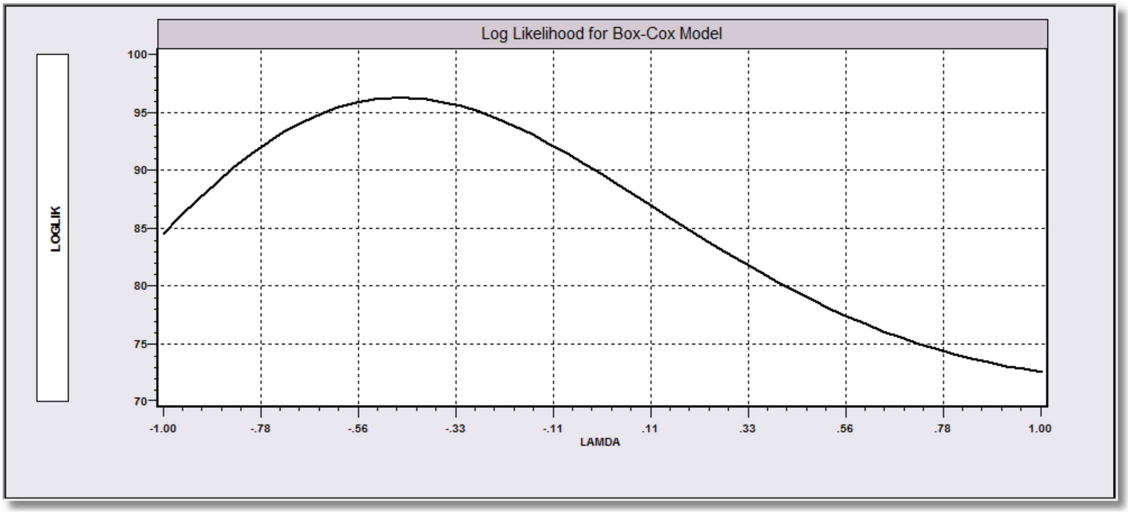

Figure E13.1 Plot of Log Likelihood for Box-Cox Model

E13.6 Technical Details

Estimation of the Box-Cox model is done in one of two ways. In the grid search procedure, the estimator is ordinary or weighted least squares. The following is needed for computation of the asymptotic covariance matrix. The maximum likelihood method is applied simply by treating the problem as an ordinary optimization problem.

The Box-Cox transformation of a variable x, for nonzero λ is:

$$x^{(\lambda)} = (x^{\lambda} - 1) / \lambda.$$

This transformation obeys the following differential equation for i = 1,...

$$d^i x^{(\lambda)}/d\lambda^i = [x^{\lambda} (\log x)^i - i(d^{i-1}x^{(\lambda)}/d\lambda^{i-1})] / \lambda.$$

The first term in the sequence is $x^{(\lambda)}$ when i=0. If λ equals 0, the preceding are replaced by:

$$x^{(0)} = \log x$$

and $$d^i x^{(\lambda)}/d\lambda^i{}_{|\lambda=0} = (\log x)^{i+1} / (i+1).$$

For purposes of the discussion to follow, it is convenient to define a notation for the function and its first and second derivatives. Thus, let

$$x_\lambda = dx^{(\lambda)}/d\lambda \quad \text{and} \quad x_{\lambda\lambda} = d^2x^{(\lambda)}/d\lambda^2.$$

The model is $$y^{(\theta)} = \Sigma_k\beta_k x_k^{(\lambda)} + \Sigma_m\alpha_m z_m + \varepsilon.$$

The xs are the Rhs variables subject to the transformation, and the zs are the Rh2 variables that are not transformed. The variance of ε is

$$\text{Var}[\varepsilon] = f = \sigma^2[w^2]^{(\lambda)}.$$

There are various restrictions on the general model which lead to the model estimated. The case of homoscedasticity is imposed by deleting the 'w' term from the model, not by a simple parametric restriction. (Setting w = 1 is insufficient, since $1^{(\lambda)} = 0$, not 1.) Other specifications are imposed by

Model 1: $\theta = \lambda$ and all regressors classified as Rh2.
Model 2: $\theta = 1$.
Model 3: $\theta = \lambda$.

The log likelihood for the Box-Cox model is

$$\text{Log}L = (\theta\text{-}1)\Sigma_i\log y_i - ½\Sigma_i[\log 2\pi + \log f_i + \varepsilon_i^2/f_i].$$

The first derivatives of the log likelihood are obtained as follows:

Let $$f_i = \sigma^2 \text{ or } \sigma^2[w\,]^{(\lambda)} \text{ whichever is appropriate.}$$

For a vector, $\mathbf{x}_i$, let $$\mathbf{x}_i^{(\lambda)} = \text{the vector of transformed variables, and}$$

$$\mathbf{x}_{i\lambda} = [x_{i1\lambda}, x_{i2\lambda},\ldots,x_{iK\lambda}]'.$$

Thus, $$\varepsilon_i = y_i^{(\theta)} - \boldsymbol{\beta}'\mathbf{x}_i^{(\lambda)} - \boldsymbol{\alpha}'\mathbf{z}_i.$$

So, $$\partial\log L/\partial\boldsymbol{\beta} = \Sigma_i[\varepsilon_i/f_i]\mathbf{x}_i^{(\lambda)},$$

$$\partial\log L/\partial\boldsymbol{\alpha} = \Sigma_i[\varepsilon_i/f_i]\mathbf{z}_i,$$

and $$\partial\log L/\partial\lambda = \Sigma_i[\varepsilon_i/f_i]\boldsymbol{\beta}'\mathbf{x}_{i\lambda}.$$

If the disturbance is heteroscedastic, add

$$\Sigma_i \{\tfrac{1}{2}(\varepsilon_i^2/f_i - 1)[w_i^2]_\lambda \,/\, [w_i^2]^{(\lambda)}\} \text{ to } \partial\text{logL}/\partial\lambda.$$

If the model is Model 1, 3, or 4,

$$\partial\text{log}L/\partial\theta \;=\; \Sigma_i[-\varepsilon_i/f_i]y_{i\theta} + \text{log}y_i.$$

If the model is Model 3, so that $\theta = \lambda$, ∂logL/$\partial\theta$ is added to ∂log$L$/$\partial\lambda$. It is omitted for Model 2. Finally,

$$\partial\text{log}L/\partial\sigma^2 \;=\; \Sigma_i \tfrac{1}{2}(\varepsilon_i^2/f_i - 1)/\sigma^2.$$

The BHHH estimator of the asymptotic covariance matrix of the estimator is obtained by summing the outer products of the individual terms listed in the summations above. The Hessian is obtained as follows: Let

$$\begin{aligned}
\boldsymbol{\delta}_i &= \boldsymbol{\beta}'\mathbf{x}_{i\lambda},\\
\gamma_i &= \boldsymbol{\beta}'\mathbf{x}_{i\lambda\lambda}, \text{ extending the vector notation defined above,}\\
w_{i\lambda}^{\;2} &= (\text{d}[w_i^2\,]^{(\lambda)}/\text{d}\lambda) \,/\, [w_i^2]^{(\lambda)},\\
w_{i\lambda\lambda}^{\;2} &= (\text{d}^2[w_i^2]^{(\lambda)}/\text{d}\lambda^2) - (w_{i\lambda}^{\;2})^2.
\end{aligned}$$

The last two terms are zero if the disturbance is homoscedastic. Denote second derivatives with subscripts;

$$\partial^2\text{log}L/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' \;=\; \text{H}_{\boldsymbol{\beta\beta}}.$$

For convenience, combine $\mathbf{x}^{(\lambda)}$ and $\mathbf{z}$ in vectors $\mathbf{v}_i = [\mathbf{x}_i^{(\lambda)}\,,\ \mathbf{z}_i]$, $\mathbf{v}_{i\lambda} = [\mathbf{x}_{i\lambda}\,,\ \mathbf{0}]$, $\mathbf{v}_{i\lambda\lambda} = [\mathbf{x}_{i\lambda\lambda}\,,\ \mathbf{0}]$. Derivatives with respect to $\boldsymbol{\beta}$ below include the vector $\boldsymbol{\alpha}$ defined above. Then, the Hessian is

$$\begin{aligned}
\text{H}_{\boldsymbol{\beta\beta}} &= \Sigma_i -(1/f_i)\mathbf{v}_i\mathbf{v}_i',\\
\text{H}_{\boldsymbol{\beta}\lambda} &= \Sigma_i\; (\varepsilon_i/f_i)[\mathbf{v}_{i\lambda} - w_{i\lambda}^{\;2}\mathbf{v}_i] \;-\; (\delta_i/f_i)\mathbf{v}_i,\\
\text{H}_{\lambda\lambda} &= \Sigma_i\; (\varepsilon_i/f_i)(_{\text{i}} - (\delta_i/f_i)(\delta_i{+}2\varepsilon_i w_{i\lambda}^{\;2}) + \;\tfrac{1}{2}[w_{i\lambda\lambda}^{\;2}(\varepsilon_i^2/f_i - 1) - (\varepsilon_i/f_i)(w_{i\lambda}^{\;2})^2],\\
\text{H}_{\boldsymbol{\beta}\theta} &= \Sigma_i\; (y_{i\theta}/f_i)\mathbf{v}_i,\\
\text{H}_{\lambda\theta} &= \Sigma_i\; (y_{i\theta}/f_i)[\delta_i + w_{i\lambda}^{\;2}\varepsilon_i],\\
\text{H}_{\theta\theta} &= \Sigma_i -(1/f_i)[y_{i\theta\theta}\varepsilon_i + (y_{i\theta})^2],\\
\text{H}_{\sigma\boldsymbol{\beta}} &= \Sigma_i -(\varepsilon_i/f_i)\mathbf{v}_i/\sigma^2,\\
\text{H}_{\sigma\lambda} &= \Sigma_i -(\varepsilon_i/f_i)\delta_i/\sigma^2,\\
\text{H}_{\sigma\theta} &= \Sigma_i\; (\varepsilon_i/f_i)\text{y}_{i\theta}/\sigma^2),\\
\text{H}_{\sigma\sigma} &= \Sigma_i\; (\tfrac{1}{2} \;-\; \varepsilon_i^2/f_i)/\sigma^4).
\end{aligned}$$

The foregoing applies to Model 4. If the model is Model 3, then terms involving θ are simply added to terms involving λ. If the model is Model 2, terms involving θ are dropped. The first of these can be accomplished as follows: When $\theta = \lambda$,

$$H_{\beta\lambda} \text{ (new)} = [H_{\beta\lambda} + H_{\beta\theta}] \text{ (old)},$$

$$H_{\sigma\lambda} \text{ (new)} = [H_{\sigma\lambda} + H_{\sigma\theta}] \text{ (old)},$$

and

$$H_{\lambda\lambda} \text{ (new)} = [H_{\lambda\lambda} + H_{\theta\theta} + 2H_{\lambda\theta}] \text{ (old)}.$$

E14: Nonlinear Least Squares

E14.1 The Nonlinear Regression Model

This chapter details nonlinear least squares estimation of the general nonlinear regression model

$$y_i = f(\mathbf{x}_i,\boldsymbol{\beta}) + \varepsilon_i.$$

The function f(•,•) may be any function that is continuous in the parameters. Four estimation methods may be used:

- nonlinear ordinary least squares estimation,
- nonlinear weighted least squares estimation,
- nonlinear two stage least squares (instrumental variables - IV) estimation,
- GMM estimation.

The first two are described here. The IV estimation techniques are presented in Chapter E21. (Weights may be used with the latter two estimators as well.) GMM estimation is presented in Chapters E21 and E23.

The essential command fitting nonlinear regression models with nonlinear least squares is

NLSQ ; Lhs = dependent variable
; Fcn = the definition of the nonlinear regression function
; Labels = symbols to use for the parameters to be estimated
; Start = the starting values for the iterations $

The basic command specifies nonlinear ordinary least squares. That is, you would instruct *LIMDEP* to choose the **β** to

$$\text{Minimize wrt } \boldsymbol{\beta} \;\; \tfrac{1}{2}\Sigma_i\, [y_i - f(\mathbf{x}_i,\boldsymbol{\beta})]^2 = \tfrac{1}{2}\Sigma_i\, \varepsilon_i^2.$$

If the function you specify is linear, this will produce the ordinary least squares results. To request nonlinear weighted least squares, you will specify

; Wts = weighting variable

as usual. The estimation criterion is then,

$$\text{Minimize wrt } \boldsymbol{\beta} \;\; \tfrac{1}{2}\Sigma_i\, w_i[y_i - f(\mathbf{x}_i,\boldsymbol{\beta})]^2 = \tfrac{1}{2}\Sigma_i\, w_i\, \varepsilon_i^2.$$

where w_i is the weighting variable. If this is a correction for heteroscedasticity, the weighting variable should be the reciprocal of the disturbance variance, not the standard deviation.

E14.2 Command for Nonlinear Regression

The essential command for this estimator provides four sets of information:

```
NLSQ        ; Lhs = dependent variable
            ; Fcn = specification of f(•,•)
            ; Labels = the labels for the model parameters
            ; Start = starting values for the parameters $
```

This requests ordinary, unweighted, nonlinear least squares estimates. To use weighted least squares, instead, add

```
            ; Wts = weighting variable
```

to the command. Your function may contain up to 150 parameters to be estimated.

The Lhs, function and starting values are all mandatory. This list of starting values provides the initial values for the iterations for the estimator, and also tells *LIMDEP* how many parameters are being estimated. Thus, it is essential for you to be accurate in your specification of the starting values. You may use any of the methods discussed elsewhere in this manual to provide the list of starting values. These may appear in a vector or a matrix (read rowwise), a list of specific values, or in scalars that have been defined earlier. For example, the following passes on a set of OLS slopes, the estimated standard deviation of the disturbance, and the value 1.0 as starting values for a model:

```
NAMELIST    ; x = ... $
REGRESS     ; Lhs = y
            ; Rhs = x ; ... $
NLSQ        ; Lhs = ...
            ; Fcn = ...
            ; Start = b, ssqrd, 1.0 ; ...
            ; Labels = ...  $
```

The number of parameters would be two plus the number of variables in the namelist.

The labels are optional. If you do not provide labels for your parameters, they will be automatically named *b*1, *b*2, ..., *bK*, where *K* is the number of starting values you provide. For example, the following specifies a linear regression model:

```
NLSQ        ; Lhs = logy
            ; Fcn = b1 + b2*x2 + b3*x3
            ; Start = 0,0,0 $
```

Note that three parameters are defined by the starting value list. You will usually wish to use your own labels. To do so, use

; Labels = a list of labels, one for each starting value.

TIP: See Section E14.3.5 for an extremely useful device for defining labels in the command. You may also use the labels defined by a **CLIST** command. See Section R6.6.

TIP: Be careful to make sure that the labels you choose are not the same as other items you have created, such as matrices or scalars. In most cases, if you try to use a label that is already the name of a variable or a matrix or a scalar, *LIMDEP* will catch the error and issue an error message. But, there are ways that you can accidently avoid this filter, and this will lead to unexpected (and unwanted) results.

The preceding command could be changed to

```
NLSQ     ; Lhs = logy
         ; Fcn = gamma0 + thetak*x2 + thetal*x3
         ; Labels = gamma0,thetak,thetal
         ; Start = 0,0,0 $
```

LIMDEP will ensure that there is a correspondence between your labels and your starting values. However, it is not possible for the program to ensure that you have used all of the parameters in your function specification. If you define a parameter, but you do not use it in your function definition, then one of two things will occur. Either the iterations will never converge and they will exit on maximum iterations, with one of the parameters not changing from its initial value, or what appears to be convergence will be reached, but the estimated covariance matrix of the estimated parameters will be singular, as it will contain a row and column of zeros corresponding to the unused parameter. Here is an example. Note that the defined model parameter *c*3 does not appear in the regression function.

```
NLSQ     ; Lhs = y
         ; Fcn = c0+c1*x1+c2*x2
         ; Start = 0,0,0,0
         ; Labels = c0,c1,c2,c3
         ; Output = 3 $
```

```

E14.3 Specification of the Regression Function

NLSQ minimizes the sum of squared residuals. Your function defines the Rhs of the regression for an observation. The **; Fcn** specification is written using the rules and operators of algebra (+, -, *, /, ^). Parentheses may be used freely to force the order of evaluation of expressions. Use as many levels of parentheses as required. Entities which may appear in the specification include:

- variable names,
- any existing scalars,
- matrix elements,
- your parameters, using your labels.

Because there are a variety of named entities which can appear in the function, you should use the

; Labels = list of labels

part of the command to identify which of them are the parameters being estimated. You must then use these labels in the function you specify. Labels may be anything you like, up to eight characters.

WARNING: Use new names! Do not use program names that are in use otherwise, such as *s*, *rho*, *sigma*, *b*, etc., or the names of existing scalars or matrices. Such labels might be accepted when your command is translated, because you are free to use these entities in your function definition to supply specific values. But, later, when *LIMDEP* scans your expression to see what you have specified, it checks all other tables first, and your label list last. For example, if you use *s* as a label, and this command is the first model command that you have given, *s* will simply be taken as the as yet undefined result of a regression. The actual value would, in fact, always be fixed at 0.

The operators are +, -, *, /, ^ (for raise to the power), and @ (for the Box-Cox transformation). The usual rules are observed; ^ and @ are computed first, then * and /, and finally + and -. The CES production function provides an example. The Lhs variable in the equation might be *q*, and the command could be

```
REGRESS    ; Lhs = Log(q) ; Rhs = one,Log(k),Log(l) $
CALC       ; dkl = b(2)/(b(2)+b(3)) ; sc = b(2)+b(3) $
NLSQ       ; Lhs = q
           ; Labels = gamma,delta,r,nu
           ; Fcn = gamma * (delta*k^(-r) + (1-delta)*l^(-r)) ^ (-nu/r)
           ; Start = b(1), dkl, 1.0, sc $
```

Lastly, to use a subscripted matrix element, enclose the subscript in curled brackets, **{ }**, not parentheses. I.e., **gamma(1,1)** will confuse the compiler, use **gamma{1,1}**.

NOTE: This construction, with curled brackets, is specific to the function definition part of the **NLSQ**, **NLSUR**, **MAXIMIZE**, and **MINIMIZE** commands. Elsewhere, such as in **CALC** and **CREATE**, matrix subscripts are indicated with ordinary parentheses. Curled brackets also have a different use in **MATRIX**, but are not used in **CREATE** or **CALC**.

E14.3.1 Parameterization and Reparameterization

We will revisit this issue at several points below. In specifying a nonlinear optimization, it is often helpful to parameterize the model in such a way as to remove some of the nonlinearity. (This discussion applies generally to the several procedures in *LIMDEP* that use a user defined nonlinear optimization, and, more broadly, to optimization in general regardless of what software you might be using.) Nonlinear functions can often be written in several ways. For example:

```
NLSQ    ; Lhs = y
        ; Labels = b0, b1, b2
        ; Start = 0, 0, .5
        ; Fcn = (b0 + b1*x)^(-1/b2)  $
```

is a valid specification of the nonlinear regression model. However, with a particular data set, it is possible that the iterative procedure searching for the parameters could be unable to find a minimizer, and might break down. This can happen for several reasons. One strategy for dealing with the problem, and more generally, for facilitating estimation, is to remove unnecessary nonlinearities, such as the reciprocal of *b*2 that appears above. Even the minus sign is superfluous. The same model could be fit, possibly with greater ease, by specifying it as

```
NLSQ    ; Lhs = y
        ; Labels = b0, b1, b2
        ; Start = 0, 0, -2.0
        ; Fcn = (b0 + b1*x)^c2 $
```

Note that the -1/*b*2 has been replaced with the much simpler *c*2. Also, the starting value has been changed accordingly, from 0.5 to -2.0 = -1/0.5. If the parameter *b*2 were of particular interest, you could follow the **NLSQ** command with a

```
WALD    ; Fn1 = -1/b2  $
```

The other parts of the **WALD** command are automatic if it follows an optimization command.

The opportunities for simplification are sometimes subtle, but it helps to take them when they are available. In the CES function example at the end of the preceding section, there are two superfluous nonlinearities: The function can be specified using

```
CALC    ; sc = -sc $
NLSQ    ; Lhs = q
        ; Labels = gamma,delta,r,theta
        ; Fcn = gamma * (delta*k^(-r) + (1-delta)*l^(-r)) ^ theta
        ; Start = b(1), dkl, 1.0, sc $
```

In this example, the (-*nu*/*r*), which involves a multiplication and a reciprocal is replaced with the simpler parameter, *theta*. In fact, *theta* equals -*nu*/*r*, but since *nu* is a free parameter that appears nowhere else in the function, we can treat -*nu*/*r* as this free parameter. If *nu*, itself, is desired,

```
WALD    ; Fn1 = -r * theta $
```

would compute the estimate as well as an appropriate asymptotic standard error.

E14.3.2 Functions that May Appear in NLSQ Commands

The following functions may be used in the regression specification:

Abs(z)	= absolute value
Ac1(z)	= derivative of Ach(z) = $(z^2 - 1)^{-1/2}$
Ach(z)	= hyperbolic arc cos(z) = log(z + (z^2 – 1))
As1(z)	= derivative of Ash(z) = $(1 + z^2)^{-1/2}$
Ash(z)	= hyperbolic arc sin(z) = log($z + (1 + z^2)^{1/2}$)
At1(z)	= derivative of Ath(z) = $(1 - z^2)^{-1}$
Ath(z)	= hyperbolic arc tan(z) = .5log((1 + z)/(1 – z))
Atn(z)	= arctangent
Bds(z,a,c)	= incomplete beta function; (Bds(0,a,c) = 0, Bds(1,a,c) = 1)
Bv1(z1,z2,ρ)	= bivariate normal CDF derivative wrt x1
Bv2(z1,z2,ρ)	= bivariate normal CDF derivative wrt x2
Bvd(z1,z2,ρ)	= bivariate normal density
Bvn(z1,z2,ρ)	= bivariate normal CDF
Cos(z)	= cosine
Exp(z)	= exponent
Gma(z)	= gamma
Hc1(z)	= derivative of Hcs(z) = Hsn(z)
Hcs(z)	= hyperbolic cos(z) = .5(exp(2z)+1)/exp(z)
Hs1(z)	= derivative of Hsn(z) = Hcs(z)
Hsn(z)	= hyperbolic sin(z) = .5(exp(2z)-1)/exp(z)
Ht1(z)	= derivative of Htn(z) = 1/Hcs^2(z)
Htn(z)	= hyperbolic tan(z) = Hsn(z)/Hcs(z)
Inp(z)	= inverse of standard normal CDF
Lgd(z)	= logit density = Lgp*(1-Lgp)
Lgm(z)	= log of gamma
Lgt(z)	= logit = log(z/(1-z))
Lgp(z)	= logit probability = 1/(1+Exp(-z)) = Prob($Z \le z$)
Lmm(z)	= -N01(z)/Phi(z) = E[z | $z \le 0$] for z ~ N[0,1]
Lmp(z)	= N01(z)/Phi(-z) = E[z | $z \ge 0$] for z ~ N[0,1]
Log(z)	= natural logarithm
Max(z1,z2)	= maximum
Min(z1,z2)	= minimum
N01(z)	= standard normal density
Phi(z)	= standard normal CDF
Psi(z)	= log derivative of Gma, $\Psi = \Gamma'/\Gamma$
Psp(z)	= $\Psi' = \Gamma''/\Gamma - \text{Psi}^2$
Sgn(z)	= signum = -1 if z < 0, 0 if z = 0, +1 if z > 0
Sin(z)	= trigonometric sine
Tvm(z)	= 1 - Lmm × (z + Lmm) = Var[z | z < 0] for z ~ N[0,1]
Tvp(z)	= 1 - Lmp × (z + Lmp) = Var[z | z < 0] for z ~ N[0,1]

The incomplete beta function is

$$\text{Bds}(z,a,c) \;=\; \frac{\Gamma(a)\Gamma(c)}{\Gamma(a+c)}\int_0^z \; t^{a-1}(1-t)^{b-1}dt \text{ for } 0 < z < 1.$$

In the beta and bivariate normal functions, if any of the parameters separated by commas are expressions, it is necessary to enclose them in parentheses. I.e., use **Bvn((1+x'b),z,r)**, not **Bvn(1+x'b,z,r)**. The list may contain variables, labels, scalars, and expressions contained in parentheses. Functions may be nested to any depth and expressions may appear as arguments in the functions, as in

; Fcn = Log (Phi(a1 + a2 * (x/y)^2)).

This would be a valid expression and would evaluate exactly as given.

E14.3.3 Linear Functions and Dot Products

Many expressions in econometric models will involve dot products of parameters and variables. For example, a model built as an extension of a probit model will likely involve an expression of the form **Phi(b'x)**. Dot products may appear in exactly this form in your function definitions. Typically, the '**x**' would be a namelist. To use the parameter vector, use the first name in your labels list. For example, in

```
NAMELIST    ;  x = one,x1,z,p  $
NLSQ        ; Labels = b0,b1,b2,b3
            ; Fcn = ... Phi(b0'x)  ; ... $
```

the term **b0'x** is evaluated as $b0\times one + b1\times x1 + b2\times z + b3\times p$. Once again, in a dot product, the sum is evaluated from left to right using your list of labels in the order in which they appear in **; Labels = list**. If the namelist and the labels list do not have the same number of elements, then the dot product is simply evaluated out to the shorter of the two lists. In the example, if there were additional names in *x*, they would not change **b0'x** because starting at *b*0, there are only four parameters.

NOTE: This replaces the function Dot[.] used in earlier versions of *LIMDEP*. The Dot[.] function is retained for backwards compatibility, though you will probably find it easier to use the more natural syntax. Also, the operation described above does allow a bit more flexibility. For completeness, we note the counterparts to the constructions described above are **Dot[x]** = **b0'x** and **Dot[b3,second]** = **b3'second**. You may use either form.

Suppose you want to pick up just a few of the parameters in a dot product. For example, suppose your parameters are **; Labels = b1,b2,b3,b4,b5,b6,b7** and as part of your function, you want $b3*x14 + b4*xyz + b5*wvs$. You could first define the namelist for the dot product function, with, say,

```
NAMELIST    ; second  = x14,xyz,wvs $
```

Then, to obtain that function, just begin the dot product with **b3** instead of **b1**. Thus, **b3'second** evaluates exactly to $b3*x14 + b4*xyz + b5*wvs$.

It is also possible to skip over parameters in dot products, by putting columns of zeros in your namelists. This may be convenient in specifying your function, especially if it involves many parameters. For example, using the list above, you could obtain $b2 \times x14 + b5 \times xyz$

```
CREATE      ; zero = 0 $
NAMELIST    ; second = x14,zero,zero,xyz $
NLSQ        ; ... b2'second ...
```

Dot products need not be only a mix of variables and parameters. They may also include vectors (matrices) that do not appear elsewhere in the function, and they may be products of variables or parameters. When you are specifying your functions, there are several ways you can shorten your commands by making use of the dot product notation, and using lists. The following constructions can all be used in specifying your functions: Let

a and **d** denote the names of any vectors in your matrix work area,
x and **y** denote the names of any namelists,
cj be any of the labels in your **; Labels = ...** specification.

Then, any of the following can appear in your function

a'a = inner product of the vector,
a'd = dot product of two vectors,
a'x = linear combination of variables, for each observation,
x'y = sum of cross products of the variables, at each observation,
x'x = sum of squares of observation on variables,
cj'a = product of vector elements and parameters,
cj'x = the familiar index function product of coefficients and variables.

Products can be computed beginning with any of the parameters in the list. For example, consider fitting a probit model by least squares (rather than maximum likelihood):

```
NLSQ        ; Lhs = y
            ; Labels = a1,a2,a3
            ; Start = 0,0,0
            ; Fcn = Log(Phi(2*(y-1)*(a1 + a2*x1 + a3*x2))) $
```

Alternatively, with

```
NAMELIST    ; xa = one,x1,x2  ; xb = x1,x2 $
```

Then

```
            ; Fcn = Log(Phi(2*(y-1) * a1'xa))
```

is the same as

```
            ; Fcn = Log(Phi(2*(y-1) * (a1 + xb'a2))).
```

E14.3.4 Bilinear and Quadratic Forms

Bilinear and quadratic forms may also appear in function definitions. Suppose that *c* and *d* indicate elements of the parameter vector, which point to specific parts of the vector, and **z** is a namelist and **A** is a matrix. The following forms may appear in your function definition

(bilinear) **c'**[**z**]**d** $= \Sigma_j \, c_j \, d_j \, z_j$,

c'[**z**]**c** $= \Sigma_j \, c_j^2 z_j$

(quadratic) **c'**[**A**]**c** $= \Sigma_j \Sigma_l \, c_j \, c_l \, A_{jl}$

E14.3.5 Automatically Generating a List of Labels

For large problems, you may use a shortcut for the labels definition,

; Labels = number_label

produces 'number' sequentially numbered repetitions of the label. For example, **5_b** gives **b1,b2,b3,b4,b5**. The number may be a literal value or a scalar. With this device, you can make your model command independent of the size of the model, and you can accommodate a model of any size. For example:

```
NAMELIST    ; xa  =  ... (up to 150 names)
            ; xb  =  ... (up to 150 names) $
CALC        ; ka  =  Col(xa)
            ; kb  =  Col(xb) $
MATRIX      ; ca  =  Init(ka,1,0.)
            ; cb  =  Init(kb,1,0.0) $
NLSQ        ; Lhs =  y
            ; Start =  ca,cb,
            ; Labels =  ka_ba , kb_bb
            ; Fcn =  Index = ba1'xa  +  bb1'xb |
                     ... the rest of the function $
```

This template could be used for a model of any size. Only the namelists would have to be changed from one specification to another.

E14.3.6 Lists of Labels

The label list may be the object of a **CLIST** command. For example,

```
CLIST       ; probfn = pr0,pr1,pr2 $
NLSQ        ; …
            ; Labels = probfn $
```

E14.4 Quadrature and Simulation

You can use the function optimization programs such as **NLSQ** to maximize or minimize functions that contain integrals of the form

$$F(\boldsymbol{\beta}) \;=\; \int_{-\infty}^{\infty} \exp(-v^2)G(\boldsymbol{\beta},v)dv$$

by using Gauss-Hermite quadrature. This is a very accurate approximation which is computed using

$$F(\boldsymbol{\beta}) \;\approx\; \sum_{h=1}^{H} w_h G(\boldsymbol{\beta}, z_h)$$

where H is the number of points for the quadrature, w_h is the weight and z_h is the node at point h of the quadrature. You set the number of points, H for the quadrature. The G(.) function is unrestricted – it can be any function that is allowable in **NLSQ**, **NLSURE**, **MINIMIZE**, or **MAXIMIZE**. The variable of the integration, v, may or may not actually appear in the function. (Exp($-v^2$) integrates to sqr(π), so if v does not appear in G(.,.), then $F(\boldsymbol{\beta})$ will equal sqr(π)$G(\boldsymbol{\beta})$.) You can also include functions of the form

$$F(\boldsymbol{\beta}) \;=\; \int_{0}^{\infty} \exp(-v\ \ )G(\boldsymbol{\beta},v)dv$$

(notice that the exponent is exp($-v$) rather than exp($-v^2$), and the range of integration is from 0 to +∞ rather than from -∞ to ∞. Integrals of this form are accurately approximated using Gauss-Laguerre integration, rather than Gauss-Hermite integration. Finally, you can include functions that include subfunctions that are expectations of the form

$$F(\boldsymbol{\beta}) \;=\; E_v\,[F(\boldsymbol{\beta},v)].$$

where v is distributed as standard normal. These can be approximated quite accurately by simulation, by using

$$F(\boldsymbol{\beta}) \;\approx\; (1/R)\sum_{r=1}^{R} \;F(\boldsymbol{\beta},v_r)$$

where v_r is one of a sufficiently large R random draws from the standard normal distribution.

To use one of these integrals in your regression function, you must set up the operation as follows:

NLSQ **; Lhs = dependent variable**
; Fcn = name = Ntg(the function to be integrated) | the rest of the function, which will probably involve 'name'
; Hrq = name of the variable over which integration is done for Hermite integration
or **; Glq = name** of the variable over which integration is done for Gauss-Laguerre integration
or **; Sim = name** of the variable over which summation is done for integration by simulation
; Start = parameter values, as usual
; Labels = labels for parameters in the model, as usual
; other options $

Note the ' | ' at the end of the first line of the function definition. The function is being defined recursively. Recursive function definitions are described in the next section. The following requirements apply:

- You can have more than one integral in the final function, but each must be a named subfunction. If you specify 'Ntg(...)' within a function definition, an error will occur during compilation claiming that you have an unidentified symbol.

- Integrals should not be functions of other integrals. The results will be unpredictable, and almost certainly incorrect.

- You may have only one kind of integral in your function definition. Each Hrq, Glq, or Sim which appears in a command overrides previous ones.

To set the number of points for the approximation, you will use (as with other applications)

; Hpt = number of points for Hermite quadrature
; Lpt = number of points for Laguerre quadrature
; Pts = number of points for simulations

See Section R26.7 for discussion of the available values for these parameters.

NOTE: The seed for the random number generator is set to the same value each time a computation is done for a specific individual. Thus, you can replicate a computation done earlier by setting the main seed for the program before estimation.

Two examples follow. Note that this is not necessarily a 'good model,' and unless the data actually do satisfy the assumptions of the model, estimation will not produce very appealing results. (One would not normally fit a probit model by nonlinear least squares.) The example is intended only to illustrate use of the tools.

Heterogeneity in a Probit Model

Consider a probit model in which there is normally distributed, unobserved individual heterogeneity,

$$y = 0 \text{ or } 1,$$

$$\text{Prob}[\, y = 1 \mid v\,] = \Phi(\boldsymbol{\beta}'\mathbf{x} + \theta v) \text{ where } v \text{ is standard normally distributed.}$$

(A nonunitary standard deviation of v would be absorbed into the free parameter θ.) The probability that enters the log likelihood is Prob[y = 1] = E_v [Prob[y = 1 | v]]. The expectation is exactly equal to

$$\text{Prob}\,[\, y = 1\,] = \int_{-\infty}^{\infty} (1/\sqrt{2\pi})\exp(-v^2/2)\Phi(\boldsymbol{\beta}'\mathbf{x} + \theta v)dv = P(y).$$

In the integral, let $u = v/\sqrt{2}$, so $v = u\sqrt{2}$. Make the change of variable in the integral, to produce

$$\text{Prob}\,[\, y = 1\,] = \int_{-\infty}^{\infty} (1/\sqrt{\pi})\exp(-u^2)\Phi(\boldsymbol{\beta}'\mathbf{x} + \theta u\sqrt{2})du = P(\text{y})$$

This is now exactly in the form noted earlier for Hermite quadrature. (It can be simplified a bit more by defining $\gamma = \sqrt{2}\,\theta$.) The model could be estimated with the commands

```
NAMELIST    ; x = ... list of variables $
PROBIT      ; Lhs = y ; Rhs = x $
CALC        ; kx = Col(x) $
NLSQ        ; Lhs = y              ? Note the separator for the subfunction.
            ; Labels = kx_b, c
            ; Start = b, 0
            ; Fcn = Prob = Ntg(1/Sqr(pi) * Phi(b1'x + c*u)) | Prob
            ; Hrq = u
            ; Hpt = 20 $
```

A second way to approximate the expected value would be by simulation and averaging. That is, the probability can be approximated by averaging the probabilities obtained with a sample of random draws from the distribution of v. The change in the preceding would be only to the method of integration. The resulting **NLSQ** command would be

```
NLSQ        ; Lhs = y
            ; Fcn = Prob = Ntg(1/Sqr(pi) * Phi(b1'x + t*Sqr(2)*u)) | Prob
            ; Start = b, 0
            ; Labels = kx_b, t
            ; Sim = u
            ; Pts = 100 $
```

E14.5 Recursive Functions

There are many settings in which certain parts of a regression function or a minimand involve constructions that appear more than once in a function. For example, consider the nonlinear regression function

$$E[y|\mathbf{x}] = \boldsymbol{\beta}'\mathbf{x} + \sigma \times \phi((L\text{-}\boldsymbol{\beta}'\mathbf{x})/\sigma) / \Phi((L\text{-}\boldsymbol{\beta}'\mathbf{x})/\sigma)$$

(this is the conditional mean function for a truncated regression model). Based on the preceding, the function could be specified with

```
NAMELIST    ; x = ... $
NLSQ        ; Lhs = y
            ; Start = the set of starting values
            ; Labels = b0,b1,b2,...,sg
            ; Fcn = b0'x + sg * N01((L-b0'x)/sg) / Phi((L-b0'x)/sg) $
```

The string **(L-b0'x)/sg** appears twice in the function definition. (In some settings, this sort of construction could appear many times.) You can build up such a function recursively by defining parts of it by name, then using the names of the parts later in the function. For the example above, an alternative form would be

```
; Fcn = dev = (L-b0'x)/sg                  |
        b0'X + sg*N01(dev)/Phi(dev)
```

The general form of a recursive definition is

```
; Fcn = name = string                      |
        ... next string can use name ...   |
        ...                                |
        function
```

Note that the ‘ | ’ character is used to separate the named strings from the parts that use them later. The last substring to be evaluated must produce the desired function. You may define up to 49 substrings in this fashion – the 50th would have to give the function, itself. Also, subfunctions may use earlier subfunctions. For examples,

```
; Fcn = cx   = c0+c1*x     |
        e    = y-cx        |
        e^2
```

or

```
; Fcn = cx   = c0+c1*x     |
        e    = y-cx        |
        esq  =  e^2        |
        e^2 + esq^2
```

NOTE: Functions are interpreted from left to right, or top to bottom. If you use a name which is defined *after* the function you are defining, an error will occur in which the name you are using does not appear to have been defined.

E14.6 Providing Analytic Derivatives

In computing nonlinear least squares estimates, *LIMDEP* uses numeric (synthetic) derivatives of the sum of squares. You can provide your own derivatives for some or all of the parameters in the function as follows: The regression function is $f(\beta_1,...,\beta_K$, anything else). You can provide derivatives for the regression function (not the sum of squares). Derivatives are specified in the same fashion as the subfunctions above, except that the name is the parameter label, preceded by an underscore. For example, suppose we were estimating a probit model by nonlinear least squares. The conditional mean would be $\Phi(\boldsymbol{\beta}'\mathbf{x})$, and the derivative vector is $\phi(\boldsymbol{\beta}'\mathbf{x}) \times \mathbf{x}$. Use

```
NLSQ      ; ... ; Labels = c0, c1
          ; Fcn = cx    = c0 + c1*x   |
                  fcx   = N01(cx)     |
                  _c0   = fcx         |
                  _c1   = fcx *x      |   Phi(cx) $
```

The function definition above contains both a subfunction and analytic derivatives. You may provide derivatives for any of the parameters, or all of them. Any derivatives that are not provided are evaluated numerically. Regardless of the complexity of the function, there is no difference in the amount of time saved by giving explicit derivatives for one parameter as opposed to another. Some time is saved if all derivatives are provided compared to just some of them.

WARNING: If the derivatives that you provide do not match the function, the optimization procedure will eventually break down, claiming to be unable to minimize the function.

To illustrate the use of analytic derivatives, we use one of the National Institute of Standards and Technology (NIST) benchmark problems for testing nonlinear regression programs. This test problem may be found at http://www.itl.nist.gov/div898/strd/nls/data/hahn1.shtml. The data are at the same site. (See Section E14.13 for further details.) The nonlinear regression model is

$$\text{Hahn1 Function: } y = \frac{\beta_1 + \beta_2 x + \beta_3 x^2 + \beta_4 x^3}{1 + \beta_5 x + \beta_6 x^2 + \beta_7 x^3} + \varepsilon \quad \text{(average level of difficulty)}$$

```
Description:   These data are the result of a NIST study involving
               the thermal expansion of copper.  The response
               variable is the coefficient of thermal expansion, and
               the predictor variable is temperature in degrees kelvin.

```

The NIST problems are provided with two sets of starting values for the iterations, as seen in the example above. The first set of values are always farther from the solution than the second, so estimation beginning with the first set is always ‘harder’ than with the second set. In the following, we solve the problem from the first set of starting values. (We chose this particular problem out of the 27 problems provided because *LIMDEP* is able to solve all but three, including this one, using the default settings without using analytic derivatives.)

The direct approach is the 'default' solution: (the **; Output** and **; Dfc** options are described in Section E14.7.4.) *LIMDEP* is not able to solve this problem with the direct solution.

READ **; Nobs = 236 ; Nvar = 2 ; Names = y,x ; By Variables $**
(The data follow, exactly as shown above)
CREATE **; x2 = x*x ; x3 = x2*x$**
NLSQ **; Lhs = y**
; Fcn = (b1+b2*x+b3*x2+b4*x3)/(1+b5*x+b6*x2+b7*x3)
; Labels = b1,b2,b3,b4,b5,b6,b7
; Output = 1
; Dfc
; Maxit = 500
; Start = 10,-1,.05,-.00001,-.05,.001,-.000001$

After 500 iterations, this formulation exits at a point that is nowhere near the correct solution:

```
Iteration=500; Sum of squares=  7.99101926    ; Gradient=  .106836976E-02
Maximum iterations exceeded
```

```

```

We now reformulate the problem with analytic derivatives. Note that the derivatives for *b*6 and *b*7 are formulated recursively, using their predecessors as if they were ordinary, predefined functions (which they are).

```
NLSQ    ; Lhs = y
        ; Fcn = top  = (b1+b2*x+b3*x2+b4*x3)   |
                bot  = (1+b5*x+b6*x2+b7*x3)    |
                q    = 1/bot                   |
                _b1 = q                        |
                _b2 = x*q                      |
                _b3 = x2*q                     |
                _b4 = x3*q                     |
                _b5 = -top * q * q * x         |
                _b6 = _b5 * x                  |
                _b7 = _b6 * x                  |
                top * q   ?  This defines the regression function.
        ; Labels = b1,b2,b3,b4,b5,b6,b7
        ; Output= 1
        ; Dfc
        ; Start = 10,-1,.05,-.00001,-.05,.001,-.000001$
```

By changing the estimation to use analytic derivatives, we now obtain the NIST solution, after 98 iterations:

```
Begin NLSQ iterations. Linearized regression.

E14.7 Options for Nonlinear Least Squares

The following lists the options available for the nonlinear least squares program.

E14.7.1 Fixing Some of the Parameters

It is sometimes necessary to minimize the sum of squares while holding some of the parameters fixed at known values, for example for hypothesis testing. To do so, you can simply specify the problem in the command exactly as if the parameters were not to be fixed. Include the known values in the appropriate places in the list of starting values. Then, add the specification

; Fix = parm1,parm2,...

where the names in the **; Fix = ...** list will be some of those in your **; Labels** list. For example, suppose you wanted to obtain a CES model with constant returns to scale. This is done by setting *nu* at 1.0.

```
NLSQ      ; Lhs = Q
          ; Labels = gamma,delta,r,nu
          ; Start = 2.3, .3,  .1,  1.
          ; Fix = nu
          ; Fcn = gamma*(delta*k^(-r) + (1-delta)*l^(-r))^(-nu/r) $
```

If you have fixed the values of parameters, with the **; Fix** option, these will be among the values placed in the matrix *b* when the model results are kept for later use.

You might want to compute the sum of squares function at a particular set of parameters. You can do this by specifying that *all* parameters are to be fixed at the starting values. This is

; Fix all

(not **; Fix = all**). The full set of output will be produced, but no iterations will be done. Note that **; Fix all** is the same as **; Maxit = 0**, except the latter also produces a Lagrange multiplier statistic.

Standard Model Specifications for the Nonlinear Regression Model

This is the full list of general specifications from Chapter E1. See Chapter E1 and references noted there for further details on these specifications.

Controlling Output from Model Commands

; Table = name saves model results to be combined later in output tables.
; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Robust Asymptotic Covariance Matrices

	; Cluster = spec	cluster form of corrected covariance estimator.
or	**; Robust**	requests a ‘sandwich’ estimator or robust covariance matrix for TSCS and several discrete choice models.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Lpt = n	sets the number of points to use for Laguerre quadrature.
; Hpt = n	sets the number of points to use for Hermite quadrature.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; CML: spec defines a constrained maximum likelihood estimator.
; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions – same as **; Test: spec**.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values sets up Lagrange multiplier test of restrictions.
; Fix = list fixes the named parameters at the start values.

E14.7.2 Setting the Algorithm

Six algorithms are available: Gauss-Marquardt (the default), Davidon-Fletcher-Powell, Newton's method, Berndt, Hall, Hall, and Hausman, BFGS, and steepest descent. Unless your problem is globally convex (which is unlikely) you will probably want to use the first of these, which is the default. This is a very effective algorithm, which has been used in a wide variety of settings. Newton's method may require somewhat less computing owing to the necessity of BFGS and DFP to do a line search at each iteration; Newton's method uses a step length on 1.0. However, Newton's method is very likely to overshoot and subsequently to diverge. Choose the algorithm with

; Alg = Newton or BHHH or BFGS or DFP or Steepest Descent

Other options,

; Output = setting
; Tlb ; Tlf and ; Tlg
; Maxit = maximum
; Covariance Matrix (or ; Printvc)

all operate as usual. A setting that is specific to nonlinear least squares is

; Tln = convergence tolerance for Gauss-Marquardt method

E14.7.3 Heteroscedasticity Robust Covariance Matrix

The asymptotic covariance matrix for the nonlinear least squares estimator is estimated with

$$\mathbf{V}_{nls} = \frac{\mathbf{e}'\mathbf{e}}{n}\left(\mathbf{X^0}'\mathbf{X^0}\right)^{-1}$$

where the ith row of $\mathbf{X^0}$ is the vector of derivatives of the regression function,

$$\mathbf{x}_i^0 = \frac{\partial f(\mathbf{x}_i, \boldsymbol{\beta})}{\partial \boldsymbol{\beta}'}$$

This is the counterpart to the usual calculation for linear least squares. You may request a heteroscedasticity robust covariance matrix of the form of the White estimator by adding

; Heteroscedasticity

to the **NLSQ** command. The matrix computed is

$$\mathbf{V}_{robust} = \left(\mathbf{X^0}'\mathbf{X^0}\right)^{-1} \left[\sum_{i=1}^{n}\left(e_i\mathbf{x}_i^0\right)\left(e_i\mathbf{x}_i^0\right)'\right] \left(\mathbf{X^0}'\mathbf{X^0}\right)^{-1}$$

(There is no counterpart for the Newey-West autocorrelation consistent estimator.)

E14.7.4 Degrees of Freedom Correction

In the expression above, the disturbance variance is estimated with the mean of the nonlinear least squares residuals, with no correction for degrees of freedom. Some authors prefer to make this correction, which produces the estimator

$$s^2 = \frac{\mathbf{e}'\mathbf{e}}{n-K}.$$

The program default is to use n rather than n-K in this computation. The estimator is consistent either way, but is not unbiased in either case. Computer programs differ in this computation, and users should check the documentation of other programs that they might be using if apparent inconsistencies arise. You can request this computation with

; Dfc (degrees of freedom correction)

added to the **NLSQ** command. (Note that this form is used in the NIST benchmark tests, so we have requested it in the illustration using the NIST problem.)

E14.8 Model Output and Retrievable Results

Output from **NLSQ** consists of a table of diagnostic statistics similar to that presented for the linear regression model and a standard table of results for the parameters. The one produced by the preceding example is shown below.

```
-----------------------------------------------------------------------------
User Defined Optimization.........................
Nonlinear     least squares regression ............
LHS=Y         Mean                     =       14.21530

Note: nnnnn.D-xx or D+xx => multiply by 10 to -xx or +xx.
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

(Note that the R^2 computed as above is not bounded by zero as it would be if this were a linear least squares computation. Likewise, the F statistic, when it is produced – the one above is huge – should be ignored.) The saved results are:

Matrices:	*b*	=	the parameters
	varb	=	estimated asymptotic covariance matrix
	gradient	=	the vector of first derivatives

If you have fixed parameters, *varb* will contain rows and columns of zeros. Unless you have fixed some or all of the parameters, limited the number of iterations to less than necessary to obtain convergence, or the optimization fails, *gradient* will be approximately zero (to within the limit of your convergence criterion).

Scalars: *s* = $\sqrt{}$(1/n×sum of squared residuals,)
(The denominator is n - K if **; Dfc** is specified.)
ssqrd = s squared
ybar = mean of Lhs variable
sy = standard deviation of Lhs variable
sumsqdev = sum of squared residuals
rsqrd = 1 - *sumsqdev* / ((n-1)×**SY**×**SY**)
rho = 0.0
degfrdm = n - number of free (not fixed) parameters
kreg = total number of parameters
nreg = current sample size
logl = log likelihood = $-(n/2)[1+\log 2\pi+\log(\mathbf{e}'\mathbf{e}/n)]$

Last Function: See Section E14.9

The standard options,

; List	to display predicted values
; Keep = name	to retain for predictions, $F(\mathbf{x}_i,\boldsymbol{\beta})$
; Res = name	to retain for residuals, $y - F(\mathbf{x}_i,\boldsymbol{\beta})$
; Fill	to fill in values for unused observations

all operate as usual. If you use **; List**, your listing will contain a list of the Lhs variable and the values of $F(\mathbf{x}_i,\boldsymbol{\beta})$. Under the heading '95% Confidence Interval' will be two columns of zeros which can be ignored. The values of $F(\mathbf{x}_i,\boldsymbol{\beta})$ evaluated at the final estimates are the fitted values for this command.

For purposes of using **WALD**, the *Last Model* kept uses the labels in your **; Labels** list. To continue the earlier application, for example, to test the hypothesis that ρ equals 0 and ν equals 1 in the CES function, you could use

```
NLSQ    ; Lhs = Q
        ; Labels = gamma,delta,r,nu
        ; Start = 2.3, .3,  .1,  1.
        ; Fcn = gamma*(delta*K^(-r) + (1-delta)*L^(-r))^(-nu/r) $
WALD    ; Fn1 = r ; Fn2 = nu - 1 $
```

E14.9 Partial Effects for Nonlinear Regressions

You can obtain partial effects for any function. NLSQ does not save the function definition for computation of the partial effects or for a simulation. However, your command editor contains the function definition that you need to obtain these. NLSQ does save the parameter vector and the covariance matrix as the *Last Function*. You can use these just by reconstructing the function in the **PARTIALS** or **SIMULATE** command and using the parameters and covariance from the estimation step.

Consider the earlier example,

```
NLSQ        ; Lhs = y
            ; Fcn = top = (b1+b2*x+b3*x2+b4*x3)      |
                    bot = (1+b5*x+b6*x2+b7*x3)       |
                    q   = 1/bot                      |
            (derivatives omitted)
                    top * q   ?  This defines the regression function.
            ; Labels = b1,b2,b3,b4,b5,b6,b7
            ; Dfc
            ; Start = 10,-1,.05,-.00001,-.05,.001,-.000001$
```

We used a simplification to fit the function, substituting $x2 = x^2$ for $x*x$ and $x3 = x^3$ for $x*x*x$ in the optimization. However, the regression is, ultimately, a function only of *x*. To examine the behavior of the function after nonlinear least squares, we used the following:

```
SIMULATE    ; Scenario: & x = 0(50)1000
            ; Plot (ci)
            ; Function = (b1+b2*x+b3*x*x+b4*x*x*x) /
                         (1 + b5*x+b6*x*x+b7*x*x*x)
            ; Labels = b1,b2,b3,b4,b5,b6,b7 $
PARTIALS    ; Effects: x  & x = 0(50)1000
            ; Plot
            ; Function = (b1+b2*x+b3*x*x+b4*x*x*x) /
                         (1 + b5*x+b6*x*x+b7*x*x*x)
            ; Labels = b1,b2,b3,b4,b5,b6,b7 $
```

Note that we have replaced the shortcuts for the powers of *x*. This was useful for the optimization, but not for the simulation which needs the actual functional form to get the right derivatives. The parameter values and covariance matrix have been stored when the results were reported. The scenarios examine the values of *x* ranging from zero to 1,000 in steps of 50, which is roughly the range of *x* in the data. The simulation produces a plot with a confidence interval.

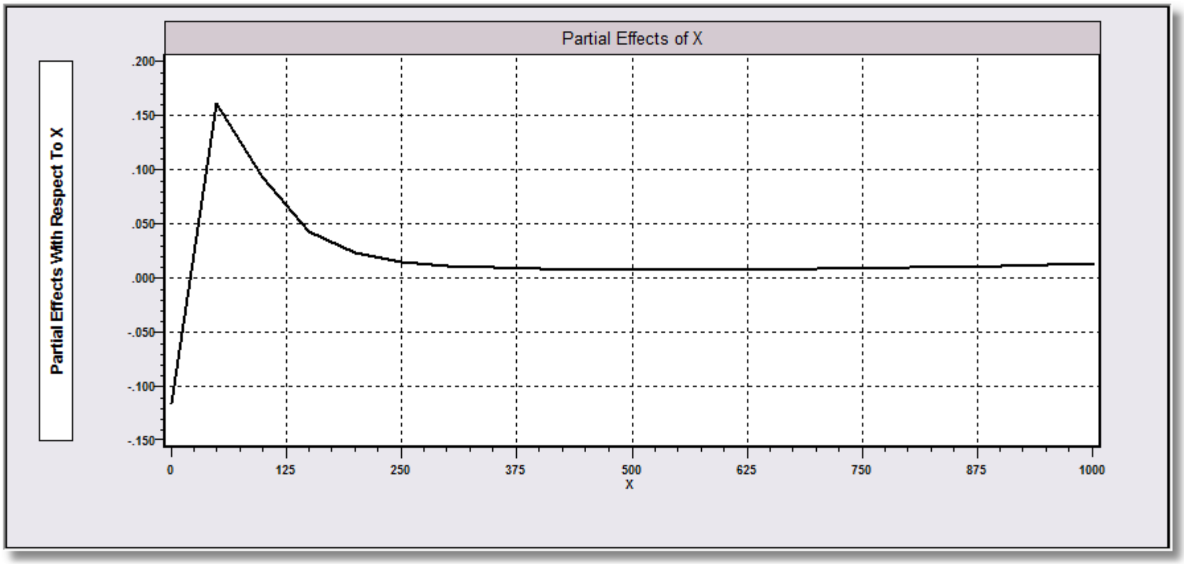

Figure E14.2 Partial Effects in Nonlinear Regression

E14.10 Imposing Restrictions and Testing Hypotheses

Since you are fully specifying the function for **NLSQ**, there is no need for a method of imposing restrictions on the parameters. For any that you desire, just build them into the function. If you wish to fix parameters at known values for the purpose of inference, use the **; Fix** option described in Section E14.7.1. After estimation, results can be retrieved for carrying out tests of restrictions on the parameters of the regression model. There are several methods of testing hypotheses with the results of **NLSQ**.

The Lagrange multiplier test described in Section R13.5 can be used if the starting values are restricted estimates from some other specification. Then,

; Maxit = 0

will produce a full set of results and the appropriate chi squared statistics.

With normally distributed disturbances, you can carry out *likelihood ratio tests* exactly as shown in Section R13.4. The scalar *logl* will contain the appropriate value for each model that you estimate.

Wald tests can be carried out by using the *Last Model* construction. See Section R13.3 for details. The labels to be used for the tests are those that appear in your **; Labels** list.

A form of F test can be based on the sum of squared residuals. The scalar *sumsqdev* contains the necessary statistic. The procedure would be

```
NLSQ        ; ... unrestricted model $
CALC        ; eeu = sumsqdev
            ; ku = kreg  $
NLSQ        ; ... restricted model $
CALC        ; eer = sumsqdev
            ; kr = kreg
            ; List
            ; dfn = ku - kr
            ; dfd = n - ku
            ; f = ((eer - eeu)/dfn) / (eeu/dfd)
            ; prob = 1 - Fds(f,dfn,dfd)  $
```

The theory surrounding this statistic for testing hypotheses is not so definitive as that for the Wald test. (See, e.g., Greene (2011) for discussion.)

The **; Test: ... restrictions** option is also available for **NLSQ**, but it will be a bit cumbersome to use. For purposes of this option if you wish to use it, the parameters in your **; Labels** list are renamed, as usual, $b(1),...,b(K)$. It will be easier to use **WALD** to obtain the same results.

E14.11 An Application

To illustrate the nonlinear least squares computation, we use a small set of data based on the Poisson regression model. This specification for a discrete random variable is

$$\text{Prob}[y_i = j] = e^{-\lambda_i} \lambda_i^{y_i} / y_i! \quad \text{where} \quad \lambda_i = e^{\boldsymbol{\beta}'\mathbf{x}_i}.$$

The conditional mean function is $E[y_i] = \lambda_i$.

E14.12 Technical Details

LIMDEP uses the Gauss-Marquardt method for nonlinear least squares. The iteration is

$$\mathbf{b}(k+1) = \mathbf{b}(k) + \left(\mathbf{X^0}(k)'\mathbf{X^0}(k)\right)^{-1}\mathbf{X^0}'(k)\mathbf{e^0}(k)$$

where the matrix of pseudo-regressors from the linearized regression has ith row equal to the transpose of

$$\mathbf{x}_i^0(k) = \frac{\partial f(\mathbf{x}_i, \mathbf{b}(k))}{\partial \mathbf{b}(k)'}$$

and $$e_i^0(k) = y_i - f(\mathbf{x}_i, \mathbf{b}(k)).$$

Convergence is measured by the ‘gradient’ measure,

$$\delta(k) = \mathbf{e^0}(k)'\left(\mathbf{X^0}(k)'\mathbf{X^0}(k)\right)^{-1}\mathbf{e^0}(k)$$

The tolerance value is 1.D-20. (Note the convergence assessment in the preceding example.

This iterative procedure can break down for two reasons. Since it is a Newton-like method without a controlled line search, it is possible for the estimated parameter vector to diverge, or to drift to a place in the parameter space where the regression function cannot be computed. If this happens, the message

```
Function is no longer computable.
```

will appear in the output. The second failure can occur when the current values of the parameters causes the second moment matrix to become nonpositive definite. For example, a regression function that includes exp($\mathbf{b}'\mathbf{x}$) might degenerate to a column of zeros for an extreme value of the parameters. In this case, the message

```
Moment matrix has become nonpositive definite.
```

will appear in your results. In both of these cases, *LIMDEP* will make one more attempt to fit the model, using a different algorithm. You will see the message

```
Switching to BFGS algorithm
Nonlinear Estimation of Model Parameter
Method=BFGS  ; Maximum iterations=100
Convergence criteria:gtHg .1000D-05 chg.F .0000D+00 max|dB| .0000D+00
Nodes for quadrature: Laguerre=40;Hermite=20.
Replications for GHK simulator= 100
```

followed by the standard output for nonlinear optimization. At this point, *LIMDEP* will have abandoned the procedure used only for nonlinear least squares, and switched to minimizing the sum of squares as an ordinary optimization problem. The starting values for this second attempt will be the ones initially used for the Gauss-Marquardt method. This is what occurred in the NIST example Hahn1 in Section E14.6.

All derivatives that you do not supply explicitly are obtained by numerical approximation, using a symmetric (two sided) rate of change. The Hessian is approximated by the summed outer products of the first derivatives. This is the BHHH estimator. Thus, it is always nonnegative definite. But, it can be singular in a particularly difficult problem. If you request Newton’s method, the Hessian is computed using two sided approximations to the second derivatives. For most problems, this will be sufficiently accurate. But, this matrix is not guaranteed to be positive definite, so you may get a diagnostic for a singular Hessian when using this method. If this happens, use one of the other methods.

E14.13 The NIST Accuracy Benchmarks

The National Institute of Standards and Technology (NIST) has published a suite of 27 benchmark problems for testing nonlinear regression programs. The NIST site contains statements of the problems and the datasets for their solutions, all of which can be downloaded from their website: http://www.itl.nist.gov/div898/strd/nls/nls_main.shtml. McCullough (1999) has extensively documented the performance of several econometric software packages, including *LIMDEP*, in solving the NIST benchmarks. Many of the NIST datasets and *LIMDEP* commands to carry out the tests are included with the *LIMDEP* program, and can be found in the last book of the Help file. Click Help, Help Topics, then double click The Nist Benchmarks book. The NIST datasets and files may also be found in the C:\LIMDEP10\Command Files folder created with program installation. All of the data and code needed to carry out the nonlinear least squares tests with *LIMDEP* are provided in both locations.

McCullough's (1999) survey suggests how the tests results can be summarized. As noted earlier, NIST provides two sets of starting values, a 'difficult' set (Start 1) and an easier set (Start 2) that is closer to the correct solution. McCullough provides a measure of the accuracy of the solutions using either set based on the number of correct digits produced, compared to the NIST certified solution. He also suggests that some other benchmarks be used to evaluate software, namely comparisons of solutions using program default settings vs. user modifications of the defaults, such as changes in the algorithms, provision of derivatives, or changes in the convergence tolerances.

The listing below shows some program code and a summary of the solutions to these problems as implemented in *LIMDEP*. A full listing of all the test runs would occupy an inordinate amount of space in this manual. The following summarizes the results:

- 26 of the 27 tests can be solved with *LIMDEP* to greater than nine digit accuracy. The exception is the Hahn1 problem examined in detail above, which is solved to 6.8 digit accuracy. 22 of the 27 solutions are obtained to greater than 10 digit accuracy.

- Of the 27 solutions obtained, all but five are reachable from Start 1.

- Using the basic defaults and Start 1, 19 of the 27 problems are solvable. The accuracy exceeds nine digits in 15 of these 19, exceeds six digits in three of the remaining four, and is at less than six digits in only one of these solutions.

In every case in which a solution is obtained, that solution is improved by including the analytic derivatives in the command. In general, this appears to be a good idea when it is feasible. This is clear with the Hahn1 problem shown earlier, for which the solution is not attainable without supplying the derivatives. The other modification which produces some benefit is to switch to the BFGS algorithm, then tighten the gradient convergence rule to, say, 1.D-12. Finally, it is occasionally necessary to increase the maximum number of iterations. Iterations in the hundreds are not uncommon.

E14.13.1 Setting up the NIST Benchmarks

To illustrate the test procedure, we show the full setup for the Hahn1 problem examined in Section E14.6. The data are presented there. We now **READ** them as variables *yh*1 and *xh*1. The parameters for the test are placed in a matrix arranged in the form

```
Number of observations                             Solutions
Number of parameters        Start 1     Start 2   Slopes    Std errors
       0               b1(0)_1     b1(0)_2  b1(*)     s1(*)
       0               b2(0)_1     b2(0)_2  b2(*)     s2(*)
       ...             ...         ...    ...      ...
Correct sum of squares   0           0        0         0

```

We use a procedure to prepare the data set and matrix elements for the execution:

```
PROC = Setup(Problem) $
CALC          ; ndata  = problem(1,1)
              ; nparm = problem(2,1)
              ; np1 = nparm+1$
MATRIX        ; start1 = Part(problem,1,nparm,2,2)
              ; start2 = Part(problem,1,nparm,3,3)
              ; trueb  = Part(problem,1,nparm,4,4)
              ; trues  = Part(problem,1,nparm,5,5)
              ; trueee= Part(problem,np1,np1,1,1) $
CALC          ; truess = trueee $
SAMPLE        ; 1 - nparm $
CREATE        ; truebeta  = trueb $
CREATE        ; truese  = trues $
SAMPLE        ; 1 - ndata $
ENDPROC
```

The procedure sets up the specific NIST nonlinear least squares problems. It sets the sample size and problem size and extracts from the setup matrix the two sets of starting values into matrices. The two sets of 'true' values are also placed in matrices, and copied into variables in preparation for the LRE (log relative error) score routine that is executed after estimation. The procedure must be executed with

```
EXEC          ; Proc = Setup(problem name) $
```

before the **NLSQ** commands can be carried out.

The next step is to compute the nonlinear least squares estimates, first using the program default values and Start 1, second using whatever methods are available – what McCullough labels an ‘all out assault’ on the solution.

Step 1. Set up the problem:

```
EXECUTE     ; Proc = Setup(Hahn1) $
TITLE       ; Nonlinear Least Squares Estimation. Data set = Hahn1 $
CREATE      ; xh12 = xh1*xh1 ; xh13 = xh12*xh1$
```

Step 2. Solution attempt using program defaults:

```
NLSQ        ; Lhs = yh1
            ; Fcn = (b1+b2*xh1+b3*xh12+b4*xh13) /
                    (1+b5*xh1+b6*xh12+b7*xh13)
            ; Labels  = b1,b2,b3,b4,b5,b6,b7
            ; Output= 0 ; Dfc ; Start = Start 1 $
```

After fitting the model, we use another procedure to ‘score’ the solution in terms of its agreement with the NIST certified solution:

```
Maximum iterations exceeded

```

This routine evaluates the quality of the solution to the **NLSQ** routine for each of the NIST problems. The computation is documented in McCullough (1999). It effectively measures the number of correct digits in the solution. The certified NIST values are given with 11 digits, so that is the maximum value. LRE scores are computed for coefficient vectors and for standard errors. The overall score for a problem is then the minimum value in the vector of LREs. No value is computed for the sum of squares, since it will be redundant. A correct solution for the coefficient vector implies a correct solution for the sum of squares, and vice versa (unique solution at the true minimum).

```
PROC  = Score $
MATRIX      ; betahat1 = b ; sehat1 = Diag(varb)
            ; sehat1 = Esqr(sehat1) ; sehat1 = Vecd(sehat1) $

WRITE       ; cert_ss , actualss , scoress ; Format = (3G20.11) $
SAMPLE      ; 1 - ndata $
ENDPROC
```

After estimation, the routine is invoked with

```
EXECUTE     ; Proc = Score $
```

It displays the results below the model output. Note that **SCORE** is wired to **SETUP**, and will only operate properly with respect to the immediately preceding **SETUP** and **NLSQ** commands.

This procedure requires only **EXECUTE ; Proc = SCORE $** to obtain the results. As noted earlier, this default solution ends up nowhere near the correct solution. The **SCORE** routine provides the following results: Note that the LRE score is essentially 0. This is the number of correct digits, with 11.0 being a perfect score.

```

E15: Linear Models for Time Series/Cross Section Data

E15.1 Introduction

The models described in this chapter are of a type based on balanced panels in which the regression specification accommodates the natural grouping in the data in a more structured (and less flexible) fashion than the panel data models to follow in Chapters E16-E19. They are accessed with the command

TSCS ; Lhs = dependent variable
; Rhs = independent variables
; Pds = number of observations per group $

for the first case, in which the panel structure of the data is built into the disturbance covariance matrix, and

REGRESS ; Lhs = dependent variable
; Rhs = independent variables
; Pds = number of observations per group
; RCM $

for the second case in which the panel data aspect of the model appears in variation of the regression parameters.

The essential structure of the first form of the model is

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$$

The *groupwise covariance structures* model considered in this chapter is

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}, \text{Cov}[\varepsilon_{it},\varepsilon_{js}] = \sigma_{ij}\times\mathbf{1}(t = s).$$

In this model, the regression function is assumed to be the same for all groups, and the structure of the model is built into the pattern of heteroscedasticity and contemporaneous correlation across groups. This model also allows for first order autocorrelation of the form Corr$[\varepsilon_{it},\varepsilon_{is}] = \rho_i^{|t-s|}$. The second form of the model is

$$y_{it} = \boldsymbol{\beta}_i'\mathbf{x}_{it} + \varepsilon_{it}$$

where the variation in the parameter vector is built on a random parameter structure,

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \mathbf{w}_i, \mathbf{w}_i \sim f(\mathbf{0},\boldsymbol{\Gamma}).$$

E15.2 Panel Data Arrangement and Setup

Your data for this model are assumed to consist of variables:

$$y_{it}, x_{1it}, x_{2it}, ..., x_{Kit}, I_{it}, \; i=1,...,N, t = 1,...,T,$$

y_{it} = dependent variable,
$\mathbf{x}_{it}$ = set of independent variables,
K = number of regressors, including *one*,
N = number of groups,
T = fixed number of observations in group 'i.'

The data set for all panel data models in *LIMDEP* will normally consist of multiple observations, denoted $t = 1,...,T_i$, on each of $i = 1,...,N$ observation units, or 'groups.' A typical data set would include observations on several persons or countries each observed at several points in time, T_i, for each country. In the following, we use 't' to symbolize 'time' purely for convenience. The panel could consist of N cross sections observed at different locations or N time series drawn at different times, or, most commonly, a cross section of N time series, each of length T_i. The estimation routines are structured to accommodate large values of N, such as in the national longitudinal data sets, with T_i being as large or small as dictated by the study but not directly relevant to the internal capacity of the estimator. Data for the panel data estimators in *LIMDEP* are assumed to be arranged contiguously in the data set. Logically, you will have

$$Nobs = \sum_{i=1}^{N} T_i$$

observations on your independent variables, arranged in a data matrix

$$\mathbf{X} = \begin{bmatrix} T_1 \text{ observations for group 1} \\ T_2 \text{ observations for group 2} \\ \cdots \\ T_N \text{ observations for group } N \end{bmatrix}$$

and likewise for the data on $\mathbf{y}$, the dependent variable. When you first read the data into your program, you should treat them as a cross section with *Nobs* observations. The partitioning of the data for panel data estimators is done at estimation time. Chapter R5 contains further details on how to set up and use panel data sets.

NOTE: The estimators described in this chapter require a *balanced* panel. T_i must be the same for all i. These are the only panel data models in *LIMDEP* that have this restriction.

E15.3 Groupwise Heteroscedasticity, Correlation and Autocorrelation

This chapter describes estimation of a form of panel data model in which data are (typically) observed for a relatively large number of periods and for a relatively small number of cross sectional units – the reverse of the more familiar panel arrangement. Typical applications involve cross country studies, such as the 30 OECD countries, observed for a relatively large number of years. The model is

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it},\ i = 1,...,N,\ t = 1,...,T.$$

The subscript 'i' indexes groups, 't' indexes periods. The coefficient vector is assumed to be constant over time and for all groups. The model allows for:

- groupwise heteroscedasticity, $E[\varepsilon_{it}^2] = \sigma_{ii}$,
- cross group correlation, $\text{Cov}[\varepsilon_{it},\varepsilon_{jt}] = \sigma_{ij}$,
- within group autocorrelation, $\varepsilon_{it} = \rho_i\varepsilon_{i,t-1} + u_{it}$.

For the nonautocorrelated models, the estimator may be two step FGLS or iterated FGLS which produces a maximum likelihood estimator. For the models with autocorrelation, the estimator may be three step GLS or iterated GLS, which though convergent, does not produce the MLE because of the Jacobian term.

The number of cross sectional units, N, is limited to 100. The number of periods per group must be fixed at some T. The full sample is limited to 200,000 observations for this estimator.

The TSCS model formulation provides three forms of the regression, labeled

S0 = homoscedastic and uncorrelated across groups (linear regression),
S1 = groupwise heteroscedastic,
S2 = groupwise heteroscedastic and correlated across groups.

The basic model command requests estimation and display of all three forms of the model. There are also three forms of the autocorrelation model:

R0 = no autocorrelation,
R1 = common autocorrelation coefficient, ρ,
R2 = group specific autocorrelation coefficient, ρ_i.

With no further modification, this creates nine different variants of the model, S0,R0, S0,R1, etc. Results presented with this model will include a full set of results for all models, the three base cases, or the nine permutations if you specify **; AR1**. You may limit estimation to one of the specific models with the **; Model = Ss,Rd** specification in the command, for example, **; Model = S1,R1**. All forms up to this model in the order, S0,R0, S1,R0, S2,R0, S0,R1, ... are estimated, but only the one you request is actually reported. Estimation stops at that point, so any saved results are based on the model you specify. Otherwise, the saved results are based on S2,R0 if you do not specify **; AR1** or S2,R2 if you do.

E15.3.1 Command and Options

The basic command for the 'Time Series/Cross Section' estimator is

TSCS ; Lhs = ...
; Rhs = ...
; Pds = number of periods $

You may use **REGRESS ; TSCS** instead of **TSCS** if you prefer. These are synonyms. Although this is a panel data estimator, its construction differs slightly from the ones in the preceding sections.

- The panel must be balanced. The construction of the disturbance covariance matrix, **Σ** requires this.
- There is no stratification indicator. The data set consists of *N* blocks of *T* observations.

Options are

; AR1	to request the models of autocorrelation
; MLE	to request the iterative estimators (also for AR1)
; Model = S0,R0 or **S1,R0**, etc.	

The **; Model = type** specification allows you to stop estimation at, and save the results for a particular specification rather than estimating all forms of the model and saving the last one estimated. The standard options available for **TSCS** also include:

; Wts =	an optional weighting variable
; Res = name	to retain residuals
; List	to display fitted values, residuals, and forecast intervals
; Keep = name	to retain predictions
; Output = 4	to list various covariance matrices
; Labels =	a list of names for the groups

Labels are used to label the rows and columns of residual covariance and correlation matrices. They can also be used in the next specification, which is used to place some rows and columns of zeros in the disturbance covariance matrix;

; Group = the list labels or numbers of groups that are freely correlated.

For the **; Group** option, any group not included in the list is assumed to be uncorrelated with all groups in the list as well as all other groups not in the list. If you have not used **; Labels**, then use simple group numbers. If you have used labels, then the list should use the labels you supply. For example: In the Grunfeld data, five of the ten groups (firms), GM, GE, Chrysler, U.S. Steel, and Westinghouse. The following two specifications would be equivalent:

```
TSCS        ; Lhs = i
            ; Rhs = one,f,c
            ; Pds = 20
            ; Group = 1,3,4
            ; Output = 4 $
```

and

```
TSCS        ; Lhs =  i
            ; Rhs = one,f,c
            ; Pds = 20
            ; Labels = gm,ge,chrysler,us_steel,westnghs
            ; Group = gm,chrysler,us_steel
            ; Output = 4 $
```

The correlation matrix reported would be as follows for the second form – the first would use simple firm numbers 1-5 instead of the names:

```
Matrix r(ei,ej) has  5 rows and  5 columns.
          GM                   GE         CHRYSLER     US_STEEL     WESTNGHS
        +---------------------------------------------------------------------
GM      |    1.0000    .0000000D+00    -.3576       -.4907    .0000000D+00
GE      | .0000000D+00    1.0000    .0000000D+00 .0000000D+00 .0000000D+00
CHRYSLER|    -.3576    .0000000D+00    1.0000        .8837    .0000000D+00
US_STEEL|    -.4907    .0000000D+00     .8837       1.0000    .0000000D+00
WESTNGHS| .0000000D+00 .0000000D+00 .0000000D+00 .0000000D+00    1.0000
```

NOTE: The zero correlation assumption is forced on the estimator, so GLS is done with the zeros specified in the covariance matrix.

E15.3.2 Results

The results from this model are extensive, as illustrated in the next section. Results which are kept for later use, as well as the residuals and predictions are based on the last model estimated, which will be S2,R0 or S2,R2 or on the model indicated in the **; Model = type** specification. These are:

Matrices: *b* = coefficient vector
varb = estimated asymptotic covariance matrix for **B**
sigma = $N \times N$ covariance matrix of *nonautocorrelated* disturbances
tscs_rho = $N \times 1$ vector of estimated autocorrelation coefficients.
The values of ρ_i in *tscs_rho* are always estimated, even without **; AR1**.

Scalars: *rho* = average autocorrelation for the groups (see below),
kreg = number of regressors
nreg = number of periods (not total number of observations)

Last Model: *b_variable* labels to use for Wald tests

Last Function: Conditional mean = **b′x**

In the general form for the TSCS model, the appropriate asymptotic covariance matrix for the ordinary least squares estimator would be

$$\text{Var}[\mathbf{b}] = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{\Omega}\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

where, since this is OLS, $\mathbf{X}$ would be the stack of $\mathbf{X}$ and $\mathbf{\Omega}$ would be the block matrix, with *ij*th block equal to $\sigma_{ij}\mathbf{I}$. Expanding this gives

$$\text{Var}[\mathbf{b}] = [\Sigma_i\mathbf{X}_i'\mathbf{X}_i]^{-1} \times [\Sigma_i\Sigma_j\, \sigma_{ij}\, \mathbf{X}_i'\mathbf{X}_j] \times [\Sigma_i\mathbf{X}_i'\mathbf{X}_i]^{-1}$$

A consistent estimator of this is easily obtained by just using $s_{ij} = \mathbf{e}_i'\mathbf{e}_j/T$ for σ_{ij}. By default, the reported covariance matrix for the first (S0,R0) OLS estimates in this model is just $s^2(\mathbf{X}'\mathbf{X})^{-1}$. You can request the preceding alternative estimator by adding

; PCSE (panel corrected standard errors)

NOTE: This correction (which originates with Beck and Katz (1995)) only applies to the standard errors computed for the OLS estimates (form S0,R0).

The panel corrected standard errors estimator is a special case. Panel corrected standard errors (PCSE) in TSCS allows more than 100 groups; there is no limit on the number of groups; the limit is only 200,000 observations in total. The reason is that it is not necessary to compute the $N\times N$ matrix $\mathbf{\Sigma}$ for this calculation. The example below for the Grunfeld data (Greene, 2011, Table F10.4) illustrates the difference.

TSCS ; Lhs = i ; Rhs = one,f,c ; Pds = 20 ; Model = S0,R0 $

```

If you include **; MLE** in your command, then the FGLS estimators will be iterated to convergence. This gives the maximum likelihood estimators for the R0 cases. When there is autocorrelation, this is only approximately MLE. The problem is the first observation and the Jacobian term in the log likelihood. In any event, with MLE in the command, the results will contain an additional table, like the one shown below. Note that the log likelihood for all nine cells is calculated correctly. However, the R1 and R2 parameter estimates are not the true MLEs, as noted above. Thus, one might want to be careful in using these for any kind of formal testing. Note, for example, that the value of logL shown for S2,R2 is less than that for S2,R1, whereas if the estimates were true MLEs, the reverse would be true.

Log-likelihood functions for estimated models

	R0 Log-L	R0 Parameters	R1 Log-L	R1 Parameters	R2 Log-L	R2 Parameters
S0	-1191.802	4	-1116.263	5	-1119.031	14
S1	-956.689	13	-889.176	14	-896.558	23
S2	-798.888	58	-782.462	59	-800.379	68

NOTE: In the GLS estimator for TSCS, it is necessary to invert the *N*x*N* covariance matrix of the group specific residuals, **S**. This matrix has rank less than or equal to the minimum of *N* and *T*. Since **S** is a sum of *T* rank one matrices, its rank cannot exceed *T*. If *T* is less than *N*, **S** must be singular, and GLS cannot be computed. In words, if you have more periods than groups (e.g., countries), then GLS will not be possible. The condition $N > T$ is autodetected. When this condition is detected, a long warning is given, then the routine switches to PCSE with least squares, and halts the estimation. The following illustrates. The Grunfeld data set we are using contains ten firms. In the regression below, we use all $N = 10$ firms, and the first $T = 8$ observations to trigger the warning. The ‘correction’ noted in the warning is the PCSE estimator.

```
+-----------------------------------------------------------+
| You have T =   8 periods and N =    10 groups. When N > T |
| the NxN residual covariance matrix EtE/T has rank   T < N |
| and cannot be inverted. The full GLS estimator cannot be  |
| computed. The results below include only OLS with a cor-  |
| rection to the estimated covariance matrix.               |

E15.3.3 Application

We continue the application developed in the previous sections. The data and model are the same. The command, which requests most of the available output, is the first one below. In the second, we allow a different constant term for each firm (which makes this equivalent to a 'fixed effects' model). The results from the regressions are largely the same as those shown in the earlier examples, and are not shown. The **PLOT** command displays the residuals from the two regressions.

```
INCLUDE    ; New ; Firm <= 5 $
CLIST      ; firms = gm,ge,chrysler,us_steel,wstnghse $
CREATE     ; Expand(firm) = d1,d2,d3,d4,d5 $
TSCS       ; Lhs = i ; Rhs = one,f,c ; AR1
           ; Pds = 20 ; Output = 4 ; Res = e
           ; Labels = firms $
TSCS       ; Lhs = i ; Rhs = d1,d2,d3,d4,d5, f, c ; AR1
           ; Pds = 20 ; Labels = firms ; Res = e _i  $
PLOT       ; Rhs = e,e_i ; Spikes = 20.5,40.5,60.5,80.5 ; Bars = 0
           ; Title = Residuals for TSCS Regression
           ; Vaxis = Residual $
```

The following figure is a plot of the residuals from the two regressions. The figure is particularly revealing. Not only does it show quite clearly the groupwise heteroscedasticity induced by the model (same coefficient vector for all firms), but also the autocorrelation. It is also clear that assuming the same coefficient vector applies to all firms induces quite a serious misspecification for the third and fifth firms. Allowing the constant terms to differ by firm partly mitigates the effect, but even with this extension, this would still appear to be a badly specified model.

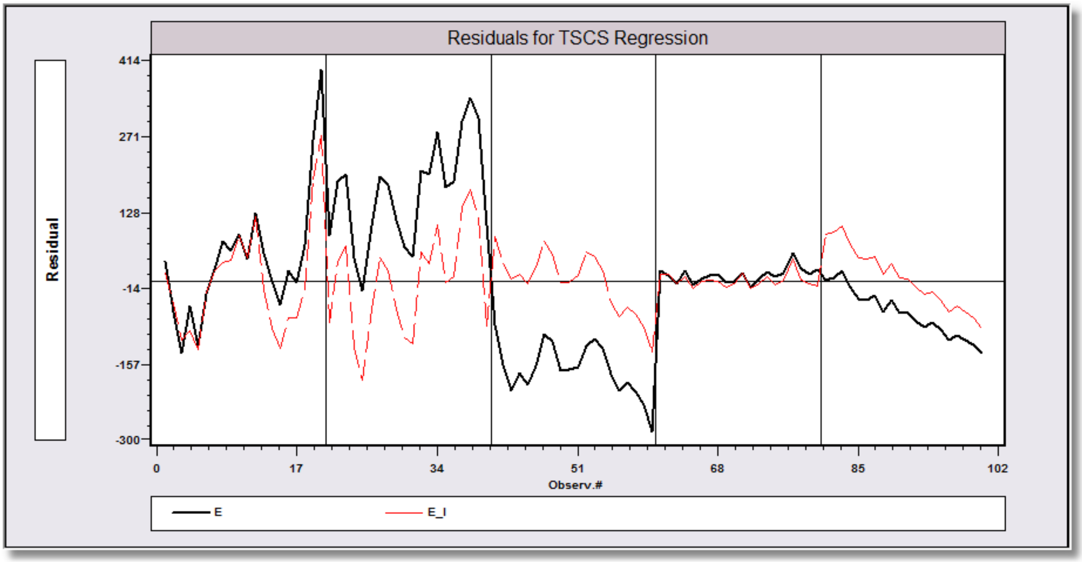

Figure E15.1 TSCS Residuals

E15.3.4 Technical Details

We use the same general procedure for all computations:

Let $\boldsymbol{\Sigma}$ = $N \times N$ period specific covariance matrix, $[\sigma_{ij}]$.

There are three cases:

S0: $\boldsymbol{\Sigma}$ = $\sigma^2\mathbf{I}$, homoscedastic regression,
S1: $\boldsymbol{\Sigma}$ = diag$[\sigma_{11},\sigma_{22},...,\sigma_{NN}]$, groupwise heteroscedastic,
S2: $\boldsymbol{\Sigma}$ = an $N \times N$ positive definite matrix, groupwise heteroscedastic and cross group correlated.

Let $\boldsymbol{\rho}$ = $N \times 1$ vector of group specific autocorrelation coefficients.

There are also three cases:

R0: $\boldsymbol{\rho}$ = $\mathbf{0}$, nonautocorrelated,
R1: $\boldsymbol{\rho}$ = $(\rho,\rho,...,\rho)$, common autocorrelation coefficient,
R2: $\boldsymbol{\rho}$ = $(\rho_1,\rho_2,...,\rho_N)$.

Thus, there are nine models when all three contemporaneous covariance specifications ($\mathbf{\Sigma}$) are crossed with the three autocorrelation specifications. Our approach is to compute all of them as restrictions on the model (S2,R2). The computations are as follows:

Step 1. Ordinary, pooled least squares.

Substep 1. Use OLS residuals to estimate $\boldsymbol{\rho}$. The procedures are as follows:

R0: Set $\rho_i = 0$.
R1: The common ρ is estimated as $(1/N)\Sigma_i r_i$ where r_i is the group specific residual autocorrelation.
R2: Use r_i as noted above.

Substep 2. With $\boldsymbol{\rho}$ in hand, first transform the data using the Prais-Winsten transformation.

Step 2. Compute OLS estimates using the data which have been transformed to remove the autocorrelation. Use the OLS residual sum of squares and cross products to compute

$$\mathbf{S} = [s_{ij}] = \mathbf{e}_i'\mathbf{e}_j/(T-l), \text{ where } l=0 \text{ for R0 and } l=1 \text{ for R1 and R2.}$$

Step 3. FGLS regression.

$$\hat{\boldsymbol{\beta}} = [\mathbf{X}'(\mathbf{S}^{-1}\otimes\mathbf{I})\mathbf{X}]^{-1}\mathbf{X}'(\mathbf{S}^{-1}\otimes\mathbf{I})\mathbf{y} = [\Sigma_i\Sigma_j s^{ij}\mathbf{X}_i'\mathbf{X}_j]^{-1}[\Sigma_i\Sigma_j s^{ij}\mathbf{X}_i'\mathbf{y}_j],$$

and

$$\text{Est.Asy.Var}[\hat{\boldsymbol{\beta}}] = [\mathbf{X}'(\mathbf{S}^{-1}\otimes\mathbf{I})\mathbf{X}]^{-1}.$$

The different specifications are estimated by restricting $\mathbf{\Sigma}$ and/or $\boldsymbol{\rho}$.

Three diagnostic statistics are computed for testing the hypothesis of the restrictions S0 on S1 and S1 on S2. For testing homoscedasticity as a restriction on S1,

$$\textbf{Wald} = (T/2)\Sigma_i\,[s^2/s_{ii} - 1]^2,$$
$$\textbf{LM} = (T/2)\Sigma_i\,[s_{ii}/s^2 - 1]^2, \text{ and}$$
$$\textbf{LR} = T(N\log s^2 - \Sigma_i \log s_{ii})$$

in which s^2 is the pooled OLS residual variance. All have limiting chi squared distributions with N-1 degrees of freedom under the hypothesis of homoscedasticity. The LR statistic is computed using estimates from S0 and S1, while both Wald and LM are based on S1. (LM should, in fact, be based on S0, so this is an approximation.) For testing groupwise heteroscedasticity as a restriction on S2, we compute

$$\textbf{LM} = T\Sigma_i\Sigma_{j<i}\,[s_{jj}^2/(s_{ii}s_{jj})] \text{ (the squared cross group correlation),}$$

and

$$\textbf{LR} = T(\Sigma_i \log s_{ii} - \log|\mathbf{S}|).$$

LM is computed using the final GLS estimates while LR is based on both S1 and S2.

No specific test is given for autocorrelation. One can test the significance of the estimated correlations, themselves, by referring $(T\text{-}1)r/(1 - r^2) \approx \chi^2[1]$ to the value 3.84, which is the 95% critical value from the chi squared distribution with one degree of freedom.

As shown in the example above, the TSCS estimator produces a large amount of output. With **; AR1**, there are nine regressions. In addition, several different forms of **Σ** are shown:

- For all estimators, the untransformed covariance matrix of the residuals for the model. For the three specifications, these are:

  S0: **Σ** = σ^2**I**. We display the estimate of σ^2.
  S1: **Σ** = a diagonal matrix. The diagonal matrix is displayed. Note that, in fact, $\mathbf{e}_{j\,i}'\mathbf{e}_j/T$ will not equal zero, but the model assumes σ_{ij} = zero.
  S2: **Σ** = a positive definite matrix. We display the full matrix. For this case, we also display **R** = the matrix of cross sectional correlations.

- For Models R1 and R2, the first display is the covariance matrix of the nonautocorrelated residuals. These are the residuals that result from the Cochrane-Orcutt transformation. Then, we also display the derived covariance matrix of the autocorrelated residuals. The computations are as follows: The disturbances are $\varepsilon_{it} = \rho_i\,\varepsilon_{it} + u_{it}$. The first matrix displayed is the estimate of **Σ** = Cov[u_{it},u_{jt}]. This is followed by the estimate of

  $$\mathbf{\Sigma}^{**} = \text{Cov}[\varepsilon_{it},\varepsilon_{jt}] = \sigma_{ij} / [(1 - \rho_i)(1 - \rho_j)].$$

  These matrices are normally not displayed with the standard output. To request them as part of the output, add

  ; Output = 4 to the **TSCS** command.

If you would prefer to see only a particular set of results for one of the nine models, use

; Model = S0,R0 or **S1,R0**, etc.,

for any of the nine forms of the model. Only that set of results will be displayed, and the final results saved as *b*, *varb*, etc. will be based on that model.

Two Important Technical Points

The covariance matrix, **S**, for Model S2 (the full model) is based on the residuals computed from the results of Model S1, the groupwise heteroscedastic regression. The standard textbook treatment of this model prescribes computing **S** using the results of OLS at the first step. The former is appropriate both under the null of the classical model and the alternative of the full model, so in terms of the asymptotic properties of the estimator, it makes no difference. But, the difference will be noticeable numerically in a finite sample. To use the textbook variant, add

; OLS

to the **TSCS** command. This requests the estimator of **Σ** based on the OLS residuals. There is no wisdom on which is a preferable estimator. In some limited experiments, we have found that the iterated FGLS estimator converged more readily using the default estimator rather than the OLS estimator, but we could find no theoretical basis on which to explain the finding.

The second point relates to the computation of **S** in the S2 formulation of the model. (This is one of our most frequently asked questions.) Let $\mathbf{e}_t$ denote the column vector of N residuals for all N groups at a particular time, t. For Model S2, **S** is computed using the formula

$$\mathbf{S} = \frac{1}{T}\sum_{t=1}^{T}\mathbf{e}_t\mathbf{e}_t{}'$$

This $N\times N$ matrix has rank less than or equal to the minimum of N and T – it is a sum of T rank 1 $N\times N$ matrices. This means that *if you have more countries than periods, it is not possible to invert* **S**, *so it is not possible to compute Model S2*. This is a general result having nothing to do with the software. The example shown earlier at the end of Section E15.3.2 shows the program reaction to finding that your model has this problem.

E15.4 Hildreth, Houck, and Swamy's Random Coefficients Model

The Hildreth/Houck/Swamy variant of the random coefficients model (*RCM*) is

$$\begin{aligned}
\mathbf{y}_i &= \mathbf{X}_i\boldsymbol{\beta}_i + \boldsymbol{\varepsilon}_i,\ i = 1,\ldots,N \text{ groups},\\
E[\boldsymbol{\varepsilon}_i \mid \mathbf{X}_i] &= \mathbf{0},\ \text{Var}[\boldsymbol{\varepsilon}_i \mid \mathbf{X}_i] = \sigma_i^2\mathbf{I},\\
\boldsymbol{\beta}_i &= \boldsymbol{\beta} + \mathbf{v}_i,\\
E[\mathbf{v}_i \mid \mathbf{X}_i] &= \mathbf{0},\ \text{Var}[\mathbf{v}_i \mid \mathbf{X}_i] = \boldsymbol{\Gamma}.
\end{aligned}$$

(See Swamy (1971, 1974), Hsiao (1986), and Hildreth and Houck (1968).) A linear regression model applies to each group. The coefficient vector within the group is a random draw from a distribution with overall mean, $\boldsymbol{\beta}$ which we seek to estimate. The reduced form of the model is

$$\begin{aligned}
\mathbf{y}_i &= \mathbf{X}_i\boldsymbol{\beta} + (\boldsymbol{\varepsilon}_i + \mathbf{X}_i\mathbf{v}_i)\\
&= \mathbf{X}_i\boldsymbol{\beta} + \mathbf{w}_i,
\end{aligned}$$

with $E[\mathbf{w}_i \mid \mathbf{X}_i] = \mathbf{0}$

and $\text{Var}[\mathbf{w}_i \mid \mathbf{X}_i] = \sigma^2\mathbf{I} + \mathbf{X}_i\boldsymbol{\Gamma}\mathbf{X}_i{}' = \mathbf{A}_i.$

This is a groupwise heteroscedastic and autocorrelated (correlation across observations within groups) regression model.

E15.4.1 Command

This model is set up as a panel data regression model. The command is

```
REGRESS     ; Lhs = ... ; Rhs = ...
            ; Panel
            ; RCM
            ; Str = the stratification indicator
       or   ; Pds = group size $
```

In the example of the previous section, the stratification indicator would be *firm*. As part of the labeling of your output, your command may include

; Labels = a set of alphanumeric labels for up to 500 groups.

In this setting, there may be any number of groups, $i = 1,...,N$. (The limit of 20,000 in earlier versions of *LIMDEP* no longer applies.) The number of coefficients is limited to 150 as usual. The panel may be unbalanced, with the number of observations in group i equal to T_i. As before, there is no limit on T_i. Once again, the stratification variable need not be the set of consecutive integers. It can be any set of distinct values, so long as each i has a value. (See Chapter R5 for discussion of setting up panel data for estimation.)

The estimation results will include only the feasible GLS (FGLS) estimates. A deeper analysis involving display of results for each group, including the group specific prediction of $\boldsymbol{\beta}_i$, is requested with

; Output = 4

The **REGRESS** command builder dialog boxes will construct the instruction for the random coefficients model. The regression is set up as described in Section E16.2 for the panel data, linear regression model. On the Options page, first select Panel data model, then in the Model type window, select Random Coefficients. Next, click Settings to open the dialog box of options for the random coefficients model.

- Other options for the classical model apply as usual, but **; AR1** is not available.
- **; Res** and **; Keep** for residuals and predictions are based on the estimated overall mean,
- Values saved include matrices *b* and *varb* as usual. The variance weighted average of the OLS values is saved as a $K\times 1$ vector *beta_hat*. If the number of groups+1 times K is less than 50,000, then the individual predictions for $\boldsymbol{\beta}_i$ are saved as columns in the matrix *bt*.

The method of computing the individual predictions is given in Section E7.3.2.

The results saved are:

Scalars: *sumsqdev, ssqrd, s* are based on the sum of squares from $\hat{\boldsymbol{\beta}}$,

rsqrd

rho, logl		are returned as zero (not computed)
ybar, sy		are based on the full, pooled data set
kreg	=	the number of Rhs variables
nreg	=	the total number of observations, $\Sigma_i T_i$
degfrdm	=	*nreg* - *kreg*
ngroup	=	the number of groups
exitcode	=	zero unless data are collinear or a setup error occurs

Matrices:

b	=	$\hat{\boldsymbol{\beta}}$, the feasible GLS estimate of the mean $\boldsymbol{\beta}$
varb	=	the estimated asymptotic covariance matrix for $\hat{\boldsymbol{\beta}}$
bt	=	$K\times N$ matrix whose *i*th column is the estimate of $\boldsymbol{\beta}_i$
gamma	=	the estimate of $\boldsymbol{\Gamma}$
beta_hat	=	the variance matrix weighted average of the least squares vectors $\mathbf{b}_i$. (Sets $\boldsymbol{\Gamma} = \mathbf{0}$ in $\mathbf{W}_i$ in the expression in Section E15.4.3.)

Last Model: *b_variables*

Last Function: Conditional mean function = **β'x**

You may specify that the coefficients on certain variables are not random. These coefficients will still be estimated by FGLS. But, under this specification, there are rows and columns of zeros in **Γ**, the covariance matrix for the slopes, for these coefficients. Use the specification,

; Rh2 = list of variables whose coefficients are not random.

You may also specify that there is only a single common σ^2 instead of group specific disturbance variances, σ_i^2. The estimate is the pooled OLS estimator, based on a single OLS vector of coefficients. A different estimate, s^2* can also be requested. This estimate is based on the sum of group specific sums of squares, based on group specific OLS coefficient vectors. This estimate will always be smaller than s^2 based on a pooled OLS estimate. Use

	; Alg = constant	to force a common σ^2
or	**; Alg = group**	for the second estimator

We note, this estimator requires that it be possible to compute a least squares estimator, $\mathbf{b}_i$, for each group. This limits the applicability of this estimator. The Grunfeld data used earlier, and below are a natural application. The data are described in Section E7.10.1.

E15.4.2 Application

Listed below are the results of applying the random coefficients program to the five firm Grunfeld data used for our earlier examples. The command requests the preliminary OLS results (**; All**) and the individual predictions of the group specific coefficient vectors (**; Output = 4**). After estimation, we compare the residuals from three sets of estimates. The thick line in the figure tracks the GLS residuals from the model with a single coefficient vector. The lighter dashed line shows the residuals from a least squares regression in which each firm is allowed to have a separate constant term. The improvement in the fit is obvious. The lightest dashed line shows the residuals from the firm specific estimates derived in the next section. As might be expected, these appear to produce the best fit of the three. The commands used in the analysis are as follows:

```
SAMPLE      ; 1-200 $
SETPANEL    ; Group = firm ; Pds = ti $
NAMELIST    ; x = one,f,c $
```

Compute the Hildreth and Houck random coefficients regression.

```
REGRESS     ; Lhs = i ; Rhs = x ; Panel ; RCM
            ; All ; Output = 4 ; Res = e $
CREATE      ; Expand(firm) = d1,d2,d3,d4,d5,d6,d7,d8,d9,d10 $
CREATE      ; ef = 0 $
```

Compute the least squares results with firm specific constant terms.

```
REGRESS     ; Lhs = i ; Rhs = d*,f,c ; Res = e_firm $
```

Extract the individual vectors in *bt* and create the residuals using these.

```
PROCEDURE $
INCLUDE     ; New ; firm = j $
MATRIX      ; bf = bt(1:3,j:j) $
CREATE      ; ef = i - x'bf $
ENDPROC     $
EXECUTE     ; j = 1,10 $
```

Plot the three sets of residuals in the same figure.

```
SAMPLE      ; 1-200 $
PLOT        ; Rhs = e,e_firm,ef
            ; Spikes = 40.4,80.5,120.5,160.5 ; Bars = 0
            ; Fill ; Symbols ; Endpoints = 0,200
            ; Title = Residuals by Firm: FGLS and Dummy Variables
            ; Yaxis = Residual $

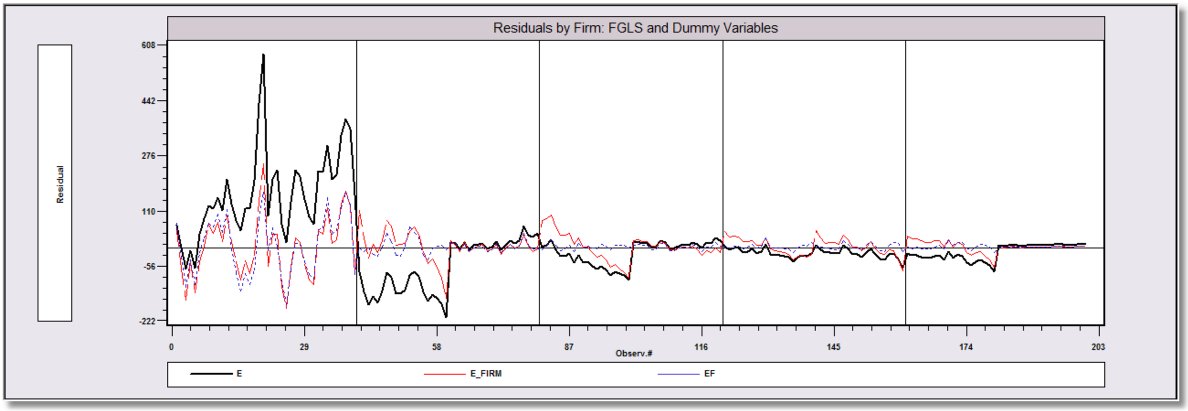

Figure E15.2 Residual Plot for Random Parameters Regression

E15.4.3 Technical Details for the Random Coefficients Estimator

Feasible Generalized Least Squares

The FGLS estimator in this model is computed as follows: Let

$$\boldsymbol{\Phi}_i = \sigma_i^2(\mathbf{X}_i'\mathbf{X}_i)^{-1}.$$

The FGLS estimator is

$$\hat{\boldsymbol{\beta}} = \Sigma_i \mathbf{W}_i \mathbf{b}_i,$$

where $\mathbf{b}_i = (\mathbf{X}_i'\mathbf{X}_i)^{-1}\mathbf{X}_i'\mathbf{y}_i$

and $\mathbf{W}_i = [\Sigma_i (\boldsymbol{\Gamma} + \boldsymbol{\Phi}_i)^{-1}]^{-1}(\boldsymbol{\Gamma} + \boldsymbol{\Phi}_i)^{-1}.$

Note that $\Sigma_i \mathbf{W}_i = \mathbf{I}$. Estimation is done in two steps, by estimating $\boldsymbol{\Gamma}$ first, then accumulating the matrix weighted average of the ordinary least squares coefficient vectors. The following technique is suggested (by Swamy (1974)). Let $\bar{\mathbf{b}} = (1/N)\Sigma_i \mathbf{b}_i$. Then,

$$\mathbf{V}_i = s_i^2(\mathbf{X}_i'\mathbf{X}_i)^{-1},$$

where $s_i^2 = \mathbf{e}_i'\mathbf{e}_i/(T_i - K).$

Estimate $\boldsymbol{\Gamma}$ with $\mathbf{G} = [1/(N\text{-}1)][\Sigma_i \mathbf{b}_i\mathbf{b}_i' - N\bar{\mathbf{b}}\,\bar{\mathbf{b}}'] - (1/N)\Sigma_i \mathbf{V}_i.$

Then, the remaining computations are straightforward. A problem may arise in that **G** may not be positive definite if the second matrix is too large. Several fixes have been suggested; the simplest is to omit the second matrix, which vanishes asymptotically anyway.

A chi squared test of the model against the alternative of the classical regression (no randomness of the coefficients) can be based on

$$\chi^2[(N\text{-}1)K] = \Sigma_i (\mathbf{b}_i - \mathbf{b}_*)'\mathbf{V}_i^{-1}(\mathbf{b}_i - \mathbf{b}_*),$$

where $\mathbf{b}_* = [\Sigma_i \mathbf{V}_i^{-1}]^{-1}\Sigma_i \mathbf{V}_i^{-1}\mathbf{b}_i.$

This is reported with the model output in the second frame of results. From the application above,

```
| Chi-squared for homogeneity test =    655.50   |
| Degrees of freedom               =        12   |
```

Predicting Group Specific Coefficient Vectors

The individual predictions of the group specific coefficient vectors are matrix weighted averages of the GLS estimator, $\hat{\boldsymbol{\beta}}$, and the group specific OLS estimates, $\mathbf{b}_i$,

$$\hat{\boldsymbol{\beta}}_i = \mathbf{Q}_i\hat{\boldsymbol{\beta}} + [\mathbf{I} - \mathbf{Q}_i]\mathbf{b}_i,$$

where $$\mathbf{Q}_i = [(1/s_i^2)\mathbf{X}_i'\mathbf{X}_i + \mathbf{G}^{-1}]^{-1}\mathbf{G}^{-1}.$$

(It can be shown that the weights in this average are proportional to the inverses of the asymptotic covariance matrices of the two parts. If there is sufficient space ($KN \leq 50{,}000$), these estimates are saved as the columns of the matrix *bt*. *LIMDEP* will also report full statistical results for the individual group predictions of $\boldsymbol{\beta}_i$ with standard errors. This produces a full set of output for each group in the sample, which can be substantial. Request this option with

; Output = 4

added to the **REGRESS ; ... ; RCM $** command. If you would like a separate report of the OLS results for the pooled sample, use

; All

E16: Linear Regression Models for Panel Data

E16.1 Introduction

Chapters E16-E23 document estimators for linear models using panel data. This chapter will detail some basic elements of the framework. The essential structure for most of the models is an 'effects' model,

$$y_{it} = \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$$

in which variation across groups (individuals) or time is captured in simple shifts of the regression function – i.e., changes in the intercepts. Chapter E17 describes the *fixed effects* (FE) model. The *random effects* (RE) models are detailed in Chapter E18. Several variations on this structure can be analyzed with this estimator, including both one and two factor models, models of autocorrelation, and simultaneous equations models. Chapter E18 also presents some major extensions including multifactor random effects models. More general forms of random parameter models are documented in Chapter E19. Chapters E20 and E21 show how to fit models with endogenous right hand side variables using two stage least squares in Chapter E22, and the Hausman and Taylor estimator for random effects and the Arellano, Bond and Bover estimator for dynamic panel data models in Chapter E23.

E16.2 Commands for Panel Data Regressions

The commands for estimation of these models are variants of the basic structure

```
SETPANEL    ; Group = group identifier variable
            ; Pds = variable to use for counts $
```

Then,

```
REGRESS     ; Lhs = y
            ; Rhs = x ...
            ; Panel
            ; ... other options $
```

The **SETPANEL** command is a global setting that needs only to be invoked once before your various panel data analyses. (See Chapter R5 for details.) Earlier versions of *LIMDEP* used one of

; Str = the name of a stratification variable

or **; Pds = specification of the number of periods, variable or fixed**

in each model command to specify the panel data structure. This construction may still be used in Version 10.

You may specify the **REGRESS** command using the command builder by selecting Model:Linear Models/Regression. The Lhs variable and the single Rhs variable are specified on the Main page.

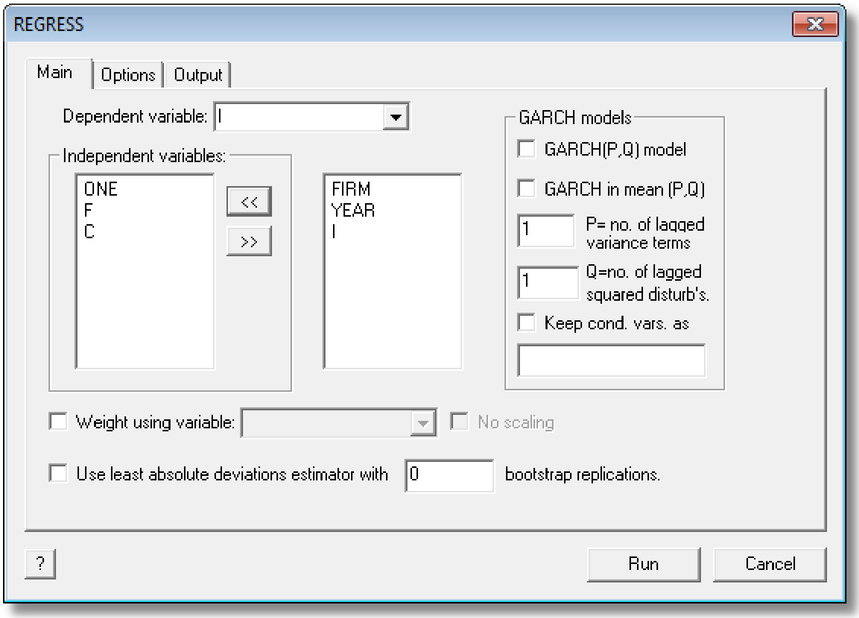

Figure E16.1 Main Page of Command Builder for REGRESS

The panel data model, and either a stratification variable or a fixed number of periods (only one would be used) are specified on the Options page.

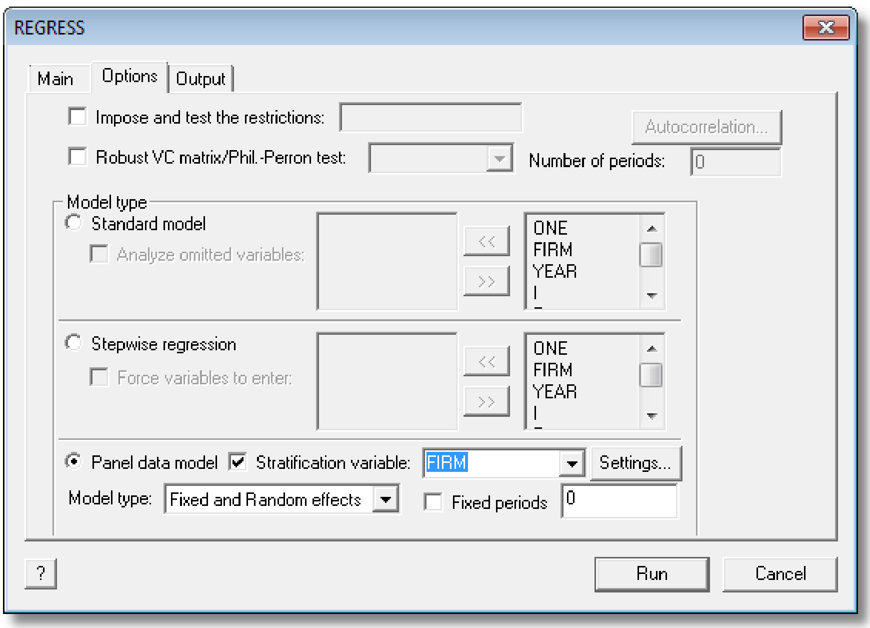

Figure E16.2 Options Page of Command Builder for REGRESS

HINT: If you have a fixed number of periods, be sure to click the Fixed periods checkbox before you enter the number of periods in the editing window. *LIMDEP* will allow you to enter the number of periods, but if you do not also click the checkbox, the panel data estimator will not be used.

E16.3 One Way Analysis of Variance

The simple one way analysis of variance for a variable is produced by the fixed effects regression model specified without covariates:

$$\begin{aligned} y_{it} &= \alpha_1 d_{1it} + \alpha_2 d_{2it} + \ldots + \varepsilon_{it} \\ &= \alpha_i + \varepsilon_{it}. \end{aligned}$$

The command for this computation is simply

REGRESS ; Lhs = the variable ; Rhs = one ; Panel $

If you have not used **SETPANEL** first, you can use

; ... stratification, either ; Str = variable or ; Pds = T $

E16.3.1 Computations and Saved Results

For the one way analysis of variance, results are based on the following computations:

N = total number of groups

T_i = number of observations in group i

$Nobs$ = $\sum_{i=1}^{N} T_i$ = total number of observations in the sample

$\bar{y}_i$ = sample mean of observations in group i

$\bar{y}$ = $\left[\sum_{i=1}^{N}\sum_{t=1}^{T_i} y_{it}\right] / Nobs$ = overall sample mean

$\sum_{i=1}^{N} T_i\left(\bar{y}_i - \bar{y}\right)^2$ = between groups sum of squares = SSB

$\sum_{i=1}^{N}\sum_{t=1}^{T_i}\left(y_{it} - \bar{y}_i\right)^2$ = within groups sum of squares = SSW

$\sum_{i=1}^{N}\sum_{t=1}^{T_i}\left(y_{it} - \bar{y}\right)^2$ = total sum of squares = SST = $SSB + SSW$

Sums of squares are computed in deviation form to achieve the maximum accuracy. Reported results are based on these statistics. Results saved for later use are:

Scalars:

ssqrd = regression variance = $SSW / (Nobs - N)$
rsqrd = proportion explained = SSB / SST
s = square root of *SSQRD*
sumsqdev = *SSB*
degfrdm = $Nobs - N$
ybar = $\bar{y}$
sy = square root of $SST / (Nobs - 1)$
kreg = N
nreg = $Nobs$

E16.3.2 Applications

We illustrate the computation with two of the NIST benchmarks for software accuracy, one each for low, medium, and high level of difficulty. See Section E2.12 for discussion of this suite of test problems. There are nine analyses of variance test problems. The problem statements given below are verbatim from the NIST website.

E16.4 The Group Means Estimator

The regression model in terms of group means is specified as

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$$

so

$$\bar{y}_i = \alpha_i + \boldsymbol{\beta}'\bar{\mathbf{x}}_i + \bar{\varepsilon}_i$$

This is a possibly heteroscedastic regression, Var[$\bar{\varepsilon}_i$] = σ^2/T_i. The coefficients are estimated by weighted least squares.

The group means estimator is computed as part of the computation of the random effects model. Since it is only an intermediate result, it is discarded at the end of estimation. If you wish to produce this as an estimator in its own right, use

; Means

in the command. In this case, the group means estimator is the only estimator produced.

For our previous application, now using all 10 firms in the sample, we obtain the following:

REGRESS ; Lhs = i ; Rhs = one,f,c ; Panel ; Pds = 20 ; Means $

```
-----------------------------------------------------------------------------
Group Means Regression............................

```

All of the standard results for regression models are saved by this estimator. Among the scalars, however, the *logl* should be ignored. Also, *rho* is not computed.

E16.5 The Pooled Regression

The pooled regression treats the panel as if it were a single cross section. This can obviously be obtained with the **REGRESS** command discussed in Chapters E7 and E8. You can use, instead,

REGRESS ; Lhs = dependent variable
; Rhs = independent variables
; Panel
; Robust ? This option requests the cluster correction
; Pooled $

to obtain additional output related to the panel. The example below illustrates. In addition to the standard regression results, this regression contains the univariate analysis of variance for the dependent variable and three specification tests for the model. The test statistics are detailed in Section E16.6.

```

E16.6 Specification Test for the One Factor Panel Models

Breusch and Pagan's Lagrange multiplier statistic,

$$\text{LM} = \frac{1}{2}\frac{\left(\sum_t T_i\right)^2}{\sum_i T_i(T_i-1)}\left[\frac{\sum_i\left(\sum_t e_{it}\right)^2}{\sum_i\sum_t e_{it}^{\ 2}} \ \text{-1}\right]^2$$

is used to test the null hypothesis that there are no group effects in the random effects model. Arguably, a rejection of the null hypothesis is as likely to be due to the presence of fixed effects. The statistic is computed from the ordinary least squares residuals from a pooled regression. Large values of LM favor the effects model over the classical model with no common effects. The Breusch and Pagan LM statistic is presented with the pooled regression results as shown in the preceding example. This is a chi squared statistic with one degree of freedom.

Two alternative forms of the LM statistic are presented in the pooled regression results. The Baltagi and Li (1990) version of LM is

$$\text{BL - LM} = \frac{1}{2}\left[\frac{\left(N\overline{T}\right)^2}{\left(\sum_i T_i^2\right)-N\overline{T}}\right]\left[\frac{\sum_i\left(\sum_t e_{it}\right)^2}{\sum_i\sum_t e_{it}^{\ 2}} \ \text{-1}\right]^2, \ \overline{T} = \frac{N}{\sum_i(1/T_i)}.$$

This statistic is identical to the Breusch and Pagan statistic when the panel is balanced. The authors argue that the small sample performance is better for unbalanced panels. A second alternative is the Moulton and Randolph (1989) statistic, which is more involved: It is computed as follows

$$\mathbf{z}_i = T_i\overline{\mathbf{x}}_i, \qquad tr_i = T_i + \mathbf{z}_i'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{z}_i,$$

$$\text{Trace} = \sum_i tr_i, \quad \text{Trace2} = \sum_i tr_i^2$$

$$\text{E} = \frac{Trace}{\sum_i T_i}, \qquad V = \frac{2\left[\left(\left(\sum_i T_i\right)Trace2\right) - Trace^2\right]}{\left(\sum_i T_i\right)^2\left[\left(\sum_i T_i\right)+2\right]},$$

$$\text{MR} = \frac{\left(\dfrac{\sum_i\left(\sum_t e_{it}\right)}{\sum_i\sum_t e_{it}^2}\right) - \text{E}}{\sqrt{V}}.$$

The limiting distribution of MR is standard normal, so values in excess of 1.96 weigh against the base regression model. The Baltagi and Li and the Moulton and Randolph statistics are presented in the results for the pooled regression.

VERSION NOTE: In earlier versions of *LIMDEP*, the Breusch and Pagan and the Baltagi and Li statistics were reported with the results for the random effects model. They have been moved to the results for the pooled regression since they are computed and used with reference to the pooled model (and are more useful there) and, in addition, they can be computed and reported without actually computing the random effects estimator. The Moulton and Randolph statistic is new with Version 10.

E16.7 One Way Fixed and Random Effects Models

The next two chapters consider formulation and estimation of one way common effects models,

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}.$$

The fixed effects model is

$$\begin{aligned} y_{it} &= \alpha_1 d_{1it} + \alpha_2 d_{2it} + \ldots + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} \\ &= \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}, \end{aligned}$$

where $E[\varepsilon_{it}|\mathbf{X}_i] = 0$, $\text{Var}[\varepsilon_{it}|\mathbf{X}_i] = \sigma^2$, $\text{Cov}[\varepsilon_{it},\varepsilon_{js}|\mathbf{X}_i,\mathbf{X}_j] = 0$ for all i,j,

$$\text{Cov}[\alpha_i,\mathbf{x}_{it}] \neq \mathbf{0}.$$

The efficient estimator for this model in the base case is least squares. This model is documented in Chapter E17. The random effects model is

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i$$

where $E[u_i] = 0$, $\text{Var}[u_i] = \sigma_u^2$ $\text{Cov}[\varepsilon_{it},u_i] = 0$.

$$\text{Var}[\varepsilon_{it} + u_i] = \sigma^2 = \sigma_\varepsilon^2 + \sigma_u^2 .$$

For a given i, the disturbances in different periods are correlated because of their common component, u_i,

$$\text{Corr}[\varepsilon_{it} + u_i,\varepsilon_{is} + u_i] = \rho = \sigma_u^2 / \sigma^2.$$

The efficient estimator is generalized least squares. This model is developed in Chapter E18.

E17: Fixed Effects Linear Regression

E17.1 Introduction

This chapter will detail estimation of linear regression models with fixed effects. The essential structure is,

$$y_{it} = \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$$

in which variation across groups (individuals) or time is captured in simple shifts of the regression function – i.e., changes in the intercepts. The user is referred to textbook treatments such as Greene (2011) or Wooldridge (2010) for background theory of the models. The two models estimated with this program are 'one way' or 'one factor' designs of the form

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$$

where ε_{it} is a classical disturbance with $E[\varepsilon_{it}|\mathrm{x}_{\mathrm{it}}] = 0$ and $\mathrm{Var}[\varepsilon_{it}|\mathrm{x}_{\mathrm{it}}] = \sigma_\varepsilon^2$ and 'two way' or 'two factor' models as shown in the first equation above.

E17.2 One Way Fixed Effects Model

In the fixed effects model (FEM), α_i is a separate constant term for each unit. Thus, the model may be written

$$\begin{aligned} y_{it} &= \alpha_1 d_{1it} + \alpha_2 d_{2it} + \ldots + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} \\ &= \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}, \end{aligned}$$

where the α_is are individual specific constants, and the d_js are group specific dummy variables which equal one only when $j = i$. The fixed effects model is an ordinary linear regression model. The complication for the least squares procedure is that N may be very large so that the usual formulas for computing least squares coefficients are cumbersome (or impossible) to apply. The model may be estimated in a simpler form by exploiting the algebra of least squares.

E17.2.1 Command for One Factor Models

The one way FEM is a linear regression with N dummy variables (and no overall constant term). To invoke this procedure, use the command the panel is set up with

SETPANEL ; Group = the group identifier ; Pds = variable to use for group counts $

Then,

```
REGRESS   ; Lhs = y
          ; Rhs = list of regressors
          ; Panel
          ; Fixed Effects $
```

You need not include *one* among your regressors. The constant is placed in the regression automatically when it is needed. You may also use:

; Output = 2

to list fixed effects in an output file. This will also produce estimated standard errors for the fixed effects. If the number of groups is large, the amount of output can be very large.

The basic command can be constructed using the **REGRESS** command builder shown earlier. You can also use the command builder for many optional features. Select Panel data model on the Options page to activate the Model type window and the Settings button. Select your model type, then click Settings to open a dialog box of optional features for that type of model. Options for fixed and random effects models are listed in the same dialog box, as shown in Figure E17.1.

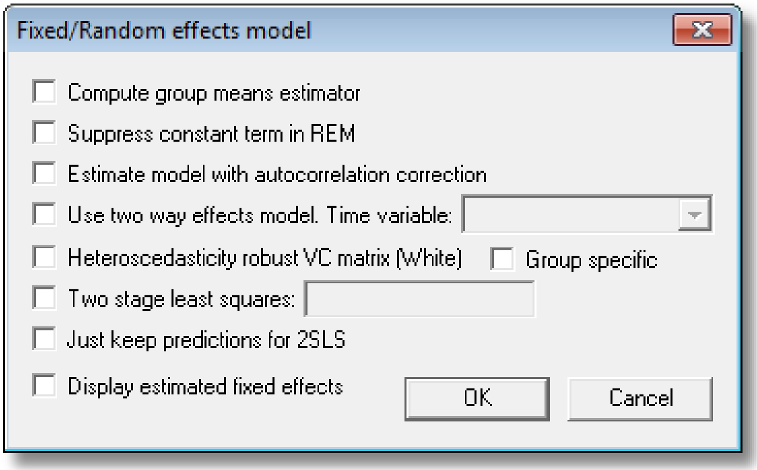

Figure E17.1 Command Builder Options for Common Effects Models

Standard options for residuals and fitted values, include the following. All of

; List	to display residuals and fitted values
; Keep = name	to retain predictions
; Res = name	to retain residuals
; Var =	a submatrix of the parameter VC matrix
; Fill	(missing observations)
; Wts = weighting variable	
; Covariance Matrix (or ; Printvc)	

are available as usual. If your stratification indicators are set up properly for out of sample observations, **; Fill** will allow you to extrapolate outside the estimation sample.

WARNING: If you do not have a stratification indicator already in use, **; Fill** will not work. The *_stratum* variable is set up only for the estimation sample. Thus, with **; Pds = T**, you cannot extrapolate outside the sample.

E17.2.2 Program Output for One Way Fixed Effects Models

Two full sets of estimates are computed by this estimator:

1. **Pooled Regression:** The fixed effects model above with all of the individual specific constants assumed equal is $y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$. This model is estimated by simple ordinary least squares.

2. **Least Squares Dummy Variable:** The fixed effects model with individual specific constant terms is estimated by partitioned ordinary least squares. For the one factor models, we formulate this model with N group specific constants and no overall constant.

The second constitutes the results for the fixed effects estimator. Define the four models:

Model	1	$y_{it} = \alpha + \varepsilon_{it}$	(no group effects or xs),
Model	2	$y_{it} = \alpha_i + \varepsilon_{it}$	(group dummies only),
Model	3	$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$	(regressors only),
Model	4	$y_{it} = \alpha_I + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$	(regressors and group effects).

Output from this program, in the order in which it will appear, is as follows:

1. Pooled linear regression of y on a single constant and the regressors, $x_1,...,x_K$. *These K variables do not include one*. This is Model 3 above. Output consists of the standard results for least squares regression. The diagnostic statistics in this regression output will also include the unconditional analysis of variance for the dependent variable. This is the usual ANOVA for the groups, ignoring the regressors. The output from this procedure could be used to test the hypothesis that the unconditional mean of y is the same in all groups. (This test is done by the program. See part 3 below.) Results at this step also include the Breusch and Pagan test statistic for common effects and two alternatives. See Section E16.6 and the application below for details.

2. Ordinary least squares estimates of Model 4 above. Output is the same as in part 1, the usual for a least squares regression. The estimates of the dummy variable coefficients and the estimated standard errors are listed in the output file if requested with **; Output = 2**. (There may be hundreds or thousands of them!)

3. Test statistics for the various classical models. The table contains

   a. For Models 1-4, the log likelihood function, sum of squared residuals based on the least squares estimates, and R^2.

   b. Chi squared statistics based on the likelihood functions and F statistics based on the sums of squares for testing the restrictions of:

      - Model 1 as a restriction on Model 2 (no group effects on the mean of y),
      - Model 1 as a restriction on Model 3 (no fit in the regression of y on xs),
      - Model 1 as a restriction on Model 4 (no group effects or fit in regression),
      - Model 2 as a restriction on Model 4 (group effects but no fit in regression),
      - Model 3 as a restriction on Model 4 (fit in regression but no group effects).

The statistic, degrees of freedom, and prob value (probability that the statistic would be equaled or exceeded by the chi squared or F random variable) are given for each hypothesis.

E17.2.3 Saved Results

The retrievable results are:

Matrices:	*b* and *varb*		
	alphafe		contains the estimates of the fixed effects, α_i. This matrix is limited to 50,000 cells, so if your data have more than 20,000 groups, *alphafe* will contain the first 50,000 fixed effects computed.
Scalars:	*ssqrd*	=	s^2 from least squares dummy variable (LSDV)
	rsqrd	=	R^2 from LSDV
	s	=	$\sqrt{s^2}$ from LSDV
	sumsqdev	=	sum of squared residuals from LSDV
	rho	=	estimated disturbance autocorrelation from whatever model is fit last
	degfrdm	=	$\Sigma_i T_i - K$
	sy	=	standard deviation of Lhs variable
	ybar	=	mean of Lhs variable
	kreg	=	K
	nreg	=	total number observations
	logl	=	log likelihood from LSDV model
	exitcode	=	0.0 if the model was estimable
	ngroup	=	number of groups
	nperiod	=	number of periods. This will be 0.0 if you fit a one way model.
Last Model:	*b_variable*		constructed as usual

Last Function: Conditional mean **= b'x**

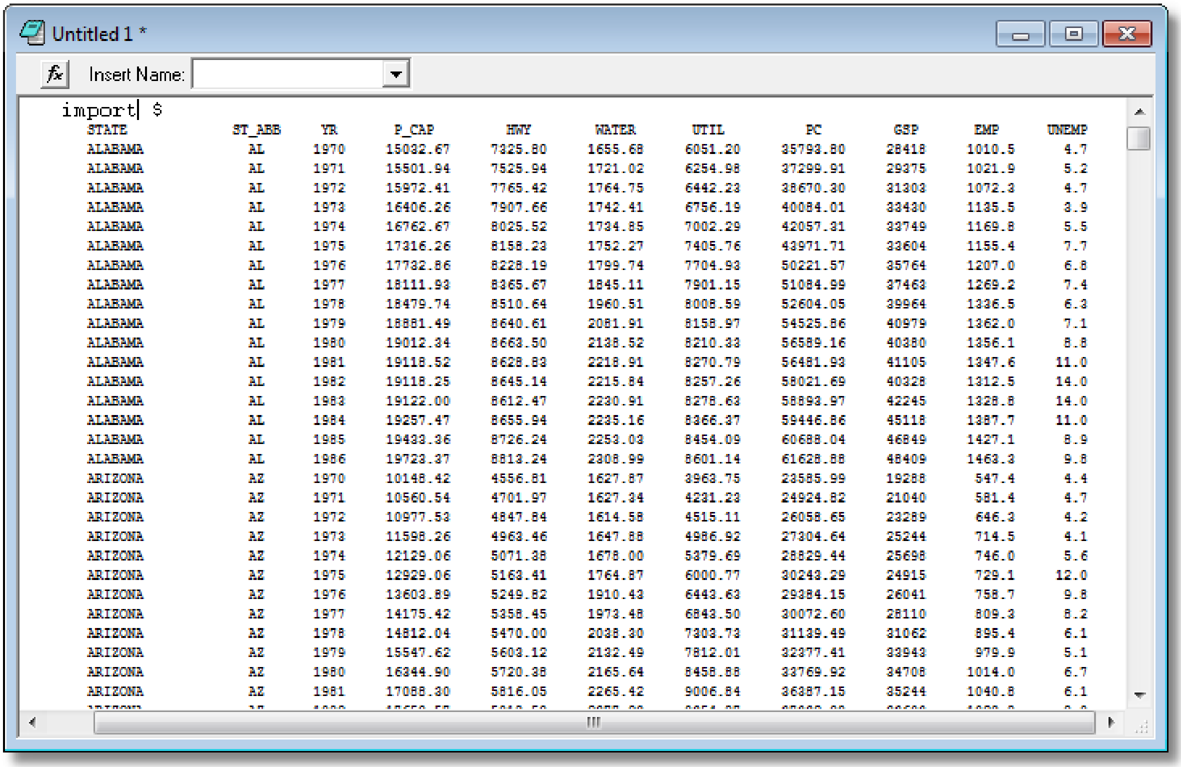
Predicted values are based on the last model estimated, one or two way, fixed or random. Predictions are not listed when you use the group means estimator, but they can be computed with **MATRIX**. Estimates of the variances or standard errors of the fixed effects are not kept. But, a simple method of computing them is given below.

Note, the implication of not storing the constants (there could be thousands of them) is that because the model is linear, **PARTIALS** will give you the right answer for partial effects even when there are interactions or nonlinearities in the model. However, **SIMULATE** will not give the correct predicted values – the appropriate function would be a_i + $\mathbf{b'x}_{it}$. Predictions using **; List** and **; Keep** and residuals requested with **; Res** are computed correctly using a_i as indicated.

E17.2.4 Application

The examples to follow are based on an application in Baltagi (2005) which describes Munnell's (1990) study of statewide productivity. The data were downloaded from the website for the text: http://www.wiley.com/legacy/wileychi/baltagi/supp/PRODUC.prn. The data are a balanced (17 years) panel of observations on the 'lower' 48 states. Variables in the data set are

state	=	state ID (changed from the name in the original)
yr	=	year, 1970,...,1986
p_cap	=	public capital
hwy	=	highway capital
water	=	water utility capital
util	=	utility capital
pc	=	private capital
gsp	=	gross state product
emp	=	employment
unemp	=	unemployment rate



STATE	ST_ABB	YR	P_CAP	HWY	WATER	UTIL	PC	GSP	EMP	UNEMP

The individual effects are accessible as a matrix in the work area. The following replicates the computations that underlie the listing after the LSDV results above. The individual effects are computed as

$$a_i = \overline{y}_i - \mathbf{b}'_{LSDV}\overline{\mathbf{x}}_i$$

The appropriate estimator of the asymptotic variance of a_i is

$$\text{Est.Asy.Var}[a_i] = \frac{s^2}{T_i} + \overline{\mathbf{x}}_i'\left[s^2(\mathbf{X}'\mathbf{M}_D'\mathbf{M}_D\mathbf{X})^{-1}\right]\mathbf{x}_i,\ s^2 = \frac{\Sigma_i\Sigma_{t=1}^{T_i}(y_{it} - a_i - \mathbf{b}'_{LSDV}\mathbf{x}_{it})^2}{(\Sigma_i T_i) - n - K}.$$

The matrix $\mathbf{XM_D'M_DX}$ is the moment matrix computed using deviations from group means;

$$\mathbf{X}'\mathbf{M}_\mathbf{D}'\mathbf{M}_\mathbf{D}\mathbf{X} = \sum_{i=1}^{n}\sum_{t=1}^{T_i}\left(\mathbf{x}_{it} - \overline{\mathbf{x}}_i\right)\left(\mathbf{x}_{it} - \overline{\mathbf{x}}_i\right)'.$$

```

E17.2.5 Robust Estimation of the Fixed Effects Covariance Matrix

Under the assumptions of the model made at the outset, the appropriate covariance matrix for the fixed effects coefficient is shown in the preceding example. If it is believed that there is residual correlation across observations in the groups even with the individual effects included, one can compute a 'cluster correction' for the asymptotic covariance matrix. The correction would be

$$Est.Asy.Var[b_{LSDV}] = (\mathbf{X'M_D'M_DX})^{-1}\left[A\sum_{i=1}^{n}\left\{\left(\mathbf{M}_D^{(i)}\mathbf{X}^{(i)}\right)\mathbf{e}_i\right\}\left\{\left(\mathbf{M}_D^{(i)}\mathbf{X}^{(i)}\right)\mathbf{e}_i\right\}'\right](\mathbf{X'M_D'M_DX})^{-1}$$

$$A = \frac{n}{n-1}\frac{(\Sigma_t T_i)-1}{(\Sigma_t T_i)-(n+K)}$$

This correction is requested by adding

; Robust

to the command. Note, this is the 'cluster estimator' used elsewhere; we use **; Robust** to distinguish it here because the calculations are already accommodating clustering. The impact on the LSDV results is shown below. The effect on the estimated standard errors is substantial. (The other statistical results are the same.)

When the **REGRESS** command contains **; Robust**, the original pooled estimator and the subsequent random effects estimator, if it is computed, are also computed with this robust covariance matrix correction.

E17.2.6 Fixed Effects Models with Time Invariant Variables

The fixed effects model generally cannot be estimated when the data contain time invariant variables. The reason is that the within groups transformation used to fit the coefficients,

regression of (y_{it} - $\bar{y}_i$) on ($\mathbf{x}_{it}$ - $\bar{\mathbf{x}}_i$) with no constant term),

produces a column of zeros for every time invariant variable. This is a problem of perfect collinearity, since a time invariant variable is just a multiple of the individual specific dummy variable. *LIMDEP* does not halt the regression when this condition is detected. For reasons noted shortly, *LIMDEP always* uses a generalized inverse and computes the regression anyway. However, the condition is noted. When there are no time invariant variables, the G-inverse gives precisely the correct result. When there are time invariant variables, there will be superfluous coefficients, but the results are still useable and clearly identified in the results. An example will illustrate. We first create a variable that contains no within state variation

CREATE ; lempbar = Group Mean(logemp, Pds = 17) $

```
+-----------------------------------------------------------------+

Note that there is an extensive warning about the time invariant variable(s). However, the regression has been computed. Most importantly, however, notice that the sum of squared residuals and the coefficients on the time varying variables in the two regressions are identical. The coefficient on the time invariant variable is not useable. The small difference in the standard errors in the second model is due to the loss of one degree of freedom (for each time invariant variable) in the second model.

This set of outcomes is noted here for two reasons: You would normally not deliberately add a time invariant variable to a fixed effects model, as we did here. However, one might include one (such as gender or education) inadvertently.

1. *LIMDEP* will warn you of this occurrence. It does not halt estimation. But, in this event, you should reconsider the specification of the model. The reduced specification is not necessarily useful.

2. Although fixed effects models cannot have time invariant variables, random effects models can. That is the reason for the computation. If you request estimation of a random effects model, the sum of squared residuals for the fixed effects model is needed for estimation of the variance components. The presence of the time invariant variables in the model does not prevent this computation. This FE model is always computed, either explicitly if you request fixed effects, or in the background if you have requested random effects (or both fixed and random effects). This method of doing the estimation allows estimation of all models to proceed even in the event of this complication.

NOTE: The recent literature contains a thread of results on a 'Fixed Effects Vector Decomposition' (FEVD) estimator that claims to solve the 'problem' of time invariant variables in a fixed effects model. (See Plumper and Troeger (2007, 2011) and Greene (2011) for discussion.) The so called FEVD estimator is not a 'solution' to this multicollinearity problem. It does reformulate the model so that it is essentially a random effects model. FEVD is not provided as a separate estimator in *LIMDEP*. It can be easily programmed. We return to the computation in Chapter E18 on fitting the random effects model.

E17.2.7 Restricted Least Squares

The (one or two way) fixed effects model can be fit with linear restrictions. (This option does not apply to the random effects estimator.) Use the standard specification,

; CLS: ... linear restrictions ...

The full set of results will be presented for the unrestricted estimates and the restricted estimates, with an F statistic for testing the hypothesis of the restrictions.

For the preceding application, the restriction of constant returns to scale – all slope coefficients sum to one – is a natural one. It is imposed by adding

```
NAMELIST   ; x = logkp,loghwy,logh2o,logutil,logemp $
REGRESS    ; Lhs = loggsp ; Rhs = x,one
           ; Panel ; Fixed Effects
           ; CLS: logkp + loghwy + logh2o + logutil + logemp = 1 $
```

to the **REGRESS** command. (The initial estimated OLS and fixed effects results are omitted.)

```

(Additional results for analysis of variance – which have changed – are omitted.)

NOTE: There is a side result which can occur with this computation. The Hausman test requires the covariance matrix of the fixed effects estimator. Normally, this will be larger than that for the REM. But, with restrictions applied to the FEM and not the REM, this need not be the case. In this case (as occurs in this application), the Hausman statistic cannot be computed. The Hausman statistic is described in Chapter E18 where the random effects estimator is documented.

The restrictions affect the estimated fixed effects as well. Fortunately, the simplicity of the LSDV estimator remains even when the restrictions are imposed. The fixed effects are still the group mean residuals, but now computed with the restricted least squares estimator. This is all handled internally. The fixed effects are adjusted for this result after the restrictions are imposed.

E17.2.8 Technical Details on Estimation of One Way Fixed Effects Models

The calculations for the balanced design case are exactly those described in Wooldridge (2011) or Greene (2011). Since these are fully documented, we will just sketch them here. We will then turn to special considerations of the model when groups have unequal numbers of observations. The notations for group and overall means used below are the standard ones. We will refer back to the descriptions and the application in the preceding two sections at various points below.

Computing the Fixed Effects Estimator

Model 1 is estimated simply as the grand mean of *y*, so the sum of squares is

$$TOTAL \quad = \sum_i \sum_{t=1}^{T_i} \left(y_{it} - \bar{\bar{y}}\right)^2.$$

R^2 for this model is zero by definition. The value of *TOTAL* appears in the ANOVA tables in the first set of output for the model.

Analysis of Model 2 is the familiar unconditional analysis of variance for *y* ignoring the regressors. The coefficients would simply be the group means. The total variation above may be decomposed into

$$WITHIN \quad = \sum_i \sum_t \left(y_{it} - \bar{y}_{i.}\right)^2$$

$$BETWEEN \quad = \sum_i T_i \left(\bar{y}_{i.} - \bar{\bar{y}}\right)^2$$

Since $TOTAL \quad = BETWEEN + WITHIN,$

we may define $R_o^2 \quad = BETWEEN \,/\, TOTAL.$

Note that this analysis is equivalent to the regression of *y* on a constant term and a set of *n*-1 group dummy variables or, equivalently, just the *N* group dummy variables with no overall constant. The values of *WITHIN* and this R_o^2 are given as the 'Sum of Squares' and '*R*-squared' in the second row of the Test Statistics for the Classical Model, so *BETWEEN* may be deduced as R_o^2 times *TOTAL*.

Model 3 is the linear regression model. Estimation is by ordinary least squares regression of y_{it} on a single constant and the set of **x**s. No new issues arise. For this model, the groupwise nature of the data set is ignored; the full set of observations is pooled. The analysis of variance for this model is the conventional one. The diagnostic statistics that precede the listing of the coefficient estimates contain the sums of squared residuals, mean and standard deviation of the Lhs variable, and so on.

Model 4 is the full 'dummy variable' model. Parameters are estimated as follows:

estimate $\boldsymbol{\beta}$ by regression of (y_{it} - $\bar{y}_i$) on ($\mathbf{x}_{it}$ - $\bar{\mathbf{x}}_i$) (with no constant term),

estimate α_i with $a_i = \bar{y}_i - \mathbf{b}'\bar{\mathbf{x}}_i$

These calculations follow from the algebra of least squares. The estimated covariance matrix of **b**, sum of squared residuals, and estimator of σ^2 from the first regression are all appropriate as they stand and need not be modified. Estimates of the standard errors of a_is are obtained by

$$\text{Est.Asy.Var}[a_i] = \frac{s^2}{T_i} + \bar{\mathbf{x}}_i'\left[s^2(\mathbf{X}'\mathbf{M}_D'\mathbf{M}_D\mathbf{X})^{-1}\right]\bar{\mathbf{x}}_i,\; s^2 = \frac{\Sigma_i\Sigma_{t=1}^{T_i}(y_{it} - a_i - \mathbf{b}_{LSDV}'\mathbf{x}_{it})^2}{(\Sigma_i T_i) - n - K}.$$

None of the preceding relies on equal group sizes. If the group sizes are unequal, as T_i, then, the means are based on the respective group sizes.

As noted earlier, although the estimated fixed effects are retained as matrix *alphafe*, the estimates of the variances are not kept. But, these are easy to obtain, and you can even recover the rest of the estimates if you have more than 50,000 groups. If you have a large number of groups and regressors, you may have to do this in parts. The program shown at the end of Section E17.2.4 can be applied to the entire sample or in separate parts of it.

Restricted Least Squares

The regression model is $y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$. We fit the model subject to the linear restrictions

$$\mathbf{Rb} - \mathbf{q} = \mathbf{0}.$$

Let **y** and **X** denote the full data matrices, and let **D** denote the full matrix of group dummy variables. Let $\mathbf{y}^*$ and $\mathbf{X}^*$ denote the matrix of data in deviations from the group means,

$$(\mathbf{X}^*,\mathbf{y}^*) = [\mathbf{I} - \mathbf{D}(\mathbf{D}'\mathbf{D})^{-1}\mathbf{D}'](\mathbf{X},\mathbf{y}).$$

Since the slopes are obtained just by applying ordinary least squares, the restricted slope estimator is obtained by the familiar formula,

$$\mathbf{b}_c = \mathbf{b} - (\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}\mathbf{R}'[\mathbf{R}(\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}\mathbf{R}']^{-1}(\mathbf{Rb} - \mathbf{q}).$$

where **b** is the LSDV estimator. We now seek the restricted estimator of the vector of fixed effects. Write the full coefficient vector as $[\boldsymbol{\alpha}',\boldsymbol{\beta}']'$ and the estimates as $\mathbf{c} = [\mathbf{a}',\mathbf{b}']'$. Also, let $\mathbf{R}_0 = [\mathbf{0},\mathbf{R}]$, where the parts are $J\times N$ and $J\times K$, and J is the number of restrictions. The zero block results from the fact that no restrictions are being imposed on the fixed effects. Thus, in terms of the full coefficient vector, we have $\mathbf{R}_0\mathbf{c} - \mathbf{q} = \mathbf{0}$. Then, in terms of the full coefficient vector, in partitioned form, we have

$$\begin{bmatrix}\mathbf{a}_c\\ \mathbf{b}_c\end{bmatrix} = \begin{bmatrix}\mathbf{a}\\ \mathbf{b}\end{bmatrix} - \begin{bmatrix}\mathbf{D}'\mathbf{D} & \mathbf{D}'\mathbf{X}\\ \mathbf{X}'\mathbf{D} & \mathbf{X}'\mathbf{X}\end{bmatrix}^{-1}\begin{bmatrix}\mathbf{0}\\ \mathbf{R}'\end{bmatrix}\left[\begin{bmatrix}\mathbf{0}' & \mathbf{R}\end{bmatrix}\begin{bmatrix}\mathbf{D}'\mathbf{D} & \mathbf{D}'\mathbf{X}\\ \mathbf{X}'\mathbf{D} & \mathbf{X}'\mathbf{X}\end{bmatrix}^{-1}\begin{bmatrix}\mathbf{0}\\ \mathbf{R}'\end{bmatrix}\right]^{-1}\left[\begin{bmatrix}\mathbf{0}' & \mathbf{R}\end{bmatrix}\begin{bmatrix}\mathbf{a}\\ \mathbf{b}\end{bmatrix} - \mathbf{q}\right].$$

Using the partitioned inverse formula (Greene (2011, eq. A-66)) produces the result for the fixed effects,

$$\mathbf{a}_c \;=\; \mathbf{a} + (\mathbf{D}'\mathbf{D})^{-1}\mathbf{D}'\mathbf{X}[\mathbf{X}'\mathbf{X} - \mathbf{X}'\mathbf{D}(\mathbf{D}'\mathbf{D})^{-1}\mathbf{D}'\mathbf{X}]^{-1}(\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}\mathbf{R}'[\mathbf{R}(\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}\mathbf{R}']^{-1}(\mathbf{Rb} - \mathbf{q})$$

$$= \mathbf{a} + \overline{\mathbf{X}}'(\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}\mathbf{R}'[\mathbf{R}(\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}\mathbf{R}']^{-1}(\mathbf{Rb} - \mathbf{q})$$

$$= \mathbf{a} + \overline{\mathbf{X}}'(\mathbf{b} - \mathbf{b}_c)$$

but $\quad \mathbf{a} = \overline{\mathbf{y}} - \overline{\mathbf{X}}'\mathbf{b}$

so $\quad \mathbf{a}_c = \overline{\mathbf{y}} - \overline{\mathbf{X}}'\mathbf{b}_c$

$$= (1/T_i)\Sigma_t\, e_{it} \text{ for each element, } i = 1,...,N.$$

Therefore, the restricted least squares estimators of the fixed effects are the group mean residuals using the restricted least squares estimators of the slopes.

E17.3 Two Way Fixed and Random Effects Models

The panel data estimator also allows ‘two way’ fixed and random effects models. The fixed effects model for a two way design is

$$y_{it} = \alpha_0 + \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}.$$

Notice that this model has an overall constant as well as a ‘group’ effect for each group and a ‘time’ effect for each period. The problem of multicollinearity – the time and group dummy variables both sum to one – is avoided by imposing the restrictions $\Sigma_i\alpha_i = \Sigma_t\gamma_t = 0$. (In an unbalanced panel, the sums are weighted by $T_i/(\Sigma_iT_i)$ or $N_t/(\Sigma_tN_t)$.) A full set of estimates is produced for the two factor model in the same fashion as for the one factor model. The random effects model for a two way design is

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i + w_t.$$

The model is described in standard textbooks such as Judge, et. al. (1985) or Greene (2011).

In this model, neither the number of time periods observed for each group nor the number of individuals observed in each period need be fixed. Your data can consist of simply a sample of observations indexed by both individual and time. The data setup is exactly as described in Section R5.3. To request the two factor model, you simply add the specification

; Period = time variable

to the usual command. Unlike a group stratification variable, the time variable must use the integers $1,2,...,T_i$. As noted earlier, *it is not necessary for every group to have data in every period; there may be gaps*. But, if you do have a balanced panel, you can easily set up the time indicator with the Trn function in **CREATE**. For example, in the data set we have been using for our application, there are 17 observations for each state. We could use

```
CREATE      ; time = Trn(-17,0) $
```

(The variable *yr*-1969 in the data set would have the right values.) If the sample is not balanced, in either dimension, it will be necessary to provide the time variable by some other means. When you request the two factor model, the command will appear as

REGRESS ; Lhs = ... ; Rhs = ... ; Panel ; Period = time $

The model is

$$y_{it} = \mu + \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}.$$

The textbook formula for two way fixed effects regression, least squares regression of $\left(y_{it} - \overline{y}_i - \overline{y}_t + \overline{\overline{y}}\right)$ on the same transformation of $\mathbf{x}_{it}$ does not work when the panel is unbalanced. It is necessary to add the time dummy variables to a one way fixed effects model (as ordinary regressors). We compute the fixed effects estimator of $\boldsymbol{\beta}$ by making this transformation. The estimated covariance matrix and sum of squares from this least squares regression as computed in the usual manner are appropriate.

NOTE: The two way fixed effects estimator must be computed by literally computing the dummy variables for the time effects. You may have up to 1,000 periods in the data set. You do not need to compute the dummy variables; this is done internally.

E17.3.1 Program Output for Two Factor Models

This estimator produces the full set of output described earlier for the one factor model defined by the **; Pds** setup and an additional set of results for the two factor model. The additional results will be

1. Full set of two factor fixed effects results. Do note, in accordance with the description above, this model, unlike the one way model, will contain an overall constant term. This model is estimated by OLS including both the time and group dummy variables.

2. Full table of estimates of fixed effects (if requested with **; Output = 2**). Note, as well, that the fixed effects produced for the groups will differ from the earlier results, since by design, the time dummy variables are not orthogonal to the group dummy variables.

3. Test statistics for the two way fixed effects model. This consists of the log likelihood, sum of squared deviations, and R^2s for five models:

   a. overall constant term only, no regressors,
   b. group dummies, no regressors,
   c. regressors and overall constant term,
   d. full one way fixed effects model,
   e. full two way fixed effects model.

   You should observe rising log likelihoods and R^2s and falling sums of squares as you go down the table, but if your regressors do not have much explanatory power the reverse could happen between b and c.

4. Full set of results for the two way random effects model including the LM statistic, Hausman statistic, estimates of the variance components, and the usual coefficient estimates with standard errors.

E17.3.2 Application

The following continues the earlier example with the two factor models.

CREATE ; t = Trn(-17,0) $
REGRESS ; Lhs = loggsp ; Rhs = x,one
; Fixed Effects ; Period = t ; Panel $

The first set of results is the same as shown earlier. The results for the two factor models are shown below.

The LM statistic has been adjusted for the two types of effects – there is no Baltagi and Li counterpart for this. The Hausman statistic is also recomputed.

E17.4 Autocorrelation

The one factor fixed and random effects models may be estimated with an autocorrelated error structure. The structural equations would be as follows:

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i + \varepsilon_{it},$$

$$\varepsilon_{it} = \rho\varepsilon_{i,t-1} + \eta_{it}.$$

Estimation is done in two steps. In the first, the model is estimated ignoring the autocorrelation just for the purpose of obtaining an estimate of ρ. The second step is the generalized least squares procedure. The following describes the commands needed to estimate this model.

Estimation is essentially the same for both the fixed and random effects models. The first command is used to produce the estimate of ρ and is the basic model command. The estimate is saved automatically in the calculator scalar, *rho*. The second command will be the same as the first, with the addition of the specification

; AR1

You should also use

; Fixed or **; Random**

to specify which type of model you wish to estimate. If you omit both of these, as usual, both the fixed and random effects estimators will be computed, and the random effects model results will be saved.

For example,

REGRESS ; Lhs = y ; Rhs = xlist ; Panel ; Str = i ; Fixed $
REGRESS ; Lhs = y ; Rhs = xlist ; Panel ; Str = i ; Fixed ; AR1 $

will estimate the fixed effects model with the autocorrelated error structure. Changing **; Fixed** to **; Random** will estimate a random effects model. This model may also be combined with the two stage least squares procedure described in the next section. (It cannot be combined with the Hausman-Taylor or DPD estimators described later in this chapter.)

The value of ρ used when you specify **; AR1** is whatever value happens to be in the calculator scalar named *rho*. This is one of the named scalars which automatically contains the residual autocorrelation after you compute a least squares or two stage least squares linear regression. This is kept automatically by the first of the two regressions above. *If your command contains* **; AR1**, *the value of rho is left unchanged by that regression.* Thus, you can use the same value of ρ in several regressions. In addition, the value of *rho* need not be that produced by a fixed or random effects model. If you precede your panel data model with any other regression, it will leave a value of ρ behind to be used by this model. Alternatively, to set ρ, you can simply use the command

CALC ; rho = desired value $

(This scalar is not 'read-only,' as this command demonstrates, even though it appears to be in the project window.)

NOTE: Estimation with autocorrelated disturbances does not require that there be the same number of observations in each group (as usual).

The output produced by the **; AR1** model will differ from the usual output only in the display of the value of *rho* in use at the beginning of the first page. In addition, the output for the LSDV and FGLS estimators will contain estimates of the autocorrelation of the residuals. But, this value will not replace the value of *rho* being used in the calculations. Do note, however, that at every step, the entire analysis is based on transformed data (e.g., $y_{it} - \rho y_{i,t-1}$). As such, many statistics, such as group means, likelihood ratio statistics, analyses of variance, etc., will be meaningless.

In both random and fixed effects models, when **; AR1** is used, the full set of analyses is applied to the transformed data

$$z_{it} = Z_{it} - \rho Z_{i,t-1}$$

where Z_{it} is either y_{it}, $\mathbf{x}_{it}$, or the same transformation of the instruments. This is the Cochrane-Orcutt transformation. As such, the first observation in each group is lost. (The 'within' transformation, i.e., forming deviations from group means, will not remove the heterogeneity if the Prais-Winsten transformation is used for the first observation.) In the fixed effects model, the transformation produces

$$y_{it} - \rho y_{i,t-1} = \boldsymbol{\beta}'(\mathbf{x}_{it} - \rho\mathbf{x}_{i,t-1}) + \alpha_i(1-\rho) + \eta_{it}.$$

Thus, the same fixed effects model applies to the transformed data. The same set of procedures as usual is used to obtain the estimates. In the displayed output, the values of α_i, not $\alpha_i(1-\rho)$ are displayed and kept. But, all other results, including the various variance parameters are based on the transformed data. If predictions are computed, the correct values of the parameters are used to predict y_{it}, not the partial differences. The random effects model produces essentially the same set of complications with **; AR1**. The constant term, α, and the common effect, u_i, are transformed to $\alpha(1-\rho)$ and $u_i(1-\rho)$ during estimation. The constant term is adjusted back in the displayed output. The variance terms estimated using the transformed data are $\sigma_\varepsilon^2(1-\rho)^2$ and $\sigma_u^2(1-\rho)^2$. The final results for the model show these estimates as well as the original parameters, σ_ε^2 and σ_u^2. An application is shown below.

The estimate of ρ from the earlier model, based on the one way fixed effects model, is 0.725563. Using this estimate of ρ, the AR1 model is as shown below. The estimates computed without the autocorrelation correction are shown for both the OLS and LSDV results.

The AR1 model for the fixed and random effects specifications is estimated by two step FGLS. In the first step, an estimator of ρ is automatically produced by whatever panel data estimator has been used. This will be any of the fixed or random effects models with one or two way specifications. The estimator is

$$r = \frac{\sum_{i=1}^{N}\sum_{t=2}^{T_i} e_{it}e_{i,t-1} / \left[\sum_{i=1}^{N}(T_i - 1)\right]}{\sum_{i=1}^{N}\sum_{t=2}^{T_i} e_{it}^2 / \left[\sum_{i=1}^{N}(T_i - 1) - K\right]}, \text{ where } e_{it} = (y_{it} - \bar{y}_{i.}) - \hat{\boldsymbol{\beta}}'(\mathbf{x}_{is} - \bar{\mathbf{x}}_{i.}).$$

The estimator of $\boldsymbol{\beta}$ is whatever the most recent one happens to be at the time the calculation is made.

E17.5 Heteroscedasticity and Autocorrelation Robust Covariance Matrix

The cluster corrected robust variance estimator described in Section E17.2.5 accommodates correlation across observations within a group. In principle, the estimator accommodates both ‘autocorrelation,’ that is correlation across observations within the group, and heteroscedasticity, that is, different variances across groups. There are also more narrowly structured robust variance matrix estimators, the White and Newey-West estimators, that accommodate each of these effects alone.

E17.5.1 Heteroscedasticity

If the variances can be assumed to be the same for all observations in the *i*th group, then each group specific variance can be estimated by the group mean squared residual, and the result inserted directly into the textbook formulas for the variance of the OLS (LSDV) estimator. In this case, $\boldsymbol{\Omega}$ becomes a block diagonal matrix, in which the *i*th diagonal block is $\sigma_i^2\mathbf{I}$. (This resembles the time series/cross section model.) In practical terms, we simply replace e_{it}^2 with s_i^2 in the estimate of the asymptotic covariance matrix. To request these estimators, add

; Het or **; Het ; Hc1** or **; Het ; Hc2** or **; Het ; Hc3**
and **; Het = group**

respectively to the **REGRESS** command.

There is a counterpart to the White estimator for unspecified heteroscedasticity for the one way fixed effects model. The model is

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}.$$

Suppose that every ε_{it} has a different variance, σ_{it}^2 In the fashion of White’s estimator for the linear model, the natural approach is simply to replace ε_{it}^2 with e_{it}^2 in the preceding, and compute

$$\text{Est.Asy.Var}[\mathbf{b}_{lsdv}] = [\mathbf{X}^{*\prime}\mathbf{X}^*]^{-1}\, X^{*\prime}\, \hat{\boldsymbol{\Omega}}\, X^*\, [\mathbf{X}^{*\prime}\mathbf{X}^*]^{-1}$$

where '*' denotes deviations from group means. This produces the same results as if the White correction were applied to the OLS results in full model including both regressors and group dummy variables. You may also specify the three variations of the White estimator suggested by Davidson and MacKinnon,

$$\textbf{Hc1:}\ \ \text{Est.Var}[\mathbf{b}] = (\mathbf{X^{*\prime}X^*})^{-1} \times \frac{n}{n-K}\sum\nolimits_{i=1}^{n} e_i^2 \mathbf{x}_i{*}\mathbf{x}_i'{*} \times (\mathbf{X^{*\prime}X^*})^{-1}$$

$$\textbf{Hc2:}\ \ \text{Est.Var}[\mathbf{b}] = (\mathbf{X^{*\prime}X^*})^{-1} \times \sum\nolimits_{i=1}^{n} \frac{e_i^2}{\left(1-\mathbf{x}_i'{*}(\mathbf{X^{*\prime}X^*})^{-1}\mathbf{x}_i{*}\right)}\mathbf{x}_i{*}\mathbf{x}_i'{*} \times (\mathbf{X^{*\prime}X^*})^{-1}$$

$$\textbf{Hc3:}\ \ \text{Est.Var}[\mathbf{b}] = (\mathbf{X^{*\prime}X^*})^{-1} \times \sum\nolimits_{i=1}^{n} \frac{e_i^2}{\left(1-\mathbf{x}_i'{*}(\mathbf{X^{*\prime}X^*})^{-1}\mathbf{x}_i{*}\right)^2}\mathbf{x}_i{*}\mathbf{x}_i'{*} \times (\mathbf{X^{*\prime}X^*})^{-1}$$

(In these expressions, 'n' indicates the full sample, which would be $\Sigma_i T_i$ observations.)

E17.5.2 Autocorrelation

The asymptotic covariance matrix for the fixed effects estimator may also be estimated with a Newey-West style correction for autocorrelation. Request this computation with

; Lags = the number of lags, up to 10.

Continuing the application from earlier, the Newey-West estimator of the covariance matrix for the LSDV coefficients produce the results below:

(Uncorrected)

E18: Random Effects Linear Models for Panel Data

E18.1 Introduction

This chapter will detail estimation of random effects linear models for panel data. The essential structure for most of them is an 'effects' model,

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i + w_t$$

in which variation across groups (individuals) or time is captured in simple shifts of the regression function – i.e., changes in the intercepts. These models are the *random effects* (RE) models characterized by u and w being uncorrelated with $\mathbf{x}$. Under this assumption, the model can be estimated consistently by ordinary least squares. The focus here is on developing efficient estimators or constructing appropriate robust covariance matrices for least squares. Several variations on this structure can be analyzed with this estimator, including both one and two factor models, models of autocorrelation, and several involved, hierarchical models.

E18.2 One Way Random Effects Model

The fundamental part of the random effects model is a one way common effects specification,

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i$$

where

$$\text{Cov}(u_i,\mathbf{x}_{it}) = 0 \text{ for all } t,$$

$$E[u_i|\, \mathbf{x}_{it}] = 0,\ \text{Var}[u_i|\, \mathbf{x}_{it}] = \sigma_u^2\ \ \text{Cov}[\varepsilon_{it},u_i|\, \mathbf{x}_{it}] = 0.$$

The random effects model is a generalized regression model. It is homoscedastic, as all disturbances have variance

$$\text{Var}[\varepsilon_{it} + u_i] = \sigma^2 = \sigma_\varepsilon^2 + \sigma_u^2 .$$

But, for a given i, the disturbances in different periods are correlated because of their common component, u_i,

$$\text{Corr}[\varepsilon_{it} + u_i,\varepsilon_{is} + u_i] = \rho = \sigma_u^2 / \sigma^2.$$

The efficient estimator is generalized least squares. *LIMDEP* provides a two step procedure and a maximum likelihood estimator under the additional assumption that ε is normally distributed. The variance components are first estimated by using the residuals from ordinary least squares regressions. Then, feasible GLS estimates are computed using the estimated variances.

An additional procedure is available to fit the model by maximum likelihood assuming normally distributed disturbances. The resulting estimator has the same properties as the FGLS estimator, so this is not a basis to choose it. But, two additional extensions of the model, exponential heteroscedasticity and nested random effects with unbalanced panels, are fairly easily handled by MLE, but are not feasible (logistically) using FGLS. These specifications trade the possibly narrow assumption of normality for the increased flexibility of the broader models. Obviously, the choice is up to the user in the context of a given application. There is no test for the specification.

E18.2.1 Command

The commands for estimation of these models are variants of the basic structure

SETPANEL ; Group = identifier ; Pds = variable name

Then, **REGRESS ; Lhs = y ; Rhs = x...**
; Panel
; Random Effects
; ... other options $

As always, you may use

; Panel
; Str = the name of a stratification variable
or **; Pds = specification of the number of periods, variable or fixed**

in the command to specify the panel instead.

The random effects model automatically includes a constant term, whether you have included *one* or not. If you want the random effects model to be fit *without a constant term*, include

; No constant

A crucial element of the computation of the random effects model is the estimation of the variance components. You may supply your own values for σ_ε^2 and σ_u^2. The specification is

; Var = s2e,s2u for the one factor model
; Var = s2e,s2u,s2w for the two factor model

This overrides all other computations. The values are checked for validity. A nonpositive value forces estimation to halt at that point.

NOTE: If you omit the **; Random Effects** part of the command, then *LIMDEP* reports full results for the pooled regression (as always) and the fixed effects (LSDV) regression in addition to the random effects results. By including **; Random Effects**, you will suppress the display of the LSDV results (though they are still computed internally).

E18.2.2 Output

After display of any previous results, including ordinary least squares and the fixed effects estimator, a display such as the following will be presented, followed by the standard form table of coefficient estimates, standard errors, etc. The results in the table are as follows:

REGRESS ; Lhs = loggsp
; Rhs = x,one
; Panel ; Random Effects $

```
-----------------------------------------------------------------------------
Random Effects Model: v(i,t)    = e(i,t) + u(i)

-----------------------------------------------------------------------------
```

1. Estimates of σ_ε^2 and σ_u^2 based on the least squares dummy variable model residuals. These are used to estimate the variance components. The technical details in Section E18.2.5 describe the computations. Since there are some potential problems that can arise, the sequence of steps taken in this part is documented in the trace file. The application shows an example. This trace output may be quite lengthy, as several attempts may be made to fit the model with different variance components estimators.

2. The estimate of $\rho = \sigma_u^2 / (\sigma_\varepsilon^2 + \sigma_u^2)$ based on whatever first round estimator has been used.

3. The sum of squares is the sum of squared residuals based on the two step FGLS coefficient vector.

4. An R^2 measure is reported (by popular request)

$$R^2 = 1 - \frac{\Sigma_{i=1}^{N}\Sigma_{t=1}^{T_i}(y_{it} - \hat{\boldsymbol{\beta}}'_{RE}\mathbf{x}_{it})^2}{\Sigma_{i=1}^{N}\Sigma_{t=1}^{T_i}(y_{it} - \bar{y})^2}.$$

   Users are warned, this measure can be negative. It is only guaranteed to be positive when OLS has been used to fit a model with a constant term. There are other measures that could be computed, such as the squared correlation between the actual and fitted values, but neither these, nor the one above, are fit measures in the same sense as in the linear model. It will always be less than the result for OLS (since OLS is LS).

5. The Hausman specification test for fixed vs. random effects if presented at the end of these results. See Section E18.2.3 for discussion.

NOTE: In computing the random effects model, the second step FGLS estimator generally relies on the first step OLS and LSDV (fixed effects) sums of squares. You may be suppressing the FE model, perhaps because of the presence of time invariant variables which preclude the FE model, but not the RE model. In previous versions of *LIMDEP*, and in some other programs, this will force the estimator to rely on another device to estimate the variance components, typically a group means estimator. In the current version of *LIMDEP*, the FE model is computed in the background, whether reported or not. The sums of squares needed are obtainable even in the presence of time invariant variables. Thus, you will get the same results for the RE model whether or not you have allowed *LIMDEP* to report the fixed effects results.

The standard table of coefficient results follows. The test statistic is denoted ‘z’ as the asymptotic normal distribution applies, rather than the finite sample t distribution.

E18.2.3 Specification Tests for Random vs. Fixed Effects

Hausman’s chi squared statistic for testing the REM against the FEM is

$$H = (\hat{\beta}_{LSDV} - \hat{\beta}_{RE})' \, [Est.Var(\hat{\beta}_{LSDV}) - Est.Var(\hat{\beta}_{RE})]^{-1} (\hat{\beta}_{LSDV} - \hat{\beta}_{RE})$$

The Hausman statistic for the specification test of fixed vs. random effects is also reported, as shown below:

REGRESS ; Lhs = loggsp ; Rhs = x,one ; Panel $

```
----------------------------------------------------------------------------
Random Effects Model: v(i,t)    = e(i,t) + u(i)
Estimates:  Var[e]              =       .001443
            Var[u]              =       .012866
            Corr[v(i,t),v(i,s)] =       .899169
            Sum of Squares            17.866362
            R-squared                   .978976
----------------------------------------------
Fixed vs. Random Effects (Hausman)     =  35.24
( 5 degrees of freedom, prob. value =  .000001)
(High (low) values of H favor F.E.(R.E.) model).
--------+-------------------------------------------------------------------
(Other results omitted)
```

The prob value and degrees of freedom for the Hausman statistic are reported.

HINT: Large values of the Hausman statistic argue in favor of the fixed effects model over the random effects model. Large values of the LM statistic argue in favor of one of the one factor models against the classical regression with no group specific effects. A large value of the LM statistic in the presence of a large Hausman statistic (as in our application) argues in favor of the fixed effects model.

NOTE: Sometimes it is not possible to compute the Hausman statistic. The difference matrix in the formula above may not be positive definite. The theory does not guarantee this. It is more likely to be so, but still not certain, if the same estimate of σ_ε^2 is used for both cases. As such, *LIMDEP* uses the FGLS estimator of this, however it has been obtained, for the computation. Still, the matrix may fail to be positive definite. (The program will issue an error message,

```
Error   425: REGR;PANEL. Could not invert VC matrix for Hausman test
```

when this occurs. In this case, a 0.00 is reported for the statistic and a diagnostic warning appears in the results. Users are warned, some other programs attempt to bypass this issue by using some other matrix or some other device to force a positive statistic. These ad hoc measures do not solve the problem – they merely mask it. At worst, the appropriate zero value can be replaced by a value that appears to be 'significant.' The better strategy in such a case is to take the difference between the two estimators to be random variation, which would favor the random effects estimator. The Wu variable addition test is also a useful alternative approach.

Wu's (1973) variable addition test is an alternative approach to computing the Hausman test for random vs. fixed effects. The test is carried out by adding the group means of the time varying variables to the random effects model then testing the joint hypothesis that the coefficients on the group means are all zero. (See Baltagi (2008) for details.) The test is not built in (since the program cannot tell from a variable list what variables are group means. But, it is straightforward to layer onto the random effects estimator. The following shows how to do so using our earlier example. The five group means are time invariant variables, which can be seen in the LSDV results. The results shown for these variables should be ignored.

```
CREATE    ; lpcbar  = Group Mean(logkp, Pds = 17) $
CREATE    ; lhwybar = Group Mean(loghwy, Pds = 17) $
CREATE    ; lh2obar = Group Mean(logh2o, Pds = 17) $
CREATE    ; lutilbar = Group Mean(logutil, Pds = 17) $
CREATE    ; lempbar = Group Mean(logemp, Pds = 17) $
REGRESS   ; Lhs = loggsp
          ; Rhs = x,lpcbar,lhwybar,lh2obar,lutilbar,lempbar
          ; Panel
          ; Test: lpcbar = 0, lhwybar = 0, lh2obar = 0, lutilbar = 0, lempbar = 0 $
```

The ordinary least squares regression results and the LSDV least squares with fixed effects results are omitted.

E18.2.4 Saved Results

Results which are saved for later use are:

Matrices: *b* and *varb* These will be the FGLS estimates of the random effects model.

Scalars:

ssqrd	=	s^2 from least squares dummy variable (LSDV) estimator or from FGLS
rsqrd	=	R^2 from LSDV
s	=	$\sqrt{s^2}$ from LSDV
sumsqdev	=	sum of squared residuals from LSDV
rho	=	estimated disturbance autocorrelation from whatever model is fit last
degfrdm	=	$\Sigma_i T_i - K$
sy	=	standard deviation of Lhs variable
ybar	=	mean of Lhs variable
kreg	=	K
nreg	=	total number observations
logl	=	log likelihood from LSDV model
ssqrdu	=	estimate of σ_u^2 from FGLS
ssqrde	=	estimate of σ_ε^2 from FGLS
ssqrdw	=	estimate of σ_w^2 from GLS if two way random effects model is fit
exitcode	=	0.0 if the model was estimable
ngroup	=	number of groups
nperiod	=	number of periods. This will be 0.0 if you fit a one way model.

Last Model: *b_variable* constructed as usual.

Last Function: Conditional mean for the linear regression = a + **b'x**

Predicted values are based on the last model estimated, one or two way, fixed or random. Since the constant term is included in the function, **SIMULATE** will give appropriate predictions. **PARTIALS** operates as usual.

E18.2.5 Technical Details

The equal group sizes case is considered first. Special considerations for the unbalanced panel case are considered next. The random effects model is a generalized regression model. The specification has

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it},$$

$$v_{it} = \varepsilon_{it} + u_i,$$

$$E[v_{it}|\mathbf{X}] = 0,$$

$$E[v_{it}^2|\mathbf{X}] = \sigma^2 = \sigma_\varepsilon^2 + \sigma_u^2,$$

$$E[v_{it}\, v_{is}|\mathbf{X}] = \sigma_u^2,$$

and $$E[v_{it}\, v_{js}|\mathbf{X}] = 0 \;\forall\; t,s \text{ if } i \neq j.$$

Estimation by feasible GLS (FGLS) is done by regressing $y_{it} - \theta\,\overline{y}_i$ on (1 - θ) and $(\mathbf{x}_{it} - \theta\,\overline{\mathbf{x}}_i)$. (1 - θ) is the constant term in this regression, where

$$\theta = 1 - \sigma_\varepsilon / \sigma_2$$

and

$$\sigma_2^2 = \sigma_\varepsilon^2 + T\sigma_u^2 .$$

Since the variances are unknown, they and θ must be estimated first. This is done as follows:

1. The residual variance from the LSDV estimator is a consistent estimator of σ_ε^2;

$$\hat{\sigma}_\varepsilon^2 = \Sigma_i\Sigma_t\, e_{LSDV,it}^{\;2} / (NT - N - K),$$

where $e_{LSDV,it}$ is the residual from the least squares dummy variable regression and '*NT*' denotes the entire sample size,

$$e_{it} = y_{it} - a_i - \mathbf{b}_{LSDV}'\mathbf{x}_{it} = (y_{it} - \overline{y}_i) - \mathbf{b}_{LSDV}'(\mathbf{x}_{it} - \overline{\mathbf{x}}_i).$$

(*The fixed effects estimator is always computed for this purpose, even if the results are not displayed.*)

2. The simple least squares estimator with no group effects can always be computed. The residual variance estimator from this procedure would be

$$s^2 = \Sigma_i\Sigma_t\, e_{OLS,it}^{\;2} / (NT - K - 1)$$

This is a consistent estimator of $\sigma_\varepsilon^2 + \sigma_u^2$, so a consistent estimator of σ_u^2 is

$$\hat{\sigma}_u^2 = s^2 - \hat{\sigma}_\varepsilon^2$$

3. This second estimate need not be positive, because of the differing degrees of freedom. In this event, a second attempt is made. If the degrees of freedom correction is not made, then by construction, both variance estimators must be positive, and estimation proceeds. The LSDV estimator must fit better than the model with only a single constant, so

$$\hat{\sigma}_u^2 = \Sigma_i\Sigma_t\, e_{OLS,it}^{\;2} / NT - \Sigma_i\Sigma_t\, e_{LSDV,it}^{\;2} / NT$$

must be positive, as will $\hat{\sigma}_\varepsilon^2 = \Sigma_i\Sigma_t\, e_{LSDV,it}^{\;2} / NT$.

4. If neither works – $\hat{\sigma}_u^2$ can be zero, though (at least in theory) not negative – then we try using the group means. (This should never happen, but we note this procedure to connect to the existing literature and to what is done in other software. The capability remains in *LIMDEP*.) In the REM,

$$\overline{y}_i = \alpha + \boldsymbol{\beta}'\overline{\mathbf{x}}_i + u_i + \overline{\varepsilon}_i$$

so

$$y_{it} - \overline{y}_i = \boldsymbol{\beta}'(\mathbf{x}_{it} - \overline{\mathbf{x}}_i) + \varepsilon_{it} - \overline{\varepsilon}_i .$$

Hence, the mean squared residual from this regression is a natural estimator of σ_ε^2. It can be shown that this one is unbiased. Of course, it might be based on a small number of observations. To estimate σ_u^2, we note that for the group means, the regression is a classical regression with disturbance variance

$$\text{Var}[u_i + \bar{\varepsilon}_{i\,.}] = \sigma_u^2 + \sigma_\varepsilon^2 / T.$$

Therefore, if we regress the group means of y on a constant and the group means of $\mathbf{x}$, the variance estimator in this regression is an unbiased estimator of

$$\sigma_1^2 = \sigma_u^2 + \sigma_\varepsilon^2 / T.$$

Since we have an estimator of σ_ε^2 in hand, we can use

$$\hat{\sigma}_u^2 = \mathbf{v}^{*\prime}\mathbf{v}^{*}/(N\text{-}K) - (1/T)\ \hat{\sigma}_\varepsilon^2$$

where $$v_i^* = \bar{y}_i - \mathbf{b}_{group\ means}{}'\,\bar{\mathbf{x}}_i$$

This is unbiased in the general case. Unfortunately, this estimator may also not be positive. An alternative can be based on the direct least squares estimates of Model 3 (or, for that matter, any other consistent estimator of $\boldsymbol{\beta}$). Using the same calculation otherwise, we would just compute

$$s_1^2 = \Sigma_\text{i}\,(\bar{y}_i - \mathbf{b}_{ols}{}'\,\bar{\mathbf{x}}_i)^2/(\text{N-K})$$

then $$\hat{\sigma}_u^2 = s_1^2 - (1/\text{T})\ \hat{\sigma}_\varepsilon^2\ .$$

If need be, *LIMDEP* tries all of these estimators. As noted, the second attempt, using the sums of squares without degrees of freedom corrections, will succeed in all but the most pathological cases. Still, it is possible that none of the procedures will produce a positive estimate of σ_u^2. In that instance, estimation is halted. The search is reported in the trace file when you fit this model, along with the decisions made at each point as the program seeks a valid estimate. The entry for the model fit in the previous section is as follows:

```
Regress ; Lhs = loggsp ; Rhs = x,one
;panel;pds=17;random effects$
Estimating variance components for random effects model.
FEM was computed. Using LSDV and OLS to get V[e] & V[u].
OLS & LSDV with d.f. provide both estimates > 0.
Exit status for this model command is   .0.
```

NOTE: The finding of a nonpositive estimate of σ_u^2 is quite common, and many programs do not use the same search we do. Notably, many do not use the second pass attempt (without degrees of freedom correction) that is used here. This leaves the negative estimate as a persistent possibility. Users should be aware of what the software does in this instance.

```
Regress ; Lhs = loggsp ; Rhs = x,one ;panel;pds=17 ; mle; hfu=ubari

```

Unequal Group Sizes

We consider the case of unequal group sizes. In the group means regression, the disturbance will now have variance

$$\mathrm{Var}[u_i + \Sigma_i \varepsilon_{it}/T_i] \;=\; \sigma_{1i}^2 \;=\; \sigma_u^2 + \sigma_\varepsilon^2/T_i.$$

Therefore, the group means regression is heteroscedastic. The unbiasedness result above does not hold any more. However, it can be shown that the ordinary least squares variance estimator in a heteroscedastic regression is a consistent estimator of

(*) $$\overline{\sigma}_1^2 \;=\; \mathrm{plim}(1/N)\Sigma_{i=1}^N \sigma_{1i}^2 ,$$

assuming that the probability limit exists. As will be useful later, the mean squared residual (using group means of y and $\mathbf{x}$) based on *any* consistent slope estimator is a consistent estimator of $\overline{\sigma}_1^2$. In this setting, we take the limit as applying to N increasing, *not* T or T_i. T or T_i is taken as fixed in this model and may not increase at all beyond a very small number. Consistency results depend on increasing N, not T or T_i. So, the variance estimator in the group means regression is a consistent estimator of

$$\begin{aligned}\overline{\sigma}_1^2 \;&=\; \sigma_u^2 \;+\; \sigma_\varepsilon^2\,\mathrm{plim}(1/N)\Sigma_i(1/T_i)\\ &=\; \sigma_u^2 \;+\; \sigma_\varepsilon^2\,\mathrm{plim}Q_N^*\\ &=\; \sigma_u^2 \;+\; \sigma_\varepsilon^2\,Q^*\end{aligned}$$

whatever that happens to be. Some assumption about the group sizes is obviously necessary. One possibility would be to assume that T_i is randomly distributed across individuals with $\mathrm{E}[T_i] = T$. Note that if $T_i = T$ for all i, then $Q_N^* = Q^* = Q = 1/T$. Suppose it is assumed that Q_N^* converges to some well defined Q^*. Then, in our sample, the statistic

$$Q \;=\; (1/N)\,(1/T_1 \;+\; 1/T_2 \;+\; \ldots \;+\; 1/T_N)$$

is a consistent estimator of Q^*, and the estimator

$$s_u^{2*} \;=\; \mathbf{v}^{*\prime}\mathbf{v}^* \,/\, (N\text{-}K) \text{ - } Q\,\hat{\sigma}_\varepsilon^{\,2}$$

is a consistent estimator as well. (If the group sizes are equal, equation (*) above emerges.) The degrees of freedom correction (N-K) instead of N is unnecessary, of course. We make it so the appropriate value will result in the equal sized groups case.

Heteroscedasticity in the Random Effects Model Due to Unequal Group Sizes

Estimation by FGLS is done by regressing

$$y_{it} - \theta_i\, \bar{y}_i \;\text{ on }\; (1 - \theta_i) \;\text{ and }\; (\mathbf{x}_{it} - \theta_i\, \bar{\mathbf{x}}_i).$$

($1 - \theta_i$ is the constant term in this regression), where

$$\theta_i = 1 - \sigma_\varepsilon / \sigma_{2i}$$

and

$$\sigma_{2i}^2 = \sigma_\varepsilon^2 + T_i\,\sigma_u^2.$$

(Note that the weights are already unequal if the group sizes vary, regardless of the heteroscedasticity.) Neglecting the heteroscedasticity and the unequal group sizes for the moment, the first step in the regression is computation of the variance components, which we do as follows:

1. Using simple OLS, use $\mathbf{e}_o'\mathbf{e}_o/NT$ to estimate $\sigma_\varepsilon^2 + \sigma_u^2$.
2. Using LSDV, use $\mathbf{e}'\mathbf{e}/NT$ to estimate σ_ε^2.
3. Estimate σ_u^2 with $\mathbf{e}_o'\mathbf{e}_o/NT - \mathbf{e}'\mathbf{e}/NT$.

Once again, 'NT' symbolizes the full sample size, ($\Sigma_i T_i$). Under homoscedasticity, both estimators are consistent.

Suppose, now, that T_i differs across groups and, as well, that so does Var[ε_{it}]. We consider estimation of σ_u^2. This estimator is, by construction

$$\hat{\boldsymbol{\sigma}}_u^2 = \sum_{i=1}^N \left(\frac{T_i}{\sum_{i=1}^N T_i}\right)\left[\frac{\mathbf{e}_{oi}'\mathbf{e}_{oi}}{T_i}\right] - \sum_{i=1}^N \left(\frac{T_i}{\sum_{i=1}^N T_i}\right)\left[\frac{\mathbf{e}_i'\mathbf{e}_i}{T_i}\right]$$

Note that this collects the sums of squares by groups, and multiplies and divides each contribution by the respective sample size.) We can write this as

$$\hat{\boldsymbol{\sigma}}_u^2 = \sum_{i=1}^N w_i\, \hat{\boldsymbol{\sigma}}_{ui}^2 \quad\text{where } w_i = T_i / (\Sigma_i T_i).$$

That is, it is an unequally weighted (unless T_i is fixed) average of N separate estimators of σ_u^2. To what does this estimator converge? The estimator can be written

$$\hat{\boldsymbol{\sigma}}_u^2 = \sum_{i=1}^N w_i \left(\widehat{\boldsymbol{\sigma}_{\varepsilon,i}^2 + \boldsymbol{\sigma}_u^2}\right) - \sum_{i=1}^N w_i\, \hat{\boldsymbol{\sigma}}_{\varepsilon,i}^2 .$$

Since each estimator within the brackets is based on the fixed and possibly small T_i observation, one cannot say that either is consistent. But, as N grows, the average in this dimension will be consistent under some fairly benign assumptions that would make an average of estimators of $\sigma_{\varepsilon,i}^2$ converge to some 'average variance,' $\bar{\sigma}_\varepsilon^2$. If so, then the first of these will converge to $\bar{\sigma}_\varepsilon^2 + \sigma_u^2$ while the second will converge to $\bar{\sigma}_\varepsilon^2$. (These are different estimators, but they should converge to the same thing.) If so, then the difference converges to σ_u^2. By this development, we use the original estimator of σ_u^2 for the FGLS estimator in this model. We then compute the heteroscedastic random effects estimator by recomputing the estimator of σ_ε^2 within each group. The group specific estimator, whether defined by the original data groups or by a higher level stratification, is obtained by the mean squared LSDV residual for that particular group. (This is the second term in square brackets in the earlier expression.)

E18.2.6 Robust Covariance Matrix

Since the random effects model is fit using two step GLS, it assumes a particular disturbance process. As such, a 'robust' covariance matrix would seem counterproductive, or at least contradictory. Nonetheless, just such an approach has been advocated in the recent literature. By adding

; Robust

to the command, you can request *LIMDEP* to abandon the FGLS covariance matrix, and use the cluster estimator shown in Section E17.2.5. For the random effects model, the estimator is

$$Est.Asy.Var[b_{FGLS}] = (\mathbf{X'X})^{-1}\left[A\sum\nolimits_{i=1}^{n}\left\{\left(\mathbf{X}^{(i)}\right)\mathbf{e}_i\right\}\left\{\left(\mathbf{X}^{(i)}\right)\mathbf{e}_i\right\}'\right](\mathbf{X'X})^{-1}$$

$$A = \frac{n}{n-1}\frac{(\Sigma_t T_i)-1}{(\Sigma_t T_i)-(n+K)},\; e_{it} = y_{it} - \hat{\boldsymbol{\beta}}'_{FGLS}\mathbf{x}_{it}$$

Results applied to our earlier example are shown below. The differences in the estimated standard errors are quite stark. Under the logic that the FGLS estimator is consistent regardless of the true underlying structure (as is OLS), we might conclude that the one way random effect model is misspecified – though this is not a formal test of that proposition.

E18.3 ML Estimation of One Way Random Effects Models

The one way random effects linear model with normally distributed disturbances can be fit using maximum likelihood rather than two step FGLS. As always, the estimator allows unbalanced panels. The estimator is requested simply by adding

; MLE

to the basic command for the random effects model. The request has no impact on the fixed effects estimator or on the FGLS estimator. The full model is fit as usual, then an additional set of results are provided for the MLE.

Three other forms of random effects linear models can be fit by maximum likelihood. After extending the basic model to an MLE, we describe a formal model for heteroscedastic disturbances. A further extension of the model provides for nested random effects up to three levels. Finally, Section E18.8 presents a model with multiple way random effects that is estimated by simulation, rather than by FGLS.

E18.3.1 Application

To illustrate the estimator, we recompute the estimates for the random effects model shown in Section E18.2.2 using the maximum likelihood estimator. Results for this model are shown below. The FGLS estimates will always appear first. The maximum likelihood estimates will follow. We note, the ML results include estimates of the slope functions and of $\theta = 1/\sigma_\varepsilon^2$ and $\tau = \sigma_u^2/\sigma_\varepsilon^2$. *LIMDEP* reparameterizes the log likelihood function for purpose of estimation. The estimates of the two underlying variance parameters are derived from these, and appear in the box above the coefficient estimates. Further details appear in the technical notes below.

E18.3.2 Technical Notes on ML Estimation of the Random Effects Model

The contribution of the ith individual to the log likelihood for the random effects model with normally distributed disturbances is

$$\log L_i(\boldsymbol{\beta},\sigma_\varepsilon^2,\sigma_u^2) = \frac{-1}{2}\left[T_i \log 2\pi + \log|\boldsymbol{\Omega}_i| + (\mathbf{y}_i - \mathbf{X}_i\boldsymbol{\beta})'\boldsymbol{\Omega}_i^{-1}(\mathbf{y}_i - \mathbf{X}_i\boldsymbol{\beta})\right]$$

$$= \frac{-1}{2}\left[T_i \log 2\pi + \log|\boldsymbol{\Omega}_i| + \boldsymbol{\varepsilon}_i'\boldsymbol{\Omega}_i^{-1}\boldsymbol{\varepsilon}_i\right]$$

where $\boldsymbol{\Omega}_i = \sigma_\varepsilon^2 \mathrm{I}_{\mathrm{Ti}} + \sigma_u^2 \mathbf{ii}'$

Note that the $\boldsymbol{\Omega}_i$ varies over i because it is $T_i \times T_i$. By expanding $\boldsymbol{\Omega}_i$ in the expression, and with some straightforward algebra, we obtain

$$\log L = \Sigma_{i=1}^N \log L_i$$

$$= -\frac{-1}{2}[(\log 2\pi + \log\sigma_\varepsilon^2)\Sigma_{i=1}^N T_i + \Sigma_{i=1}^N \log(1+T_i\rho^2)] - \frac{1}{2\sigma_\varepsilon^2}\Sigma_{i=1}^N\left[\boldsymbol{\varepsilon}_i'\boldsymbol{\varepsilon}_i - \frac{\sigma_\varepsilon^2(T_i\bar{\varepsilon}_i)^2}{\sigma_\varepsilon^2 + T_i\sigma_u^2}\right]$$

where $\rho = \sigma_u^2 / (\sigma_\varepsilon^2 + \sigma_u^2)$.

With some further transformations,

$$\theta \;=\; 1/\sigma_\varepsilon^2,\ \gamma = \sigma_u^2/\sigma_\varepsilon^2,\ R_i = T_i\gamma + 1,\ Q_i = \gamma / R_i,$$

the individual contribution to the log likelihood becomes

$$\log L_i \;=\; -(1/2)[\theta(\boldsymbol{\varepsilon}_i'\boldsymbol{\varepsilon}_i - Q_i(T_i\bar{\varepsilon}_i)^2) + \log R_i + T_i \log\theta + T_i \log 2\pi]\,.$$

We maximize the log likelihood function using *LIMDEP*'s general optimization program – BFGS is the default algorithm. The derivatives of the terms, which are summed over *i* to give the totals are

$$\frac{\partial \log L_i}{\partial \boldsymbol{\beta}} = \theta\left[\sum_{t=1}^{T_i} \mathbf{x}_{it}\varepsilon_{it}\right] - \theta\left[\frac{\gamma}{T_i\gamma+1}\left(\sum_{t=1}^{T_i}\mathbf{x}_{it}\right)\left(\sum_{t=1}^{T_i}\varepsilon_{it}\right)\right],$$

$$\frac{\partial \log L_i}{\partial \theta} = -\frac{1}{2}\left[\left(\sum_{t=1}^{T_i}\varepsilon_{it}^2\right) - \frac{\gamma}{T_i\gamma+1}\left(\sum_{t=1}^{T_i}\varepsilon_{it}\right)^2 - \frac{T_i}{\theta}\right],$$

$$\frac{\partial \log L_i}{\partial \gamma} = \frac{1}{2}\left[\theta\left(\frac{1}{(T_i\gamma+1)^2}\left(\sum_{t=1}^{T_i}\varepsilon_{it}\right)^2\right) - \frac{T_i}{T_i\gamma+1}\right],$$

$$-\frac{\partial^2 \log L_i}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'} = \left\{\left[\sum_{t=1}^{T}\theta\mathbf{x}_{it}\mathbf{x}_{it}'\right] - \frac{\theta\gamma}{T_i\gamma+1}\left(\sum_{t=1}^{T_i}\mathbf{x}_{it}\right)\left(\sum_{t=1}^{T_i}\mathbf{x}_{it}'\right)\right\},$$

$$-\frac{\partial^2 \log L_i}{\partial \boldsymbol{\beta}\partial \theta} = -\left\{\left(\sum_{t=1}^{T_i}\mathbf{x}_{it}\varepsilon_{it}\right) - \frac{\gamma}{T_i\gamma+1}\left(\sum_{t=1}^{T_i}\mathbf{x}_{it}\right)\left(\sum_{t=1}^{T_i}\varepsilon_{it}\right)\right\},$$

$$-\frac{\partial^2 \log L_i}{\partial \boldsymbol{\beta}\partial \gamma} = \left\{\frac{\theta}{(T_i\gamma+1)^2}\left(\sum_{t=1}^{T_i}\mathbf{x}_{it}\right)\left(\sum_{t=1}^{T_i}\varepsilon_{it}\right)\right\},$$

$$-\frac{\partial^2 \log L_i}{\partial \theta\partial \gamma} = -\frac{1}{2(T_i\gamma+1)^2}\left(\sum_{t=1}^{T_i}\varepsilon_{it}\right)^2,$$

$$-\frac{\partial^2 \log L_i}{\partial \theta^2} = \frac{T_i}{2\theta^2},$$

$$-\frac{\partial^2 \log L_i}{\partial \gamma^2} = \frac{\theta T_i}{(T_i\gamma+1)^3}\left(\sum_{t=1}^{T_i}\varepsilon_{it}\right)^2 - \frac{1}{2}\frac{T_i^2}{(T_i\gamma+1)^2}.$$

After estimation, we derive estimates of the underlying variances as $\sigma_\varepsilon^2 = 1/\theta$, $\sigma_u^2 = \gamma/\theta$. Estimated standard errors for these are not reported, but can be obtained easily using the delta method. Standard errors are reported for the estimates of θ and γ, though in general, one does not compute hypothesis tests about the variance parameters.

E18.4 Groupwise Heteroscedasticity in Random Effects

The random effects model can easily be extended to allow groupwise heteroscedasticity. We consider two forms. The model with the basic extension to groupwise heteroscedasticity is

$$
\begin{aligned}
y_{it} &= \boldsymbol{\beta}'\mathbf{x}_{it} + u_i + \varepsilon_{it} \\
\mathrm{E}[u_i | \mathbf{x}_{it}] &= \mathrm{E}[\varepsilon_{it}] = 0 \\
\mathrm{Cov}[u_i, \varepsilon_{is} | \mathbf{x}_{it}] &= 0 \text{ for all } i, s, t. \\
\mathrm{Var}[u_i | \mathbf{x}_{it}] &= \sigma_u^{\,2} \\
\mathrm{Var}[\varepsilon_{it} | \mathbf{x}_{it}] &= \sigma_{\varepsilon\, i}^{\;2}
\end{aligned}
$$

Thus, the variance of the unique component of the compound disturbance is allowed to vary across groups. (The variance of u_i could, in principle as well, but such a model would be inestimable, as there is only a single observation from the distribution of u_i in the sample.) This model is requested when you add

; Het = group

to the **REGRESS** command. *Note, this is not merely a correction to the asymptotic covariance matrix.* This computation produces a different set of weights and, therefore, a different set of estimates for the random effects model. The following illustrates for the data we have used in several earlier examples. The results based on homoscedasticity are shown first. The box of diagnostic statistics is identical to this case, save for the indication of the model used. Note, though, that the parameter estimates do change somewhat.

The number of groups in the sample may not exceed 50,000 when estimating this and the next model of heteroscedasticity.

```

For the models with groupwise heteroscedasticity, the computation of the estimator is changed as follows: In all cases, an estimator of

$$\theta_i = 1 - \sigma_{\varepsilon i} / \sigma_{2i}$$

where $$\sigma_{2i}^2 = \sigma_{\varepsilon i}^2 + T_i\,\sigma_u^2 .$$

is needed for each i. We have to rely on some consistency results to have in hand an estimator of σ_u^2 regardless of what happens next. We use the one from the initial OLS and fixed effects regression. From the OLS regression, ignoring the degrees of freedom correction, which is now irrelevant, this would be

$$\begin{aligned}\frac{\sum_{i=1}^{N}\sum_{t=1}^{T_i} e_{it}^2}{\sum_{i=1}^{N} T_i} &= \sum_{i=1}^{N} \frac{T_i}{\sum_{i=1}^{N} T_i}\left(\frac{1}{T_i}\sum_{t=1}^{T_i} e_{it}^2\right)\\ &= \sum_{i=1}^{N} w_i \ \text{Est.}(\sigma_{\varepsilon,i}^2 + \sigma_u^2)\\ &= \text{Est.}(\overline{\sigma}_{\varepsilon}^2 + \sigma_u^2).\end{aligned}$$

From the fixed effects regression, we would have a variance estimator of $\overline{\sigma}_{\varepsilon}^2$ which, assuming that it converges to something, would, by subtraction, still be providing the estimator of σ_u^2 that we need. In computing the FGLS estimator, computation of θ_i will require this estimate and the estimate of $\sigma_{\varepsilon,i}$. The latter is computed by computing the group specific sum of squared residuals based on the consistent estimator of $\boldsymbol{\beta}$ (this may be FE or OLS, or, for that matter, any consistent estimator of $\boldsymbol{\beta}$), dividing by T_i or T_g for the stratification case, and subtracting the unchanging estimate of σ_u^2. The estimation of θ_i is changed for each group. Note that in the unbalanced panel case with stratification, the heteroscedasticity arises from two sources. Where $\sigma_{\varepsilon,g}$ differs by stratum, and T_i varies by group within the stratum, we will have to compute

$$\theta_{i,g} = 1 - \sigma_{\varepsilon,g} / \sigma_{2\,i,g}$$

where $$\sigma_{2\,i,g}^2 = \sigma_{\varepsilon,g}^2 + T_i\,\sigma_u^2 .$$

E18.4.1 A Model with Stratification and Grouping

Suppose that the groups in the data can be grouped at some higher level of stratification. For example, consider a panel in which city data are further grouped by state, so that there are several cities per state in the data. The groupwise heteroscedasticity might then be structured as

$$\text{Var}[\varepsilon_{i\,t}] = \sigma_j^2, j = 1,...,G, \quad G < N$$

$$N_j \quad = \text{ the number of groups contained in outer grouping } j.$$

To fit a model of this sort, use

; Hfn = the grouping variable

This is a simple change to the previous model in which the grouping variable supersedes the panel specification in the GLS computation. To continue our example, suppose we arbitrarily group our 48 states into eight groups of six states. (The states are in alphabetical order in the data file, so this is a meaningless grouping just for purpose of this example.) Results appear below.

E18.4.2 Exponential Heteroscedasticity in Random Effects

The one way random effects linear model,

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + u_i + \varepsilon_{it}$$

is extended to allow specific Harvey (1976) style heteroscedasticity in either component. The models are

$$\text{Var}[\varepsilon_{it}] = \sigma_\varepsilon^2 \, [\exp(\boldsymbol{\delta}_\varepsilon'\mathbf{h_i})]^2$$

$$\text{Var}[u_i] = \sigma_u^2 \, [\exp(\boldsymbol{\delta}_u'\mathbf{z}_i)]^2$$

Note that the variables in these variance functions are assumed to be time invariant. The program assumes this. The estimator is full information maximum likelihood. This model is estimated using the same FIML procedure as defined above. In the reparameterized model, we now have

$$\theta_i = \theta \times [\exp(-\boldsymbol{\delta}_\varepsilon'\mathbf{h_i})]^2$$

and

$$\gamma_i = \gamma \times [\exp(\boldsymbol{\delta}_u'\mathbf{z}_i)]^2 \times [\exp(-\boldsymbol{\delta}_\varepsilon'\mathbf{h_i})]^2$$

modification of the derivatives is a straightforward application of the chain rule. The Hessian is tedious, but, again, straightforward.

Request this estimator with

REGRESS ; Lhs = dependent variable
; Rhs = independent variables
; Panel ; Pds = specification or ; Str = specification
; MLE

and either or both of

; Hfe = variables in h, the variance of ε
; Hfu = variables in z, the variance of u $

To illustrate, we extend the model of the previous section by specifying

$$\text{Var}[\varepsilon_{it}] = \sigma_\varepsilon^2 \exp(\delta_\varepsilon \overline{unemp}_i)$$

$$\text{Var}[u_i] = \sigma_u^2 \exp(\delta_u \overline{unemp}_i)$$

The commands and model results follow:

```
CREATE    ; ubari = Group Mean(unemp, Pds = 17) $
REGRESS   ; Lhs = loggsp
          ; Rhs = x,one
          ; Panel ; MLE
          ; Hfu = ubari ; Hfe = ubari $
```

```

```

We note, the results above look reasonable enough. However, a closer look suggests that this is a poorly specified model in spite of this. The iterations ended with a diagnostic,

```
Maximum of   500 iterations. Exit iterations with status=1.
```

This suggests that one might want to look more closely at the specification.

E18.5 Autocorrelation

The model is

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i,$$

$$\varepsilon_{it} = \rho\varepsilon_{i,t-1} + \eta_{it}.$$

Note that the autocorrelation is embodied in the unique component, ε_{it}. It would not make sense in the context of this model to assume that u_i is autocorrelated, as it is assumed to be time invariant.

The AR1 model for the random effects model is estimated by two step FGLS. In the first step, an estimator of ρ is automatically produced by whatever panel data estimator has been used. This will be any of the fixed or random effects models with one or two way specifications. The estimator based on any of the panel data models is

$$r = \frac{\sum_{i=1}^{N}\sum_{t=2}^{T_i} e_{it}e_{i,t-1} / \left[\sum_{i=1}^{N}(T_i - 1)\right]}{\sum_{i=1}^{N}\sum_{t=2}^{T_i} e_{it}^2 / \left[\sum_{i=1}^{N}(T_i - 1) - K\right]}, \text{ where } e_{it} = (y_{it} - \bar{y}_{i.}) - \hat{\boldsymbol{\beta}}'(\mathbf{x}_{is} - \bar{\mathbf{x}}_{i.}).$$

The estimator of **β** is whatever the most recent one happens to be at the time the calculation is made. The model fit above, now with a correction for first order autocorrelation, using the same estimate as before (0.725563), which is the value computed by the initial LSDV estimator – see the results in Section E17.2.4.

E18.6 Two Way Random Effects Model

The panel data estimator also allows 'two way' random effects models. The random effects model for a two way design is

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i + w_t.$$

The model is described in standard textbooks such as Wooldridge (2010) or Greene (2011).

In this model, neither the number of time periods observed for each group nor the number of individuals observed in each period need be fixed. Your data can consist of simply a sample of observations indexed by both individual and time. The data setup is exactly as described in Section E17.3. To request the two factor model, you simply add the specification

; Period = time variable

to the usual command. Unlike a group stratification variable, the time variable must use the integers 1,2,...,T_i. As noted earlier, it is not necessary for every group to have data in every period; there may be gaps. But, if you do have a balanced panel, you can easily set up the time indicator with the Trn function in **CREATE**. For example, in the data set we have been using for our application, there are 17 observations for each state. We could use

```
CREATE      ; time = Trn(-17, 0) $
```

(The variable *yr*-1969 in the data set would have the right values.) If the sample is not balanced, in either dimension, it will be necessary to provide the time variable by some other means. When you request the two factor model, the command will appear as

```
REGRESS     ; Lhs = ... ; Rhs = ... ; Panel
            ; Period = time $
```

E18.6.1 Program Output for Two Factor RE Models

This estimator produces the full set of output described earlier for the one factor model and an additional set of results for the two factor model. The additional results will be

1. Full set of two factor fixed effects results. Do note, in accordance with the description above, this model, unlike the one way model, will contain an overall constant term. This model is estimated by OLS including both the time and group dummy variables. If your command contains **; Random effects**, the fixed effects results are not shown, though they are computed internally.

2. Full table of estimates of fixed effects (if requested with **; Output = 2**). Note, as well, that the fixed effects produced for the groups will differ from the earlier results, since by design, the time dummy variables are not orthogonal to the group dummy variables.

3. Test statistics for the two way fixed effects model. This consists of the log likelihood, sum of squared deviations, and R^2s for five models:

   a. overall constant term only, no regressors,
   b. group dummies, no regressors,
   c. regressors and overall constant term,
   d. full one way fixed effects model,
   e. full two way fixed effects model.

   You should observe rising log likelihoods and R^2s and falling sums of squares as you go down the table, but if your regressors do not have much explanatory power the reverse could happen between b and c.

5. Full set of results for the two way random effects model including the LM statistic, Hausman statistic, estimates of the variance components, and the usual coefficient estimates with standard errors.

E18.6.2 Application

The following continues the earlier example with the two factor models.

```
CREATE      ; t = year - 1979  $
REGRESS     ; Lhs = loggsp ; Rhs = x,one
            ; Period = t  ; Panel $
```

The first set of results is the same as shown earlier. The results for the two factor models are shown below.

```
-----------------------------------------------------------------------------
Random Effects Model: v(i,t) = e(i,t)+u(i)+w(t)
Estimates:  Var[e]              =       .001148
            Var[u]              =       .011624
            Corr[v(i,t),v(i,s)] =       .910126
            Var[w]              =       .001536
            Corr[v(i,t),v(j,t)] =       .572300
            Sum of Squares            17.866362
            R-squared                   .978976

```

The LM statistic has been adjusted for the two types of effects – there is no Baltagi and Li counterpart for this. The Hausman statistic is also recomputed.

E18.6.3 Technical Details

The model is

$$y_{it} = \mu + \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}.$$

The random effects model is estimated as follows: With estimates of the three variance components in hand, we compute the GLS estimator by computing the moments of the transformed variables

$$z_{it}^* = z_{it} - \theta_{1i}\,\bar{z}_{i.} - \theta_{2t}\,\bar{z}_{.t} + \theta_{3it}\,\bar{\bar{z}}_{..}$$

where z_{it} is either the vector $\mathbf{x}_{it}$, including the constant, or y_{it}, and

$$\sigma_{1i}^2 = \sigma_\varepsilon^2 + T_i\sigma_u^2,$$

$$\sigma_{2t}^2 = \sigma_\varepsilon^2 + N_t\sigma_w^2,$$

$$\sigma_{3it}^2 = \sigma_\varepsilon^2 + T_i\sigma_u^2 + N_t\sigma_w^2.$$

Then,

$$\theta_{1i} = 1 - \sigma_\varepsilon/\sigma_{1i},$$

$$\theta_{2t} = 1 - \sigma_\varepsilon/\sigma_{2t},$$

and

$$\theta_{3it} = \theta_{1i} + \theta_{2t} - 1 + \sigma_\varepsilon/\sigma_{3it}.$$

If N and T are fixed, these specialize to the familiar textbook formulas.

The LM statistic, which will now have two degrees of freedom, is the earlier one plus a term which looks the same as given in Section E16.6, but in which the roles of 'i' and 't' are reversed. Note, once again, the modification necessary if the panel is unbalanced.

Finally, we note the different method of moments estimators for the variance components. Consider the balanced panel case first. As before, the sums of squared residuals from OLS and the two way fixed effects estimators provide estimates of $\sigma_\varepsilon^2 + \sigma_u^2 + \sigma_w^2$ and σ_ε^2 respectively. A third moment estimator is provided by the one way fixed effects estimator computed previously, in which the mean squared residual estimates $\sigma_\varepsilon^2 + \sigma_w^2(1 + 1/T)$ in the balanced panel case. Call these estimators m_0, m_{FE2} and m_{FE1}, respectively. Without degrees of freedom corrections, we know that $m_0 \geq m_{FE1} \geq m_{FE2}$. The method of moments estimators are

$$\hat{\sigma}_\varepsilon^2 = m_{FE2}$$

$$\hat{\sigma}_w^2 = \frac{m_{FE1} - m_{FE2}}{(1+1/T)}$$

$$\hat{\sigma}_u^2 = m_0 - \frac{m_{FE1} - m_{FE2}}{(1+1/T)} - m_{FE2}$$

The first two are guaranteed to be nonnegative. The first obviously is. The numerator of the second must be nonnegative because the sum of squared residuals falls when the time dummy variables are added to the equation. The third estimator may be negative. With a bit of manipulation, it can be written $\hat{\sigma}_u^2 = m_0 - [T/(1+T)]m_{FE1} - [1/(1+T)]m_{FE2}$. There is no assurance that this is positive. These estimators can be replaced with degrees of freedom corrected estimators, and the attempt repeated. In the unbalanced panel case, the $1/T$ term is replaced with Q, defined below, the sample average of $1/T_i$. This does not change the possible problem, however.

The initial estimators may produce a full set of positive estimates. They do in our application above. If not, *LIMDEP* undertakes a search among some possible candidates for valid estimates of the variance components. To begin, the group means estimators, if computed, provide another possibility. For the one factor model,

$$s_{ols}^2 \text{ estimates } \sigma_\varepsilon^2 + \sigma_u^2$$

and the group means estimator,

$$s_{means}^2 \text{ estimates } Q\sigma_\varepsilon^2 + \sigma_u^2,$$

where $$Q = (1/N)\Sigma_i(1/T_i).$$

These two equations can be solved to provide alternative estimates of the variance components:

$$\hat{\sigma}_\varepsilon^2 = (s_{ols}^2 - s_{means}^2) / (1 - Q)$$

and $$\hat{\sigma}_u^2 = s_{means}^2 - Q\,\hat{\sigma}_\varepsilon^2.$$

In the two way random effects model, the moment equations and their solutions would be as follows:

$$s_{ols}^2 = \hat{\sigma}_\varepsilon^2 + \hat{\sigma}_u^2 + \hat{\sigma}_w^2 \quad \text{(from the OLS regression)},$$

$$s_{group\ means}^2 = \hat{\sigma}_u^2 + Q_u\,\hat{\sigma}_\varepsilon^2 \quad \text{(from the group means regression)},$$

and $$s_{period\ means}^2 = \hat{\sigma}_w^2 + Q_w\,\hat{\sigma}_\varepsilon^2 \quad \text{(from the period means regression)},$$

where N = the total number of individuals observed,

T = the total number of periods observed,

Q_u = $(1/N)\Sigma_i(1/T_i)$ (or $1/T$ if the sample is balanced),

and Q_w = $(1/T)\Sigma_t(1/N_t)$ (or $1/N$ if the sample is balanced).

Then, $$\hat{\sigma}_\varepsilon^2 = (s_{ols}^2 - s_{group\ means}^2 - s_{period\ means}^2)/(1 - Q_u - Q_w),$$

$$\hat{\sigma}_u^2 = s_{group\ means}^2 - Q_u\,\hat{\sigma}_\varepsilon^2$$

$$\hat{\sigma}_w^2 = s_{period\ means}^2 - Q_w\,\hat{\sigma}_\varepsilon^2.$$

The preceding may yet fail to produce a positive estimator for the variance of w_t or u_i. If so, a last ditch estimator is used. In the two way fixed effects model, we may take the estimates of the dummy variable coefficients as estimators of u_i and w_t. If so, then the sample variances of a_i and c_t are used as estimators of $\sigma_u^2$and σ_w^2. We should note, the need for a protracted search such as this might be taken as a suggestion that the data are not consistent with this model.

During estimation, a log is kept of the search for the estimates of the variance components. The following shows the entry for a model estimated with the Grunfeld data in which it takes several tries to find an estimator. We have added the boldface annotation to the text from the trace file.

```

E18.7 Two and Three Way Nested Random Effects

The linear random effects model for panel data is extended to a three level nested structure,`

$$y_{ijt} = \boldsymbol{\beta}'\mathbf{x}_{ijt} + \varepsilon_{ijt} + v_{ij} + u_i$$

This is not a ‘three way’ random effects model – the effects are strictly nested. An example might be a regression of test scores by school which includes a school effect (u_i), a teacher within school effect (v_{ij}) and the period or student of observation (ε_{ijt}). The model is fit by full information maximum likelihood. (Note, the random parameters model with multiple effects described below allows for up to 10 levels in this same fashion. The estimator there is maximum simulated likelihood.)

E18.7.1 Command

The command for this estimator is

REGRESS ; Lhs = dependent variable
; Rhs = independent variables
; MLE
; Stratum = identifier for broader grouping
; Cluster = identifier for narrower grouping

This is a random effects linear regression model, and thus provides the usual optional features, including residuals, fitted values, hypothesis tests, and so on. A few options are unavailable, the linear restricted estimator, AR(1) correction and the White and Newey-West robust covariance matrices.

E18.7.2 Results

Estimates produced by this program include an initial ordinary least squares regression with all statistics usually produced. Since the command has specified a **; Cluster** and **; Stratum** correction, the OLS covariance matrix will be corrected for the clustering and stratification (appropriately so). The application below shows this result. The OLS results will be followed by the maximum likelihood estimates of the model parameters. A reparameterized form of the model is estimated – see the technical details for discussion. Results generated by this estimator are shown and annotated in the application below. In addition to the fitted values and residuals that may be requested, the following results are saved:

Matrices: *b* and *varb* These include only the regression parameters, not the variance parameters.

Scalars: *ssqrd* = σ_ε^2

$R^2 = 1 - \dfrac{\Sigma_{i,j,t}\left(y_{ijt} - \hat{\boldsymbol{\beta}}'\mathbf{x}_{ijt}\right)^2}{\Sigma_{i,j,t}(y_{ijt} - \overline{y})^2}$

s = σ_ε

sumsqdev = $\Sigma_{i,j,t}(y_{ijt} - \hat{\boldsymbol{\beta}}'\mathbf{x}_{ijt})^2$

ρ = 0

degfrdm = *NOBS* - *K*

ybar = $\Sigma_{i,j,t}y_{ijt}$ / *NOBS*

s*y* = (1/(*NOBS*-1)) $\Sigma_{i,j,t}(y_{ijt} - \overline{y})^2$

kreg = *K*,

nreg = *NOBS*

logl = log likelihood

s2u = σ_u^2

s2v = σ_w^2

E18.7.3 Application

To continue our earlier application, we have arbitrarily divided our 48 states into 12 'regions' with four states in each (actually just contiguously grouped sets of four states in the data set – just for purpose of a numerical illustration of the computation). The commands used are

CREATE ; region = Trn(68,0) $
REGRESS ; Lhs = loggsp
; Rhs = x,one
; MLE
; Cluster = 17
; Stratum = region $

```

E18.7.4 Technical Details

The analysis is based on Antweiler (2001). Antweiler analyzes a four level model, though the recursive pattern of his results suggests it would not be difficult to extend it to five or more levels. The *LIMDEP* adaptation restricts it to three levels. (The random parameters model discussed later allows higher numbers of levels.) These results are taken from the article: The four level model is

$$y_{ijkt} = \boldsymbol{\beta}'\mathbf{x}_{ijkt} + \varepsilon_{ijkt} + w_{ijk} + v_{ij} + u_i.$$

The group sizes in the nested structure are M_i, N_{ij} and T_{ijk}. The total sample size is

$$NOBS = \sum_{i=1}^{L} \sum_{j=1}^{M_i} \sum_{k=1}^{N_{ij}} T_{ijk}$$

The following are used to parameterize the log likelihood:

$$\rho_u = \frac{\sigma_u^2}{\sigma_\varepsilon^2},\ \rho_v = \frac{\sigma_v^2}{\sigma_\varepsilon^2},\ \rho_w = \frac{\sigma_w^2}{\sigma_\varepsilon^2}.$$

$$\theta_{ijk} = 1 + T_{ijk}\rho_u,\ \phi_{ij} = \Sigma_{k=1}^{N_{ij}}\frac{T_{ijk}}{\theta_{ijk}},\ \theta_{ij} = 1 + \phi_{ij}\rho_v,\ \phi_i = \Sigma_{j=1}^{M_i}\frac{\phi_{ij}}{\theta_{ij}},\ \ \theta_i = 1 + \rho_w\phi_i$$

$$e_{ijkt} = y_{ijkt} - \mathbf{x}_{ijkt}'\boldsymbol{\beta}$$

$$A_{ijk} = \Sigma_{t=1}^{T_{ijk}} e_{ijkt}^2,\ B_{ijk} = \Sigma_{t=1}^{T_{ijk}} e_{ijkt},\ B_{ij} = \Sigma_{k=1}^{N_{ij}}\frac{B_{ijk}}{\theta_{ijk}},\ \ B_i = \Sigma_{j=1}^{M_i}\frac{B_{ij}}{\theta_{ij}}$$

Then,

$$\begin{aligned}\log L = \frac{-1}{2}[NOBS\log(2\pi\sigma_\varepsilon^2) + \Sigma_{i=1}^{L}\{ & \\ & \log\theta_i + \Sigma_{j=1}^{M_i}\{ \\ & \log\theta_{ij} + \Sigma_{k=1}^{N_{ij}}\{ \\ & \log\theta_{ijk} + \frac{A_{ijk}}{\sigma_\varepsilon^2} - \frac{\rho_u}{\theta_{ijk}}\frac{B_{ijk}^2}{\sigma_\varepsilon^2}\} - \frac{\rho_v}{\theta_{ij}}\frac{B_{ij}^2}{\sigma_\varepsilon^2}\} - \frac{\rho_w}{\theta_i}\frac{B_i^2}{\sigma_\varepsilon^2}\}].\end{aligned}$$

For the three level model, we set $L = 1$ and $\rho_w = 0$. We use the BFGS method with numerical derivatives to maximize this log likelihood. Antweiler suggests that the second derivatives needed for the estimator for the asymptotic covariance matrix of the maximum likelihood estimator are intractable – and proposes numerical derivatives. However, by taking advantage of the results that for the generalized regression model, the expected Hessian of the log likelihood will be block diagonal, we do obtain a tractable form for the asymptotic covariance matrix of the slope estimator – it is the counterpart to the moment matrix that would be used for the GLS estimator:

$$\begin{aligned}-\frac{\partial^2 \log L}{\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}'} = & \frac{1}{\sigma_\varepsilon^2}\Sigma_{i=1}^{L}\Sigma_{j=1}^{M_i}\Sigma_{k=1}^{N_{ij}}\Sigma_{t=1}^{T_{ijk}}\mathbf{x}_{ijkt}\mathbf{x}_{ijkt}' \\ & - \frac{\rho_w}{\sigma_\varepsilon^2}\Sigma_{i=1}^{L}\Sigma_{j=1}^{M_i}\Sigma_{k=1}^{N_{ij}}\frac{1}{\theta_{ijk}}\left(\Sigma_{t=1}^{T_{ijk}}\mathbf{x}_{ijkt}\right)\left(\Sigma_{t=1}^{T_{ijk}}\mathbf{x}_{ijkt}'\right) \\ & - \frac{\rho_v}{\sigma_\varepsilon^2}\Sigma_{i=1}^{L}\Sigma_{j=1}^{M_i}\frac{1}{\theta_{ij}}\left(\Sigma_{k=1}^{N_{ij}}\frac{1}{\theta_{ijk}}\left(\Sigma_{t=1}^{T_{ijk}}\mathbf{x}_{ijkt}\right)\right)\left(\Sigma_{k=1}^{N_{ij}}\frac{1}{\theta_{ijk}}\left(\Sigma_{t=1}^{T_{ijk}}\mathbf{x}_{ijkt}'\right)\right) \\ & - \frac{\rho_u}{\sigma_\varepsilon^2}\Sigma_{i=1}^{L}\left(\Sigma_{j=1}^{M_i}\frac{1}{\theta_{ij}}\left(\Sigma_{k=1}^{N_{ij}}\frac{1}{\theta_{ijk}}\left(\Sigma_{t=1}^{T_{ijk}}\mathbf{x}_{ijkt}\right)\right)\right)\left(\Sigma_{j=1}^{M_i}\frac{1}{\theta_{ij}}\left(\Sigma_{k=1}^{N_{ij}}\frac{1}{\theta_{ijk}}\left(\Sigma_{t=1}^{T_{ijk}}\mathbf{x}_{ijkt}'\right)\right)\right)\end{aligned}$$

We use this matrix, specialized to three levels, for estimating the asymptotic covariance matrix of the slope estimator. As is usual in the linear regression case, we do not report asymptotic standard errors for the variance coefficients. We note, for purposes of testing for the nesting structure, one can use the likelihood ratio test.

E18.8 Multilevel and Multiple Effects in the RP Model

The following applies to all random parameters models in *LIMDEP* – the entire class of models estimable with the **; RPM** specification with only the exception of the two equation models, bivariate probit and sample selection. In this section, we document the use of the model in the linear regression case.

The model is based on an index function

$$Index_{it} = \boldsymbol{\beta}'\mathbf{x}_{it}$$

such as the linear regression model, $y_{it} = Index_{it} + \varepsilon_{it}$ or the probit model, where $y_{it} = 1(Index_{it}+\varepsilon_{it} > 0)$. We add to this M = up to 10 'effects.'

$$Index_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + c_{j1}\,\omega_{j1,i} + c_{j2}\,\omega_{j2,i} + \dots\, c_{jM}\,\omega_{jM,i}.$$

The c_{jm} are ones and zeros simply used to select the effects in the model. The effects are up to 10 normally distributed random terms associated with discrete group indicators such as strata, clusters, etc. Effects may appear singly or as products, and may be nested or simply be associated with any desired groupings of the data. The associated variables can be any desired discrete indicator that associates a unique value with a group. Consider an example based on test scores. Suppose we have nationwide data, arranged by *region*, *state*, *county*, *district*, *school*. These are individual test scores observed in five decreasing levels of aggregation. Then, in addition to the data on test scores (presumably individual students) and the covariates in **x**, we have variables with distinct codes for the five levels of aggregation – the only restriction is that codes must be integers from 1,2,...,9999. The specification is

; REM = name1, name2, ..., nameM

For our example, this would thus be

; REM = region,state,county,district,school

This estimator does not require that these 'effects' be nested. The effects can be defined at any level of aggregation, and could be a mixture of nested and nonnested groupings. Suppose, for example, you also had indicators of grouping by *type of program*, which might be one of, say, 10, which varies all over the range of observations, without respect to the other five groupings listed. For another example, one might also have a *party* effect in that list, for whether the state in question had a *Democratic*, *Republican*, or *Other Party* governor at the time This could also be included.

Effects may also be main or secondary (products). You can specify secondary effects by writing the effects as products, as in

; REM = name1, name2, name3*name4,
name2*name3*name4, name1*name4

You may define up to 10 effects or combinations of effects in total, using up to 10 basic effects. To continue the example, you might specify an interaction between state and district with

; REM = region,state,county,district,school,state*district

The **; REM** specification can be added to a random parameter model (RPM) or may appear by itself instead of **RPM ; Fcn = …**

E18.8.1 Command

This estimator uses *LIMDEP*'s package of random parameter model estimators, and thus is in a different class of estimators from those we have considered in this manual up to this point. These models are discussed in greater generality in Chapter R24. We will omit some of the detail in the specification here, as it is given in full in the broader chapter. For this application (the linear model), the essential part of the command is

REGRESS ; Lhs = the dependent variable
; Rhs = the independent variables
; RPM
; Pds = the correct specification for your panel (see below)
; REM = the specification of your random effects $

Typically, the panel specification in **; Pds = ...** would correspond to the structure of one of your effects variables. But, this is not required. Indeed, you could have **; Pds = 1**. But, if you are analyzing a panel, you should specify it as usual. Note that the command does not contain **; Panel**. This must be omitted from this command. The effects are set up as described above. There is one other specification that you should use. The estimator for this model is maximum simulated likelihood (described in the technical notes below). You may want to control the number of random draws used in the simulations. This is an extremely computation intensive estimator. The number of random draws is specified with

; Pts = the desired number

The default value is 100. For generating final results in a study, you will probably use several hundred. But, for exploratory work, as in our example below, you might want to choose a small value, such as 10 or 25.

E18.8.2 Application

In Section E18.6, we fit a two way random effects model of the form

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i + w_t.$$

For present purposes, we rewrite this as

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_\varepsilon\varepsilon_{it} + \sigma_u u_i + \sigma_v w_t$$

where now, all random effects have variance one. This model is identical to the previous one. The extension we consider here can be written

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_\varepsilon\varepsilon_{it} + \sigma_u u_i + \sigma_v w_t + \gamma(\sigma_u u_i)(\sigma_v w_t)$$

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_\varepsilon\varepsilon_{it} + \sigma_u u_i + \sigma_v w_t + \theta u_i w_t.$$

That is, we add a product term which has a freely estimated additional 'effect' on the dependent variable. The commands are

```
CALC      ; Ran(1234579) $
CREATE    ; t = yr - 1969 $
REGRESS   ; Lhs = loggsp
          ; Rhs = x,one
          ; Pds = 17
          ; RPM
          ; Pts = 50
          ; REM = state,t,state*t $
```

E18.8.3 Technical Details

Conditioned on the unobserved effects, the contribution of each observation to the log likelihood for the linear regression model is

$$\log L_i|\boldsymbol{\omega}_i = -\log\sigma_\varepsilon - ½ \log 2\pi - ½ (\varepsilon_i / \sigma_\varepsilon)^2$$

where 'i' is used generically to denote a single observation. Conditioned on the effects, the observations are independent. In the conditional form above, $\boldsymbol{\omega}_i$ is the set of up to 10 random effects. There are assumed to be T_i 'observations' for individual i. The conditional likelihood is

$$L_i \mid \omega = \prod_{t=1}^{T_i} \frac{1}{\sigma_\varepsilon\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{\varepsilon_{it}}{\sigma_\varepsilon}\right)^2\right]$$

where $\varepsilon_{it} = y_{it}$ - $\boldsymbol{\beta}'\mathbf{x}_{it}$ – *all common effects*. The unconditional likelihood function is obtained by integrating out the common effects:

$$L_i = \int_{\omega_i} \prod_{t=1}^{T_i} \frac{1}{\sigma_\varepsilon\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{\varepsilon_{it}}{\sigma_\varepsilon}\right)^2\right] f(\boldsymbol{\omega}_i)d\boldsymbol{\omega}_i.$$

This integral is approximated by simulation. The function that we maximize with respect to $(\boldsymbol{\beta},\sigma_\varepsilon,\boldsymbol{\gamma})$ is

$$\log L = \sum_{i=1}^{N} \log \frac{1}{R} \sum_{r=1}^{R} \left(\prod_{t=1}^{T_i} \frac{1}{\sigma_\varepsilon\sqrt{2\pi}} \exp\left[-\frac{1}{2}\left(\frac{\varepsilon_{itr}}{\sigma_\varepsilon}\right)^2\right]\right)$$

Further details on the maximization appears in Chapter R24. We note one important aspect of the simulation/integration. Where the common effect is of the form $\sigma_\omega u_i$ – that is, the subscript on the effect matches the index of the product operation, as in the familiar random effects model – then the preceding is exactly equivalent to that RE model. In other cases, however, the effect may be varying over a different range than the index in the product. Consider the time effects in our example. There are 17 of them in each i, since each state is observed in each period. Thus, for our example,

$$\varepsilon_{it,r} = y_{it} - \boldsymbol{\beta}'\mathbf{x}_{it} - \gamma_1 v_{i,r} - \gamma_2 w_{it,r} - \gamma_3 v_{i,r} w_{it,r}.$$

That is, the integral over periods is recomputed for each i, while the integral over v_i is only computed once. Moreover, in principle, though w_t is a 'time' effect, we are treating it as if it were a state specific time effect when we integrate it out. (There is a separate random variable w_t for each period, however.) This means that although state observations are correlated across states because of the common time effect, we are treating them as uncorrelated by this procedure. Thus, it must be considered approximate.

E19: Random Parameters Linear Models

E19.1 Introduction

LIMDEP provides two approaches to fitting linear regression models with random parameters:

- Mixed or random parameters models – parameters are distributed continuously
- Latent class or finite mixture models – parameters have a discrete distribution

The models are built around the structural equations

$$y_{it} \;=\; \boldsymbol{\alpha}'\mathbf{w}_{it} + \mathbf{x}_{it}'\boldsymbol{\beta}_i + \boldsymbol{\varepsilon}_i,\; i = 1,...,N,\; t = 1,\ldots,T_i,$$

$$\varepsilon_{\text{it}} \;\sim\; \text{N}[0,\sigma_{\text{i}}^2]$$

For the mixed model, the general form is

$$\boldsymbol{\beta}_I \;=\; \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i,$$

$$\text{E}[\mathbf{v}_i|\mathbf{x}_i,\mathbf{z}_i] \;=\; \mathbf{0},\;\; \text{Var}[\mathbf{v}_i|\mathbf{x}_i,\mathbf{z}_i] \;=\; \mathbf{I},$$

$$\text{Var}[\boldsymbol{\beta}_i|\,\mathbf{x}_i,\mathbf{z}_i] \;=\; \boldsymbol{\Sigma} = \boldsymbol{\Gamma}\boldsymbol{\Gamma}',$$

$$\sigma_i^2 \;=\; \sigma^2 \text{ (constant).}$$

The familiar linear regression model, a random effects linear model, and a hierarchical linear model are all particular cases. In the latent class model,

$$\boldsymbol{\beta}_i,\sigma_i^2 \;\in\; [(\boldsymbol{\beta}_1,\sigma_1^2), (\boldsymbol{\beta}_2,\sigma_2^2), \ldots, (\boldsymbol{\beta}_j,\sigma_j^2), \ldots (\boldsymbol{\beta}_J,\sigma_J^2)],$$

$$\text{Prob[class=}j|\mathbf{z}_i] \;=\; \pi_j(\mathbf{z}_i,\boldsymbol{\theta}_j),\; j = 1,\ldots,J.$$

Estimation of the random parameters (RP) model is described in this chapter. The latent class model is documented in Chapter E20.

The randomness of the parameters is interpreted simply as latent heterogeneity. The linear regression model with random coefficients is normally associated with panel data settings, but we allow this formulation with a cross section as well. The model is identified in a cross section, though results are generally better when this is applied to a panel.

E19.2 Random Parameters Linear Models

The structure of the basic model is

$$y_{it} = \boldsymbol{\alpha}'\mathbf{w}_{it} + \boldsymbol{\beta}_i'\mathbf{x}_{it} + \varepsilon_{it},\ i = 1,...,n,\ t = 1,\ldots,T_i.$$

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Gamma}\mathbf{v}_i.$$

The conditional mean function is

$$E[y_{it}|\, \mathbf{x}_{it}, \boldsymbol{\beta}_i] = \boldsymbol{\alpha}'\mathbf{w}_{it} + \boldsymbol{\beta}_i'\mathbf{x}_{it},\ i = 1,...,n,\ t = 1,...,T_i.$$

The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals) distribution,

$$E[\boldsymbol{\beta}_i|\, \mathbf{X}_i] = \boldsymbol{\beta},\ \ \mathbf{X}_i = [\mathbf{x}_1,\ldots,\mathbf{x}_{Ti}]$$

$$\text{Var}[\boldsymbol{\beta}_i|\, \mathbf{X}_i] = \boldsymbol{\Sigma} = \boldsymbol{\Gamma}\boldsymbol{\Gamma}'.$$

The full parameter vector is partitioned into a nonrandom part, $\boldsymbol{\alpha}$, which multiplies a set of K_0 regressors and the random part $\boldsymbol{\beta}_i$ which multiples the remaining K_1 of the total of K regressors. The random coefficient vector, $\boldsymbol{\beta}_i$ is assumed to be distributed with mean provided by the deterministic component, $\boldsymbol{\beta}$ and stochastic component, $\boldsymbol{\Gamma}\mathbf{v}_i$. The random vector, $\mathbf{v}_i$, is assumed to have mean zero (with no loss of generality, given $\boldsymbol{\beta}$) and covariance matrix equal to an identity matrix, $\mathbf{I}$. The coefficient matrix, $\boldsymbol{\Gamma}$, provides the variances and cross parameter correlations in the distribution of $\boldsymbol{\beta}_i$. For estimation purposes, $\boldsymbol{\Gamma}$ is taken to be a free lower triangular matrix, so the covariance matrix of the random parameter vector is $\boldsymbol{\Sigma} = \boldsymbol{\Gamma}\boldsymbol{\Gamma}'$. The base case assumes that $\boldsymbol{\Gamma}$ is a diagonal matrix with diagonal element γ_k.

Estimation is based on the following approach: (It is only sketched here. A fuller discussion of the method and the underlying theory is presented in Chapter R24.) The reduced form of this model is

$$y_{it}|\boldsymbol{\beta}_i = \boldsymbol{\alpha}'\mathbf{w}_{it} + \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\gamma}'[\mathbf{v}_i \otimes \mathbf{x}_{it}] + \varepsilon_{it}$$

$$= \boldsymbol{\theta}'\mathbf{h}_{it}(\mathbf{v}_i) + \varepsilon_{it}.$$

We assume that ε_{it} is normally distributed with mean zero and variance σ^2 and is uncorrelated with all other observations, ε_{js}, $j \neq i$. Conditioned on realizations $\mathbf{v}_i$, that is, on the sample of draws, $\mathbf{V} = [\mathbf{v}_1,\mathbf{v}_2,...,\mathbf{v}_n]$, the maximum likelihood estimator of the set of structural parameters, $\boldsymbol{\theta}$, is the least squares estimator. But, this is only conditional on a particular realization of the parameter vector. In order to obtain the unconditional estimator, it would be necessary to take the expectation of this estimator, over the distribution of the random parameter vector. This would be the integral of the conditional density over the range of $\boldsymbol{\beta}_i$ (induced by $\mathbf{v}_i$). Since this integral is unlikely to have a closed form in general, we use simulation to approximate the distribution, instead. A total of R draws of $\boldsymbol{\beta}_i$ are obtained for each i. The results are averaged over the draws. Thus, the full set of structural parameters is obtained by minimizing the sum of squares. The procedure is iterated over the estimated disturbance variance, until convergence or a maximum of 20 iterations.

NOTE: If only the constant term is considered random – the model may specify that some parameters are nonrandom – then this model is equivalent to the random effects model presented in Chapter E18.

E19.3 Command for the Random Parameters Models

The basic command for the random parameters regression estimators is

REGRESS ; Lhs = dependent variable
; Rhs = full list of independent variables
; RPM
; Fcn = random parameters specification
; other specifications $

Use

SETPANEL ; … $

and **; Panel** in the command to specify a panel. If this is omitted, the data are assumed to be a cross section.

NOTE: For this model, your Rhs list *should* include a constant term.

E19.3.1 Specifying Random Parameters

The **; Fcn = specification** is used to define the random parameters. It is constructed from the list of Rhs names as follows: Suppose your model is specified by

; Rhs = one,x1,x2,x3,x4

This involves five coefficients. Any or all of them may be random; any not specified as random are assumed to be nonrandom (i.e.,) constant. For those that you wish to specify as random, use

; Fcn = variable name (distribution),
variable name (distribution), ...

Three distributions may be specified All random variables have mean 0.

n = standard normal distribution, variance = 1,
t = triangular (tent shaped) distribution in [-1,+1], variance = 1/6,
u = standard uniform distribution [-1,1], variance = 1/3
or *c* = variance = 0. (The parameter is not random.)

For an example, to specify that the constant term and the coefficient on *x*1 are normally distributed with fixed mean and variance, use

; Fcn = one(n), x1(n).

This specifies that the first and second coefficients are random while the remainder are not. The parameters estimated will be the mean and standard deviations of the distributions of these two parameters and the fixed values of the other three.

Each random parameter is scaled as it enters the distribution, so the variance is only that of the random draw before multiplication. For example, if you specify that a parameter is normally distributed, then that parameter is $\beta_{k,i} = \beta_k + \sigma_k v_{i,k} \sim N[\beta,\sigma_k^2]$. For a variable with the triangular or uniform distribution, the variance of $\beta_{k,i}$ is $\sigma_k^2/6$ or $\sigma_k^2/3$, respectively. (See Chapter R24 for discussion of this computation. There are several additional specifications for random parameters discussed there as well. Some are provided to reduce the amount of variation in the tails of the distribution of the parameters across individuals and to limit the range of variation. (See Train (2009) for discussion.)

E19.3.2 Constraining the Sign of a Parameter – Lognormal and Triangular

Two methods are provided for constraining the sign of a parameter.

1. **Lognormal distribution:** $\beta_i = \exp(\beta + \gamma v_i) = \exp(\beta)\times[\exp(v_i)]^\gamma$.

The parameter thus specified is constrained to be positive. Use

; Fcn = variable (l) (type ‘el’ not ‘one’)

The lognormal distribution is effective, but can cause problems in estimation. If your theory specifies a positive parameter for all *i*, but the model is not well specified, then the estimator may be improperly attempting to force the parameter to be positive. The situation can be visualized by considering a model in which the simple least squares estimate of β is large and negative. If you then try to force the parameter to be positive by specifying a lognormal distribution, the end result will be that the mean will gravitate toward $-\infty$ and σ will tend toward zero. The second complication with lognormal parameters is that the distribution has a long thick tail and can allow large a probability of implausible values even if they do have the right sign. Given these two results, we find that the lognormal specification can be a difficult model to work with.

2. **One sided triangular distribution:** $\beta_i = \beta + \beta v_i$.

This specification is obtained with

; Fcn = variable (o).

The distribution is produced by forcing equality of the mean parameter and the scaling parameter. The result ranges between 0 and 2β, which is always positive if β is positive and always negative if β is negative. This specification has the advantage that it will accommodate the underlying data and not force a sign on the coefficient.

E19.3.3 Correlated Random Parameters

The preceding defines an estimator for a model in which the covariance matrix of the random parameters is diagonal. To extend it to a model in which the parameters are freely correlated, add

; Correlation (or just ; Cor)

to the command. The uncorrelated case is characterized by the diagonal matrix, Γ, so that the full set of random parameters is

$$\beta_{k,i} = \beta_k + \gamma_k v_{k,i},\ k = 1,\ldots,K_1.$$

In order to induce the correlation across parameters, the below diagonal elements of Γ are allowed to be nonzero. In this case, we have

$$\beta_{1,i} = \beta_1 + \gamma_{11} v_{1,i},$$

$$\beta_{2,i} = \beta_2 + \gamma_{21} v_{1,i} + \gamma_{22} v_{2,i},$$

$$\beta_{3,i} = \beta_3 + \gamma_{31} v_{1,i} + \gamma_{32} v_{2,i} + \gamma_{33} v_{3,i},$$

and so on. The implied covariance and correlation matrices are reported with the final results of the model. We note one caution with this specification. If all random parameters are assumed to be normally distributed, the mixing of the distributions shown above will preserve the normality. In all other cases, the mixed distribution will not retain the specification of the model. For example, if you specify that parameter 1 is normally distributed and parameter 2 is uniformly distributed in your model specification, then parameter 1 will retain the specification, but parameter 2 will be distributed as the sum of a normal and a uniform random variable, which is complicated. Thus, while free correlations are estimable, it must be understood that the mixed distributions that give rise to the correlations may not have the expected shapes.

E19.3.4 Autocorrelation

The latent heterogeneity may evolve over time, rather than remain constant. To accommodate this, you may specify that

$$v_{ikt} = \rho_k v_{ik,t-1} + u_{ikt}$$

that is, the familiar AR(1) kind of model. For only a nonrandom constant term, this is similar to the autocorrelation setup for the random effects model, but note that a crucial difference here is that it is the common term that evolves over time (comparable to u_i) rather than the unique term, ε_{it}. The specification is

; AR1

E19.4 Hierarchical Model – Heterogeneity in the Means

We obtain a hierarchical model by allowing the mean of the parameters to vary with a set of covariates,

$$y_{it} = \boldsymbol{\beta}_i'\mathbf{x}_{it} + \varepsilon_{it},\ i = 1,...,n,\ t = 1,\ldots,T_i.$$

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i.$$

(We are allowing some of the parameters to be nonrandom. For convenience, the term $\boldsymbol{\alpha}'\mathbf{w}_{it}$ is absorbed in $\boldsymbol{\beta}_i'\mathbf{x}_{it}$.) The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals) distribution,

$$E[\boldsymbol{\beta}_i|\ \mathbf{z}_i] = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i,$$

This expanded formulation produces two useful special cases:

$\boldsymbol{\Delta} = \mathbf{0}$ is the familiar random parameters model, as in Section E19.3.
$\boldsymbol{\Gamma} = \mathbf{0}$ produces a hierarchical model with some interaction terms.

The implied form of the coefficients and the regression function are

$$E[\beta_{ki}] = \beta_k + \Sigma_m\, \delta_{km}\, z_{mi}$$

$$y_{it}|\boldsymbol{\beta}_i = \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}'[\mathbf{z}_i \otimes \mathbf{x}_{it}] + \boldsymbol{\gamma}'[\mathbf{v}_i \otimes \mathbf{x}_{it}] + \varepsilon_{it}$$

$$= \boldsymbol{\theta}'\mathbf{h}_{it}(\mathbf{v}_i) + \varepsilon_{it}$$

where z_m is a variable that is measured for each individual. The command is be modified to

; RPM = list of variables in z (must not include one).

In a panel data set, these variables must be repeated for each observation in the group. They are assumed not to vary over time. (Typically, they would be sociodemographic variables such as gender or education.)

A device is provided to allow the list of variables z_i to differ across coefficients. The general format is as follows: The specification **; RPM = list of variables** provides the full list of variables to be used. For example, if **; RPM = z1,z2,z3,z4**, then

; Fcn = x1(n)

specifies that the coefficient is $\beta_{1i} = \beta_1 + \delta_{11}z1_i + \delta_{12}z_{2i} + \delta_{13}z_{3i} + \delta_{14}z_{4i} + \gamma_1 v_{1i}$. To remove $z2$ and z_3 from this mean, use

; Fcn = x1(n | # 1001).

The vertical bar is followed by a # sign followed by a string of 0s and 1s to indicate exclude or include the respective zs from the mean of the coefficient. This device can be used with any specific coefficient, or all of them. Note that the number of digits after the # must exactly match the number of variables in the RPM list.

E19.5 Saved Results

Results saved automatically by this estimator are:

Matrices:	*b*	=	estimate of θ
	varb	=	asymptotic covariance matrix for estimate of θ.
	gammarpm	=	maximum likelihood estimate of Γ
	sdrpm	=	vector of estimated standard deviations from $\Gamma\Gamma'$ computed as the square roots of the diagonals of $\Gamma\Gamma'$.
Scalars:	*kreg*	=	number of variables in Rhs
	nreg	=	number of observations
	logl	=	log likelihood function

Last Model: *b_variables*

Last Function: None

There is no *Last Function* saved for the **PARTIALS** or **SIMULATE** command by the random parameters models, because of the need to simulate the parameters to do the computations. Partial effects and predicted values are computed locally within the estimator, and can be requested with

; Partial Effects

and **; Keep = variable** and/or **; Res = variable**.

E19.6 Controlling the Simulation

There are three parameters of the simulations that you can change. The number of points in the simulation is *R*. Authors differ in the appropriate value. Train recommends several hundred. Bhat suggests 1,000 as an appropriate value. The program default is 100. You can choose the value with

; Pts = number of draws, *R*

The values of 25 or 50 that we set in our experiments are chosen purely to produce an example that you can replicate without spending an inordinate amount of waiting for the results. (Simulation based estimation is unavoidably a time intensive computation.)

In order to replicate a simulation based estimation, you must use the same random draws. One implication of this is that if you give the identical model command twice in sequence, you will not get the identical set of results because the random draws in the sequences will be different. To obtain the same results, you must reset the seed of the random number generator with a command such as

CALC ; Ran(seed value) $

The specific value you use for the seed is not of consequence; any odd number will do. (That value is modified internally to produce a seed for each individual in the sample. But, it remains that you can replicate a set of results by using the same global seed.)

In this connection, we note a consideration which is crucial in this sort of estimation. The random sequence used for the model estimation must be the same in order to obtain replicability. In addition, during estimation of a particular model, the same set of random draws must be used for each person every time. That is, the sequence $\mathbf{v}_{i1}$, $\mathbf{v}_{i2}$, ..., $\mathbf{v}_{iR}$ used for individual i must be the same every time it is used to calculate a probability, derivative, or likelihood function. (If this is not the case, the likelihood function will be discontinuous in the parameters, and successful estimation becomes unlikely.) One way to achieve this that has been suggested in the literature is to store the random numbers in advance, and simply draw from this reservoir of values as needed. Because *LIMDEP* is able to use very large samples, this is not a practical solution, especially if the number of draws is large as well. We achieve the same result by assigning to each individual, i, in the sample, their own random generator seed which is a unique function of the global random number seed, S, and their group number, i;

$$\text{Seed}(S,i) = S + 123.0 \times i, \text{ then minus 1.0 if the result is even.}$$

Since the global seed, S, is a positive odd number, this seed value is unique, at least within the several million observation range of *LIMDEP*.

The standard approach to simulation estimation is to use random draws from the specified distribution. As suggested above, good performance in this connection requires very large numbers of draws. The drawback to this approach is that with large samples and large models, this entails a huge amount of computation and can be very time consuming. Some authors have documented dramatic speed gains with no degradation in simulation performance through the use of a small number of Halton draws instead of a large number of random draws. Halton sequences are discussed in Chapter R24. Authors (e.g., Bhat (2001)) have found that a Halton sequence of draws with only one tenth the number of draws as a random sequence is equally effective. (The efficiency does fall as the number of parameters rises, but large gains persist.) To use this approach, add

; Halton

to your model command.

E19.7 Other Options

Other optional features for the random parameters regression model are the usual, including

; Keep = name	to retain predictions
; Prob = name	to retain fitted probabilities
; Res = name	to retain residuals
; Covariance Matrix	to display the estimated asymptotic covariance matrix, same as **; Printvc**
; List	to display predicted values
; Table= name	to retain the model results for constructing tables
; Test:	to test hypotheses about $\boldsymbol{\beta}$.

In spite of the fact that this is a linear regression model, the estimator is nonlinear. The default (and best) algorithm for estimation is BFGS. But, all other algorithms are available as are other settings for the optimization process:

; Alg = DFP, BFGS, Newton	
; Maxit = n	to set maximum iterations
; Tlg[= value]	to set tolerance for convergence on gradient
; Tlb[= value]	to set tolerance for convergence on change in parameters
; Tlf [= value]	to set tolerance for convergence on change in log likelihood
; Output = value	to control output during iterations

This estimator can accommodate restrictions, so

; Rst = list

and **; CML: specification**

are both available. Do note that forcing the ancillary parameter, in this case, the variance parameters, to equal a slope parameter will almost surely produce unsatisfactory results, and may impede or even prevent convergence of the iterations.

E19.8 Individual Specific Estimates

Individual specific estimates of $E[\boldsymbol{\beta}_i|\text{data}_i]$ can be obtained by the method described in Chapter R24, by adding

; Parameters

to your command. This requests computation of matrices *beta_i* and *sdbeta_i* that contain the estimated means and standard deviations of the conditional distributions of β_i. Some discussion appears below in the applications.

E19.9 Applications

We provide two illustrations to demonstrate the linear RP model.

E19.9.1 Random Parameters Linear Regression Model

This application shows a straightforward application of the RP model in an unbalanced panel. There are three random parameters, which are assumed to be correlated. The simulation uses Halton sequences rather than random draws, so there is no need to set the seed for the random number generator.

E19.9.2 Conditional Estimates of Means of Random Parameters

Data file dairy.dat contains six years of observations on 247 dairy farms in northern Spain, drawn from 1993-1998. The raw data consist of the *farm* and *year* identification, plus measurements on one output, *milk*, and four inputs, *cows*, *land*, *labor* and *feed*. Figure E19.1 displays several observations.

dairy

Figure E19.1 ***Excel*** **Display of Dairy Farm Data**

To illustrate the random parameters (*RP*) estimator, we will fit a Cobb-Douglas production function,

$$\log y_{it} = \mathbf{x}_{it}'\boldsymbol{\beta}_i + \varepsilon_{it}$$

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Gamma}\mathbf{v}_i$$

where $\mathbf{x}_{it}$ = (1, log $cows_{it}$, log $land_{it}$, log $labor_{it}$, log $feed_{it}$). The data have been normalized so that the logs of the inputs sum to zero over the 1,482 observations. In the first application, we assume $\boldsymbol{\Gamma}$ is diagonal. To illustrate the difference across farms in the coefficients, we produce a centipede plot of the farm specific expected values of the coefficient on log *feed*. We also plot a kernel density estimator of the 247 observations on $E[\beta_{feed,i}|\text{data}_i]$. The second set of results is for a model in which $\boldsymbol{\Gamma}$ is unrestricted, so the parameters are freely correlated.

First, compute the random parameters regression.

```
REGRESS     ; Lhs = yit
            ; Rhs = one,x1,x2,x3,x4
            ; RPM
            ; Parameters
            ; Fcn = one(n),x1(n),x2(n),x3(n),x4(n)
            ; Pds = 6 ; Pts = 50 ; Halton $
```

We call the fifth coefficient *b*4, as it is the coefficient on *x*4 (*feed*). This picks up the estimates of $E[\beta_i 4 \mid \text{data}_i]$ and the conditional standard deviations.

```
MATRIX      ; b4 = beta_i(1:247,5:5)
            ; sb4 = sdbeta_i(1:247,5:5)
```

This forms an interval of the conditional mean plus/minus two standard deviations.

```
            ; lower = b4 - 2*sb4 ; upper = b4 + 2*sb4 $
```

Now prepare a centipede plot.

```
CREATE      ; i = Trn(1,1)$
SAMPLE      ; 1-247 $
MATRIX      ; farmid = i $
MPLOT       ; Lhs = farmid
            ; Rhs = lower,upper
            ; Centipede ; Endpoints = 0,250
            ; Yaxis = BetaFeed
            ; Title = Farm Specific E[b_feed|data] $
```

Display a kernel density estimator.

```
CREATE      ; b4i = b4 $
KERNEL      ; Rhs = b4i
            ; Title = Kernel Density Estimator for Conditional Means of Beta(4) $
```

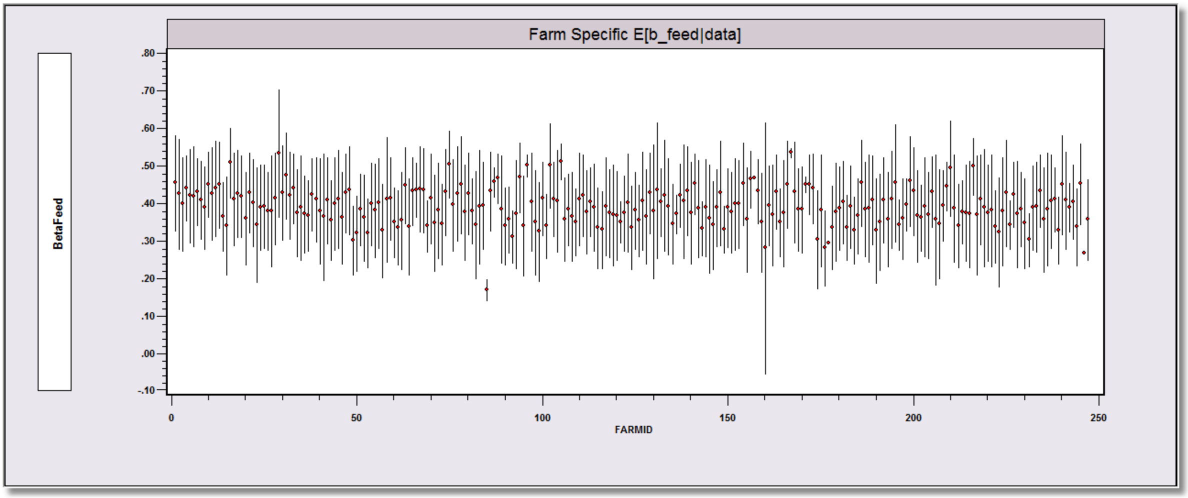
Figure E19.2 Matrices Created by Random Parameters Regression



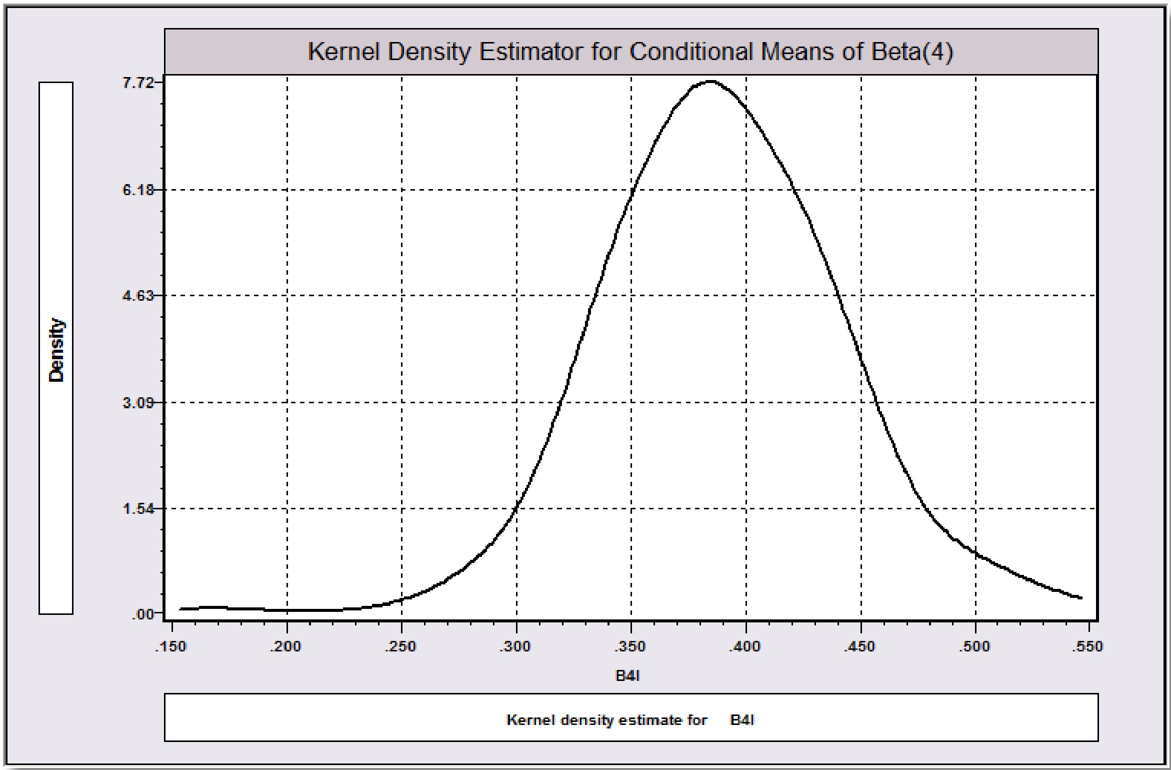


Figure E19.3 Distribution of Individual Specific Means

E19.10 The Parameter Vector and Starting Values

Starting values for the iterations are obtained by fitting the basic model without random parameters by least squares. Other parameters are set to zero. Thus, the initial results in the output for these models will be the simple linear regression model. You may provide your own starting values for the parameters with

; Start = ... the list of values for θ.

The parameter vector is laid out as follows, in this order:

$\alpha_1, ..., \alpha_K$	are the K nonrandom parameters.
$\beta_1,...,\beta_M$	are the M means of the distributions of the random parameters.
$\sigma_1,\sigma_2,...,\sigma_M$	are the M scale parameters for the distributions of the random Parameters.

These are the essential parameters. If you have specified that parameters are to be correlated, then the σs are followed by the below diagonal elements of **Γ**. (The σs are the diagonal elements.) If you have specified heterogeneity variables, **z**, then the preceding are followed by the rows of **Δ**. The autocorrelation model adds yet another vector of parameters. Consider an example: The model specifies:

; RPM = z1,z2
; Rhs = one,x1,x2,x3,x4 ? base parameters β_1, β_2, β_3, β_4, β_5
; Fcn = one(n),x2(n),x4(n)
; Cor

Then, after rearranging, the model becomes

Variable	**Parameter**
$x1$	α_1
$x3$	α_2
one	$\beta_1 + \sigma_1 v_{i1} + \delta_{11} z_{i1} + \delta_{12} z_{i2}$
$x2$	$\beta_2 + \sigma_2 v_{i2} + \gamma_{21} v_{i1} + \delta_{11} z_{i1} + \delta_{12} z_{i2}$
$x4$	$\beta_3 + \sigma_3 v_{i3} + \gamma_{31} v_{i1} + \gamma_{32} v_{i2} + \delta_{11} z_{i1} + \delta_{12} z_{i2}$

and the parameter vector would be

$$\boldsymbol{\theta} = \alpha_1, \alpha_2, \beta_1, \beta_2, \beta_3, \sigma_1, \sigma_2, \sigma_3, \gamma_{21}, \gamma_{31}, \gamma_{32}, \delta_{11}, \delta_{12}, \delta_{21}, \delta_{22}, \delta_{31}, \delta_{32}.$$

You may use **; Rst** and **; CML:** to impose restrictions on the parameters. Use the preceding as a guide to the arrangement of the parameter vector. (We concede the complexity of this. In point of fact, this is a complex model, unavoidably so.)

The variances of the underlying random variables are 1 for the normal distribution, 1/3 for the uniform, and 1/6 for the tent distribution. The σ parameters are only the standard deviations for the normal distribution. For the other two distributions, σ_k is a scale parameter. The standard deviation is obtained as $\sigma_k/\sqrt{3}$ for the uniform distribution and $\sigma_k/\sqrt{6}$ for the triangular distribution. When the parameters are correlated, the implied covariance matrix is adjusted accordingly. The correlation matrix is unchanged by this. All variance parameters are labeled 'scale parameter' in the model results.

E19.11 Technical Details on the RP Model

The structure of the random parameters model is based on the conditional density

$f[y_{it} \mid \mathbf{x}_{it}, \boldsymbol{\beta}_i]$ = Normal with mean $(\boldsymbol{\beta}_i'\mathbf{x}_{it})$, $i = 1,...,N$, $t = 1,...,T_i$, and variance σ^2.

NOTE: The force of the conditional normality assumption is only that the parameters are estimated by least squares.

The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals) mean

$E[\boldsymbol{\beta}_i \mid \mathbf{z}_i] = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i$, (the second term is optional – the mean may be constant)

$\text{Var}[\boldsymbol{\beta}_i \mid \mathbf{z}_i] = \boldsymbol{\Sigma}$

so that $\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i$.

As noted earlier, the heterogeneity term, $\boldsymbol{\Delta}\mathbf{z}_i$, is optional. In addition, it may be assumed that some of the parameters are nonrandom. It is convenient to analyze the model in this fully general form here. One can easily accommodate nonrandom parameters just by placing rows of zeros in the appropriate places in $\boldsymbol{\Delta}$ and $\boldsymbol{\Gamma}$. The actual treatment is discussed in the preceding sections.

The log likelihood function is

$$\log L = \Sigma_i \log L_i$$

where $\log L_i$ is the contribution of the ith individual (group) to the total. Conditioned on $\mathbf{v}_i$, the joint density for the ith group is

$$f[y_{i1},...,y_{iT_i} \mid \mathbf{x}_{i1,...,}\mathbf{z}_{i,}\mathbf{v}_i] = \prod_{t=1}^{T_i} f(y_{it} \mid \mathbf{x}_{it}, \boldsymbol{\beta}_i)$$

$$= \left(2\pi\sigma^2\right)^{-T_i/2} \exp\left[\frac{-1}{2\sigma^2}\sum_{t=1}^{T_i} \left(y_{it} - \boldsymbol{\beta}_i'\mathbf{x}_{it}\right)^2\right]$$

Since $\mathbf{v}_i$ is unobserved, it is necessary to obtain the unconditional log likelihood by taking the expectation of this over the distribution of $\mathbf{v}_i$. For convenience, write the tth term in the density above as $f(y_{it}, \boldsymbol{\beta}_i'\mathbf{x}_{it})$, so that

$$L_i \mid \mathbf{v}_i \;=\; \prod_{t=1}^{T_i} f(y_{it}, \boldsymbol{\beta}_i'\mathbf{x}_{it}).$$

Then,

$$L_i \;=\; \mathbf{E}_{\mathbf{v}i}\,[L_i \mid \mathbf{v}_i] \;=\; \int_{\text{Range of } \mathbf{v}_i} g(\mathbf{v}_i) \prod_{t=1}^{T_i} f(y_{it}, \boldsymbol{\beta}_i'\mathbf{x}_{it})\, d\mathbf{v}_i$$

(Note that this is a multivariate integral.) Then, finally,

$$\log \mathrm{L} \;=\; \sum_{i=1}^{N} \log L_i.$$

For convenience in what follows, let $\boldsymbol{\theta} = (\boldsymbol{\beta}, \boldsymbol{\Delta}, \boldsymbol{\Gamma})$. The likelihood function is maximized by solving the likelihood equations:

$$\frac{\partial \log L}{\partial \boldsymbol{\theta}} \;=\; \sum_{i=1}^{N} \frac{\partial \log L_i}{\partial \boldsymbol{\theta}} \;=\; \mathbf{0}.$$

Note that $\boldsymbol{\Gamma}$ is a lower triangular matrix; $\boldsymbol{\theta}$ is understood to contain only the nonzero elements, moving rowwise through the matrix (one element in row one, two in row two, and so on). Estimation is done conditionally on an estimate of σ^2. This is described below.

The integration is done by Monte Carlo simulation. In general, we use the approximation strategy:

$$\mathbf{E}_{\mathbf{v}i}\,[L_i \mid \mathbf{v}_i] \;\approx\; \frac{1}{R} \sum_{r=1}^{R} L \mid \mathrm{v}_{ir},$$

where $\mathbf{v}_{ir}$ is a random draw from the distribution of $\mathbf{v}_i$. See Brownstone and Train (1999), Train (1998), and Revelt and Train (1998) for discussion. The approximation improves with increased R (this is under your control) and with increases in N, though the simulation variance which decreases with increases in R does not decrease with N.

Collecting terms, then, the log likelihood is computed with

$$\log L \;\approx\; \sum_{i=1}^{N} \log\left\{\frac{1}{R}\sum_{r=1}^{R}\left[\prod_{t=1}^{T_i} f(y_{it}, \boldsymbol{\beta}_{ir}'\mathbf{x}_{it})\right]\right\},$$

where

$$\boldsymbol{\beta}_{ir} \;=\; \boldsymbol{\beta} \;+\; \boldsymbol{\Delta}\mathbf{z}_i \;+\; \boldsymbol{\Gamma}\mathbf{v}_{ir}.$$

The derivatives of the log likelihood function are approximated as well.

$$\frac{\partial \log L_i}{\partial \boldsymbol{\theta}} = \frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}$$

$$\frac{\partial L_i}{\partial \boldsymbol{\theta}} = \int_{\text{Range of } \mathbf{v}_i} g(\mathrm{v}_i)\frac{\partial}{\partial \boldsymbol{\theta}}\prod_{t=1}^{T_i} f(y_{it},\boldsymbol{\beta}_i'\mathbf{x}_{it})\, d\mathrm{v}_i$$

$$\frac{\partial}{\partial \boldsymbol{\theta}}\prod_{t=1}^{T_i} f(y_{it},\boldsymbol{\beta}_i'\mathbf{x}_{it}) = \sum_{t=1}^{T_i}\left[\frac{\partial f(y_{it},\boldsymbol{\beta}_i'\mathbf{x}_{it})}{\partial \boldsymbol{\theta}}\right]\prod_{s\neq t} f(y_{it},\boldsymbol{\beta}_i'\mathbf{x}_{is})$$

$$= \prod_{t=1}^{T_i} f(y_{it},\boldsymbol{\beta}_i'\mathbf{x}_{it})\sum_{t=1}^{T_i}\left[\frac{\partial \log f(y_{it},\boldsymbol{\beta}_i'\mathbf{x}_{it})}{\partial \boldsymbol{\theta}}\right]$$

Collecting terms once again, we obtain the approximation,

$$\frac{\partial \log L}{\partial \boldsymbol{\theta}} = \sum_{i=1}^{N} \frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}$$

$$\approx \sum_{i=1}^{N} \frac{\left\{\frac{1}{R}\sum_{r=1}^{R}\left[\prod_{t=1}^{T_i} f(y_{it},\boldsymbol{\beta}_{ir}'\mathbf{x}_{it})\right]\left[\sum_{t=1}^{T_i}\frac{\partial \log f(y_{it},\boldsymbol{\beta}_{ir}'\mathbf{x}_{it})}{\partial \boldsymbol{\theta}}\right]\right\}}{\left\{\frac{1}{R}\sum_{h=1}^{H}\left[\prod_{t=1}^{T_i} f(y_{it},\boldsymbol{\beta}_{ir}'\mathbf{x}_{it})\right]\right\}}$$

Note that L_i and its derivatives are approximated separately. The index is

$$\begin{aligned} w_{irt} &= \boldsymbol{\beta}_{ir}'\mathbf{x}_{it} \\ &= \boldsymbol{\beta}'\mathbf{x}_{it} + \mathbf{z}_i'\boldsymbol{\Delta}'\mathbf{x}_{it} + \mathbf{v}_{ir}'\boldsymbol{\Gamma}'\mathbf{x}_{it} \end{aligned}$$

We will need
$$\frac{\partial w_{irt}}{\partial \boldsymbol{\theta}} = \begin{bmatrix} \mathbf{x}_{it} \\ \mathbf{z}_i \otimes \mathbf{x}_{it} \\ \mathbf{v}_{ir} \otimes \mathbf{x}_{it} \end{bmatrix} = \mathbf{h}_{irt}$$

Then,
$$\frac{\partial \log f(y_{it}, w_{irt})}{\partial \boldsymbol{\theta}} = [(y_{it} - w_{irt})/\sigma^2]\mathbf{h}_{irt} = \mathbf{g}_{irt}.$$

In the vector at the end of the expression, the lower term is the result of the term $\mathbf{x}_{it}'\boldsymbol{\Gamma}\mathbf{v}_{ir}$. Since $\boldsymbol{\Gamma}$ is a lower triangular matrix, this term actually involves the $K(K+1)/2$ terms that are nonzero in the matrix $\boldsymbol{\Gamma}$.

The estimate of σ^2 is obtained residually while the estimates of the other parameters are obtained by maximizing the likelihood. The initial estimator of σ^2 is the ordinary least squares estimator. The likelihood function above is then maximized conditionally on this estimate of σ^2. After convergence, σ^2 is reestimated with

$$\hat{\sigma}^2 = \frac{\sum_{i=1}^{N} \frac{1}{R}\sum_{r=1}^{R} \sum_{t=1}^{T_i} \left(y_{it} - \hat{\boldsymbol{\beta}}'_{ir}\mathbf{x}_{it}\right)^2}{\sum_{i=1}^{N} T_i}$$

The parameters of the model are then reestimated using this estimate of σ^2. After convergence, σ^2 is recomputed again and the iterations are entered a third time. This process continues until σ^2 stabilizes, which will usually occur in only a few passes. After this last estimation, σ^2 is recomputed, and this is the value reported in the results.

The Hessian is fairly complicated, so we will only sketch the necessary components. Let

$$f_{ir} = \prod_{t=1}^{T_i} f_{irt}$$

$$\mathbf{g}_{ir} = \sum_{t=1}^{T_i} \mathbf{g}_{irt}$$

Then,

$$\frac{\partial \log L_i}{\partial \boldsymbol{\theta}} = \frac{1}{L_i}\frac{1}{R}\sum_{r=1}^{R} f_{ir}\mathbf{g}_{ir} = \frac{1}{L_i}\mathbf{g}_i$$

Since each of the three parts is a function of $\boldsymbol{\theta}$, the Hessian will have three parts. The end result is

$$\frac{\partial^2 \log L_i}{\partial \boldsymbol{\theta}\partial \boldsymbol{\theta}'} = -\left(\frac{1}{L_i}\mathbf{g}_i\right)\left(\frac{1}{L_i}\mathbf{g}_i\right)' + \frac{1}{L_i}\frac{1}{R}\sum_{r=1}^{R} f_{ir}\mathbf{H}_{ir} + \frac{1}{L_i}\frac{1}{R}\sum_{r=1}^{R} f_{ir}\mathbf{g}_{ir}\mathbf{g}_{ir}'$$

where

$$\mathbf{H}_{ir} = \sum_{t=1}^{T_i} \frac{\partial^2 \log f_{irt}}{\partial \boldsymbol{\theta}\partial \boldsymbol{\theta}'}$$

The asymptotic covariance matrix may be estimated by the BHHH estimator,

$$\textbf{BHHH} = \left[\sum_{i=1}^{N} \left(\frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}\right)\left(\frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}\right)'\right]^{-1}$$

or with the actual second derivatives.

The remaining detail concerns the random draws, $\mathbf{v}_i$, which are discussed in Chapter R24.

E20: Latent Class Linear Models

E20.1 Introduction

LIMDEP provides two approaches to fitting linear regression models with random parameters:

- Mixed, or random parameters model – parameters are distributed continuously;
- Latent class, or finite mixture model – parameters have a discrete distribution.

The models are built around the structural equations

$$y_{it} = \mathbf{x}_{it}'\boldsymbol{\beta}_i + \varepsilon_{it},\ i = 1,...,N,\ t = 1,\ldots,T_i,$$
$$\varepsilon_{\text{it}} \sim N[0,\sigma_i^2]$$

For the mixed, or random parameters model,

$$\begin{aligned}
\boldsymbol{\beta}_i &= \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i,\\
\text{E}[\mathbf{v}_i|\mathbf{z}_i,\mathbf{x}_{it}] &= \mathbf{0},\ \text{Var}[\mathbf{v}_i] = \mathbf{I},\\
\text{Var}[\boldsymbol{\beta}_i|\mathbf{z}_i,\mathbf{x}_{it}] &= \boldsymbol{\Sigma} = \boldsymbol{\Gamma}\boldsymbol{\Gamma}',\\
\sigma_i^2 &= \sigma^2 \text{ (constant)}.
\end{aligned}$$

In the latent class model

$$\begin{aligned}
(\boldsymbol{\beta}_j,\sigma_j^2) &\in [(\boldsymbol{\beta}_1,\sigma_1^2), (\boldsymbol{\beta}_2,\sigma_2^2), \ldots, (\boldsymbol{\beta}_J,\sigma_J^2)],\\
\text{Prob}[\text{class}=j|\mathbf{z}_i] &= \pi_j(\mathbf{z}_i,\boldsymbol{\theta}_j),\ j = 1,\ldots,J.
\end{aligned}$$

The models apply naturally to panel data but can be used (somewhat less effectively) with cross sections as well. The mixed model is estimated by maximum simulated likelihood. The latent class model is estimated by maximum likelihood. The random parameters linear model is developed in Chapter E19. This chapter documents how to fit a latent class linear model.

E20.2 Latent Class Linear Regression Model

A linear regression model for a panel of data, $i = 1,...,N$, $t = 1,...,T_i$ is specified in terms of the density,

$$f(y_{it} \mid \mathbf{x}_{it}) = f(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it}) = \phi(i,t).$$

(We allow for the cross section case of $T_i = 1$.) For this special case of the linear regression model, we assume that the underlying distribution is normal with mean $\boldsymbol{\beta}'\mathbf{x}_{it}$ and variance σ^2. Henceforth, we use the term ‘group’ to indicate the T_i observations on respondent i in periods $t = 1,...,T_i$. Unobserved heterogeneity in the distribution of y_{it} is assumed to impact the density in the form of a random effect. The continuous distribution of the heterogeneity such as discussed in the preceding chapter is approximated by using a finite number of ‘points of support.’ The distribution is approximated by estimating the location of the support points and the mass (probability) in each interval. In implementation, it is convenient and useful to interpret this discrete approximation as producing a sorting of individuals (by heterogeneity) into J classes, $j = 1,...,J$. (Since this is an approximation, J is chosen by the analyst.)

Thus, we modify the model for a latent sorting of y_{it} into J 'classes' with a model which allows for heterogeneity as follows: The probability of observing y_{it} given that regime j applies is

$$\phi(i,t|j) = \phi(y_{it}|\, \mathbf{x}_{it}, j),$$

where the normal density is now specific to the group. The analyst does not observe directly which class, $j = 1,...,J$ generated observation $y_{it}|j$, and class membership must be estimated. Heckman and Singer (1984) suggest a simple form of the class variation in which only the constant term varies across the classes. This would produce the model

$$\phi(i,t|j) = \phi[y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta_j], \text{Prob[class} = j] = F_j$$

We formulate this approximation more generally as,

$$\phi(i,t|j) = \phi[y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}_j'\mathbf{x}_{it}], F_j = \exp(\theta_j) / \Sigma_j \exp(\theta_j), \text{ with } \theta_J = 0.$$

In this formulation, each group has its own parameter vector, $\boldsymbol{\beta}_j' = \boldsymbol{\beta} + \boldsymbol{\delta}_j$, though the variables that enter the mean are assumed to be the same. (We show how to modify this assumption in Section E20.4.) In sum, then, for this application, the model is

$$f(y_{it} \,|\, \text{class} = \text{j}) = \text{N}[\boldsymbol{\beta}_j'\mathbf{x}_{it}, \sigma_j^2], \text{Prob(class} = \text{j}) = F_j = \exp(\theta_j) / \Sigma_j \exp(\theta_j).$$

Thus, the within class model is the linear regression model with normally distributed disturbances. Thus far, it is assumed that the prior class probabilities are constants, π_j. In Section E20.5, we detail how to introduce covariates into the class probabilities.

E20.3 Command for Latent Class Regression

The estimation command for this model is

REGRESS ; Lhs = ...
; Rhs = independent variables
; LCM (for latent class model)
; Panel
; Pts = the number of classes $

As noted, this model can be (and often is) applied to cross section data. Thus, you may omit the **; Panel** in the command, in which case it is assumed that $T_i = 1$. The default number of support points is five. But, this is fairly high. You may set J to 2, 3, 4, 5, 6, 7, 8, or 9 with

; Pts = the value you wish

Other options and further details on the model appear in Chapter R25. The latent class model provides estimates of the J class member parameter vectors for the model and the class probabilities.

Estimates retained by this model include:

Matrices: *b* = full parameter vector, [$\boldsymbol{\beta}_1'$, $\boldsymbol{\beta}_2'$,... F_1,...,F_J]
varb = full covariance matrix
Note that *b* and *varb* involve $J \times (K+1)$ estimates.

Three additional matrices are created,

b_class = a $J \times K$ matrix with each row equal to the corresponding $\boldsymbol{\beta}_j$
class_pr = a $J \times 1$ vector containing the estimated class probabilities
beta_i = individual conditional (posterior) expectations of β_i

Scalars: *kreg* = number of variables in Rhs list
nreg = total number of observations used for estimation
logl = maximized value of the log likelihood function
exitcode = exit status of the estimation procedure.

Last Function: None

E20.4 Restricted Models

There are several interesting special cases of the latent class linear regression – these will be extended to latent class models generally in the development of other models. Restrictions can be imposed on the coefficients of the LC model, both within class and across classes. The **; Rst = list** specification is used for this purpose. The parameters of the LC linear regression model, in the order in which they appear in the program, are

$$\Theta = \beta_1,\sigma_1,\ \beta_2,\sigma_2,\ \ldots,\ \beta_J,\sigma_J,\ \theta_1,\ \theta_2,\ \ldots,\ \theta_J$$

Depending on the model, β_j may have 1, 2, up to K elements. Note that the variance parameter is σ_j, not σ_j^2. The last *J* parameters are the structural parameters in the class probabilities. There are *J* of these, though the last one equals zero. The list of items in **; Rst = list** provides either symbols or values for the elements in Θ. Equality restrictions are imposed by using the same name. Fixed values are imposed by placing the fixed value in the list. For an example, consider a three class model with four regressors, so that the command is

REGRESS ; LCM ; Lhs = y ; Rhs = one,x1,x2,x3,x4 ; Pts = 3 $

The unrestricted model would be specified (redundantly) by

; Rst = a1,b11,b12,b13,b14,sg1, a2,b21,b22,b23,b24,sg2, a3,b31,b32,b33,b34,sg3, t1,t2,t3.

(Note, we chose the symbols *aj* and *bjk* purely for convenience and clarity. You may use any symbols you like.) This **; Rst** specification does not impose any constraints. Suppose it were desired to force the coefficient on x4 to be the same in all three classes. The list is changed to

; Rst = a1,b11,b12,b13,b4,sg1, a2,b21,b22,b23,b4,sg2, a3,b31,b32,b33,b4,sg3, t1,t2,t3.

Note that *b*14, *b*24 and *b*34 have all been changed to *b*4. Since the name is the same in all three sets of symbols, this will impose the constraint that the parameter is equal in all three places. Second, suppose, in addition to the equality constraint on *bj*4, we wished to fix *b*11 at zero and *b*21 at one. We would use

; Rst = a1,0,b12,b13,b4,sg1, a2,1,b22,b23,b4,sg2, a3,b31,b32,b33,b4,sg3, t1,t2,t3.

You may impose any number of equality and fixed value constraints with this device. Note, however,

- Although you provide a place holder for σ_j, you should generally not constrain these parameters. (It is allowed by the specification, but it will likely lead to very poor results.)

- You must provide place holders for the θ parameters, but you should never constrain these. Note, as well that although the third will be constrained to equal zero, the program will do this. You should treat this parameter as unconstrained.

Heckman and Singer

Heckman and Singer's specification is obtained by forcing all classes to have the same coefficients save for the constant terms. By way of the preceding example, this is specified as follows:

; Rst = a1,b1,b2,b3,b4,sg, a2,b1,b2,b3,b4,sg, a3,b1,b2,b3,b4,sg, t1,t2,t3.

This produces a random effects regression in which the effect has a discrete distribution. The implied random effects model is

$$y_{it|j} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + \delta_j,\ j = 1,2,3$$

$$P(\delta = \delta_j) = \pi_j.$$

$$E[\delta] = 0.$$

More generally, the Heckman and Singer formulation is obtained by forcing all coefficients in the classes to be equal save for a class specific constant term.

Exclusions

There are cases in which the analyst believes a priori that different models apply to the different classes. We will examine a number of such cases in applications in later chapters. One of these cases relates to the prior information (belief) that certain variables do not appear in the model in certain classes. (Note that this implies that the classes are not completely latent.) This type of specification can be obtained by imposing zero restrictions. Zeros and other fixed values may be placed wherever it is desired in the list, though we emphasize once again, fixed value restrictions on the disturbance standard deviations generally produce undesirable results.

E20.5 Modeling Class Probabilities

The prior probabilities of class membership, π_1, π_2,…, π_J are estimated with the model parameters. In order to impose the constraints $\pi_j > 0$ and $\Sigma_j\pi_j = 1$, the probabilities are parameterized with a multinomial logit form,

$$\pi_j = \frac{\exp(\theta_j)}{\Sigma_{j=1}^J \exp(\theta_j)},\ \theta_J = 0.$$

(The constraint on the last θ is imposed because only J-1 parameters are needed to specify the J probabilities. The last probability is one minus the sum of the first J-1.)

The prior probabilities may be extended to depend on variables in the data set. For example, in a typical application, the prior probabilities are often made a function of demographics such as age or gender. The expanded model is

$$\pi_j(\mathbf{z}_i) = \frac{\exp(\boldsymbol{\theta}'_j\mathbf{z}_i)}{\Sigma_{j=1}^J \exp(\boldsymbol{\theta}'_j\mathbf{z}_i)},\ \boldsymbol{\theta}_J = \mathbf{0}.$$

Variables $\mathbf{z}_i$ are added to the model by specifying

; LCM = the list of variables (must not include one)

For example,

; LCM = age,sex

specifies a model in which age and sex enter the class probabilities. An application appears in Section E20.7.

E20.6 Posterior Class Probabilities and Predicting Class Membership

After estimation of the model parameters, a secondary exercise is estimation of the posterior probabilities,

$$\text{Prob}[\text{class}=j|\{(y_{it},\mathbf{x}_{it}),t=1,\ldots,T_i\},\mathbf{z}_i],$$

which we denote $P(j|i)$. To derive $P_j(j|i)$, use Bayes theorem as follows: The probability that individual is a member of class j given the information in the sample about them is denoted $P(j|i)$. The joint density of the class membership and the observed outcome is denoted $P(i,j)$. By definition,

$$\text{P}(j|i) = P(i,j)/P(i).$$

The joint density of the outcome and the class membership is the product of the conditional times the marginal, and the marginal has already been defined as the prior probability, π_j;

$$P(i,j) = P(i|j)\pi_j.$$

$P(i|j)$ is the density for individual i given they are in class j, which is the contribution of individual i to the likelihood function given class j, $f(i|j) = \Pi_t f(y_{it}|j)$. By definition, the marginal density is the sum of the joint densities, so that the unconditional density for individual i is

$$P(i) = \Sigma_j P(i,j) = \Sigma_j P(i|j)\pi_j.$$

Collecting terms, we find the posterior probabilities,

$$P(j\,|\,i) = \frac{\pi_j\left(\Pi_{t=1}^{T_i} f(y_{it}\,|\,j)\right)}{\Sigma_{j=1}^{J}\pi_j\left(\Pi_{t=1}^{T_i} f(y_{it}\,|\,j)\right)}.$$

As noted earlier, the prior probabilities may involve covariates in $\pi_j(\mathbf{z}_i)$. The marginal densities in the products are the normal densities with mean $\boldsymbol{\beta}_j'\mathbf{x}_{it}$ and standard deviations σ_j. Assembling all the parts, then,

$$P(j\,|\,i) = \frac{\pi_j(\mathbf{z}_i)\prod_{t=1}^{T_i}\frac{1}{\sigma_j}\phi\left(\frac{y_{it}-\boldsymbol{\beta}_j'\mathbf{x}_{it}}{\sigma_j}\right)}{\sum_{j=1}^{J}\pi_j(\mathbf{z}_i)\prod_{t=1}^{T_i}\frac{1}{\sigma_j}\phi\left(\frac{y_{it}-\boldsymbol{\beta}_j'\mathbf{x}_{it}}{\sigma_j}\right)}.$$

The posterior probabilities will embody the model estimates and the sample information about the individual. A natural next step is to use the posterior class probabilities to predict the class membership. We predict (albeit imperfectly) that individual i is a member of class j if $P(j|i) > P(m|i)$ for all other m – i.e., we predict the class with the highest posterior probability.

Posterior probabilities and the class predictions can be retained in the data set as follows: For the probabilities, it is necessary to create (or provide) a set of J existing variables, in a namelist, in the REGRESS command, using

; Classp = the namelist.

For an example, to extend the earlier example, we used

```
CREATE      ; p1 = 0 ; p2 = 0 ; p3 = 0 $
NAMELIST    ; cp = p1,p2,p3$
REGRESS     ; Lhs = yit
            ; Rhs = one,x1,x2,x3,x4
            ; LCM
            ; Pts = 3
            ; Parameters
            ; Pds = 6
            ; Classp = cp $
```

This produces new variables in the data area, as shown in Figure E20.1.

Figure E20.1 Estimated Class Probabilities

Note that the posterior probabilities will differ substantially from the priors. In the model estimated above, the prior probabilities are 0.323, 0.185 and 0.492. Second, note that the probabilities are repeated for each observation in the group in a panel.

Finally, you may request the class assignments to be saved as a variable by adding

; Group = variable name

to create the new variable. The variable will contain the index of the class with the largest posterior probability. The results in the last column in Figure E20.1 are obtained with

; Group = class

E20.7 Applications

We examine two applications. The first purely for illustration, considers the classic 'mixture of normals' application. The second applies the methods to a regression model using the panel data on dairy farm production that was used in Chapter E19 for the mixed regression model.

E20.7.1 Finite Mixture of Normals

The mixture of normals is simply a latent class application to the marginal distribution of a variable. We treat it here by treating the marginal normal distribution as a regression model in which there are no regressors, only a constant term. The first result below is the base case. The second specifies that the prior class probabilities depend on gender. The very large increase in the log likelihood suggests that gender is, indeed, relevant in the class probabilities.

E20.8 Technical Details and the EM Algorithm

Details on estimation of the latent class model are provided in Chapter E26. The estimates are computed by directly maximizing the log likelihood function. For the latent class linear regression model, the log likelihood is

$$\log L(\Theta) = \sum_{i=1}^{n} \log \left\{ \sum_{j=1}^{J} \frac{\exp(\theta_j' \mathbf{z}_i)}{\Sigma_{m=1}^{J} \exp(\theta_m' \mathbf{z}_i)} \prod_{t=1}^{T_i} \frac{1}{\sigma_j} \phi\left(\frac{y_{it} - \boldsymbol{\beta}_j' \mathbf{x}_{it}}{\sigma_j} \right) \right\}.$$

We note, the EM algorithm has gained some attention in the recent literature. The algorithm provides a method of maximizing the log likelihood via the following iteration:

Step 0. Enter with initial values of $\boldsymbol{\theta}_j$ and $(\boldsymbol{\beta}_j,\sigma_j)$.

Step 1. Compute new estimates of the posterior probabilities derived in Section E20.6. This provides a different n set of weights, $P(j|i)$ for each of the j classes.

Step 2. Using the weights, in each class separately, maximize the log likelihood function. For the linear regression model, this means compute weighted least squares estimates of β_j, followed by a weighted sum of squared residuals estimate of σ_j. This step will involve J such weighted least squares regressions to produce the set of J vectors $(\mathbf{b}_j,s_j)$. Note that given the weights that are constant within the groups, this regression pools the panel data.

Step 3. Return to Step 1 or exit if the estimates have stopped changing.

The EM algorithm, which is not used here, has advantages and disadvantages. In its favor, it is very stable; each step goes uphill. One disadvantage is that it usually takes many iterations – it is slow. In addition, unlike the direct MLE, the EM method does not produce an estimator of the covariance matrix. That must be obtained ex post, after estimation is completed. Contrary to impressions suggested elsewhere, EM is not a model; it is an algorithm. It does not produce different results from direct maximization of the log likelihood. For our purposes, a significant disadvantage is that the EM method does not allow the sort of restricted model construction developed in Section E20.4, for example, the Heckman and Singer model.

E21: Single Equation Instrumental Variables Estimation

E21.1 Introduction

This chapter will present several IV estimators for linear and nonlinear single equation regression models. The models considered are

$$g(y_i) = f(\mathbf{x}_i,\boldsymbol{\beta},\boldsymbol{\theta}) + \varepsilon_i$$

in which $g(\bullet)$ and $f(\bullet,\bullet)$ are continuous functions and ε is a disturbance with zero mean. The extension here is estimators that are consistent when $\text{Cov}(\mathbf{x},\varepsilon) \neq \mathbf{0}$, so that linear and nonlinear least squares will be inconsistent. This chapter is concerned with estimation of slope parameters, $\boldsymbol{\beta}$, ancillary parameters, $\boldsymbol{\theta}$, and σ^2, the variance of ε, in cases in which linear and nonlinear least squares are not useable because of the correlation between $\mathbf{x}$ and ε. The essential estimation method is instrumental variables in several forms.

E21.2 Two Stage Least Squares

The standard case is the linear equation with endogenous right hand side variables,

$$\begin{aligned} y_i &= \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, \\ \text{E}[\varepsilon_i|\mathbf{x}_i] &= g(\mathbf{x}_i) \neq \mathbf{0}, \\ \text{Var}[\varepsilon_i|\mathbf{x}_i] &= \sigma^2. \end{aligned}$$

The 2SLS, or IV estimator is based on a set of instruments, $\mathbf{z}_i$ which satisfy the two necessary conditions for an instrumental variable,

$$\begin{aligned} &\text{(orthogonality)} \quad \text{E}[\mathbf{z}_i\varepsilon_i] = \mathbf{0}, \\ &\text{(relevance)} \quad \text{E}[\mathbf{x}_i\mathrm{z}_i'] \neq \mathbf{0}. \end{aligned}$$

The 2SLS estimator is

$$\hat{\boldsymbol{\beta}} = \left(\hat{\mathbf{X}}'\hat{\mathbf{X}}\right)^{-1}\hat{\mathbf{X}}'\mathbf{y}$$

$$\hat{\mathbf{X}} = \mathbf{Z}\left(\mathbf{Z}'\mathbf{Z}\right)^{-1}\mathbf{Z}'\mathbf{X}$$

The name of the estimator derives from the underlying result that the estimator can be computed by (1) regressing $\mathbf{X}$ on $\mathbf{Z}$ column by column and computing predicted values then (2) regressing $\mathbf{y}$ on the predicted values of $\mathbf{X}$ rather than the actual. The estimator is an instrumental variable estimator in that

$$\hat{\boldsymbol{\beta}} = \left(\hat{\mathbf{X}}'\mathbf{X}\right)^{-1}\hat{\mathbf{X}}'\mathbf{y}$$

$$\hat{\mathbf{X}} = \mathbf{Z}\left(\mathbf{Z}'\mathbf{Z}\right)^{-1}\mathbf{Z}'\mathbf{X}$$

because of the idempotency of $\mathbf{P}_{\mathbf{Z}} = \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$; thus, $\hat{\mathbf{X}}$ is the set of instrumental variables. The method of instrumental variables is treated at length in standard texts such as Greene (2011) or Wooldridge (2010).

E21.2.1 Command

The essential command fitting linear models by instrumental variables is

2SLS ; Lhs = dependent variable
; Rhs = list of right hand side variables (all)
; Inst = list of all instrumental variables, including one $

The command for computing instrumental variables or two stage least squares estimates differs from that for ordinary least squares (**REGRESS**) in the list of instrumental variables. All options are the same as for the linear regression model – see Chapter E7 for details. This includes the specifications of **; AR1** disturbances, **; Plot** for residuals, etc. Chapters E7, E8, E10 and E11 give full details on these options. The list of instruments may include any variables existing in the data set.

HINT: If your equation (Rhs) includes a constant term, *one*, then you should also include *one* in the list of instrumental variables. Indeed, it might be the case that Inst should include *one* even if the Rhs does not. Note that the instrument list includes all exogenous variables that are in the Rhs list, plus the additional instrumental variables. The order condition for identification (and estimation here) requires that there be at least one instrumental variable in the Inst list for each endogenous variable in the Rhs list.

Computations use the standard results for two stage least squares. (See, e.g., Greene (2011).) There are no degrees of freedom corrections for variance estimators when this estimator is used. All results are asymptotic, and degrees of freedom corrections do not produce unbiased estimators in this context. Thus,

$$\hat{\sigma}^2 = \frac{1}{n}\sum_{i=1}^{n}\left(y_i - \hat{\boldsymbol{\beta}}'\mathbf{x}_i\right)^2 .$$

This is consistent with most published sources, but (curiously enough) inconsistent with most other commercially available computer programs. It will show up as a proportional difference in all estimated standard errors. If you would prefer that the degrees of freedom correction be made, add the specification

; Dfc

to your **2SLS** command. The estimator of the covariance matrix for the 2SLS estimator is

$$\text{Est.Var}\left(\hat{\boldsymbol{\beta}}\right) = \hat{\sigma}^2\,[\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X}]^{-1}.$$

The command builder is essentially the same as that for the linear regression with the addition of the instrumental variables list. It can be opened by selecting Model:Linear Models/2SLS.

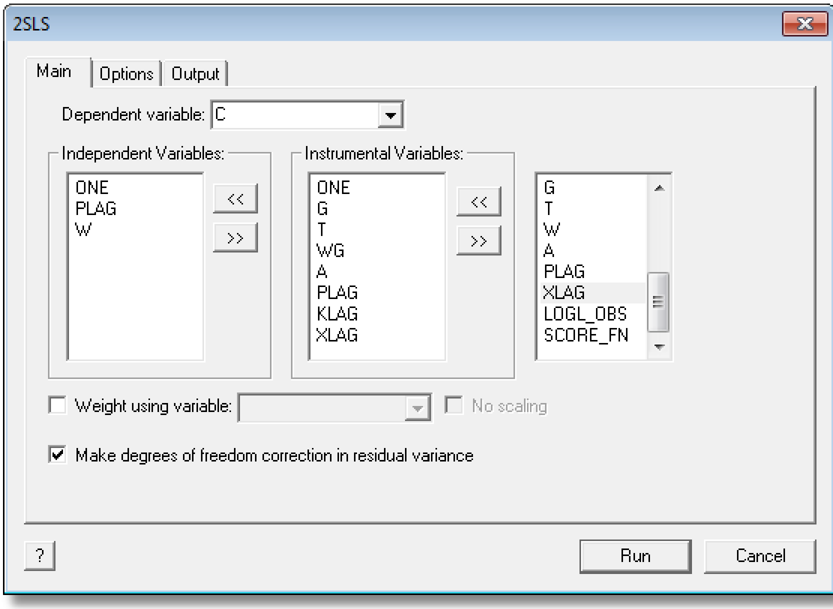

Figure E21.1 Command Builder for Two Stage Least Squares

E21.2.2 Model Output for the 2SLS Command

The output for the **2SLS** command is identical to that for **REGRESS**. The only indication that 2SLS, rather than OLS, was used in estimating the model will be a line at the top of the model results indicating that two stage least squares was used in the computations and a listing of the instrumental variables that will appear above the coefficient estimates. All retrievable results and methods for testing hypotheses are likewise identical.

E21.2.3 Robust Estimation of the 2SLS Covariance Matrix

The White and Newey-West robust estimators of the covariance matrix of the least squares estimator described in Sections E7.10.1 and E7.10.2 can also be obtained for 2SLS by requesting them in the same fashion. All necessary corrections for the use of the instrumental variables are made in the computation. The calculation is otherwise the same as described in Section E7.10. The only difference here is that some of the columns of **x** are replaced by fitted values in the calculation.

E21.2.4 Application

The data listed below are Klein's data for estimation of his 'Model I.' These are used for testing simultaneous equations estimators and for demonstrating the techniques in most textbooks (in spite of the relative antiquity of the data). The model that is estimated by 2SLS is

$$\begin{array}{llllllll}
\text{(Consumption)} & c_t & = \alpha_0 & + \alpha_1 p_t & + \alpha_2 p_{t\text{-}1} & + \alpha_3(wp_t + wg_t) & + \varepsilon_{1t}, \\
\text{(Investment)} & i_t & = \beta_0 & + \beta_1 p_t & + \beta_2 p_{t\text{-}1} & + \beta_3 k_{t\text{-}1} & + \varepsilon_{2t}, \\

E21.2.5 Specification Tests: Hausman and Wu

Two specification tests for exogeneity have been developed for the linear model. The Hausman test is based on a comparison of 2SLS to OLS. The model is specified as

$$y = \boldsymbol{\beta}_1'\mathbf{x}_1 + \boldsymbol{\beta}_2'\mathbf{x}_2 + \varepsilon$$

where $\mathbf{x}_2$ is K_2 variables. The question is whether the covariance of x_2 and ε is nonzero (that is, whether $\mathbf{x}_2$ is endogenous). Two competing estimators are **b**(ols) and **b**(2sls). The test is based on the difference, **d** = [**b**(2sls) - **b**(ols)]. Under the null hypothesis of exogeneity, plim **d** = **0**; under the alternative it is not. The Hausman (1978) test uses a Wald statistic to test the joint hypothesis that **d** equals zero. For the covariance matrix, the theorem in Hausman prescribes the difference in the two covariance matrices, **V**(2sls) - **V**(ols). A refinement needed to insure nonnegative definiteness of the matrix is to use instead of $\hat{\sigma}^2_{2sls}(\mathbf{X}'\mathbf{X})^{-1}$ instead of $s^2_{ols}(\mathbf{X}'\mathbf{X})^{-1}$ – this is a robust estimator of σ^2. The difference matrix then becomes $\hat{\sigma}^2\ [(\mathbf{X}'\mathbf{X})^{-1} - (\mathbf{X}'\mathbf{P_Z}\mathbf{X})^{-1}]$. A second complication is that this matrix is singular, so a generalized inverse matrix that uses only K_2 of the dimensions is employed.

The Hausman test can be constructed as follows:

```
? These three lines are specific to the application

NAMELIST   ; x = the Rhs variables in the model $
NAMELIST   ; z = the full set of instruments, including exogenous elements of X $
CREATE     ; y = the dependent variable $

? These remaining lines carry out the test.  They are generic and need not be changed.

2SLS       ; Quietly ; Lhs = y ; Rhs = x ; Inst = z $
MATRIX     ; vh = varb - ssqrd*<x'x> ; dh = b - <x'x>*x'y $
MATRIX     ; list ; hausman = dh'*ginv(vh)*dh $
```

The number of degrees of freedom for the Hausman test is the number of variables in $\mathbf{x}_2$.

Note the following about the Hausman test.

1. The specification is a joint test against the exogeneity of the variables that appear in the *x* list that are not in the *z* list.

2. Applying this test to individual variables in the lists is not a valid test of any hypothesis. It is not possible for one element of the OLS estimator (that associated with a particular variable) to be inconsistent while the others are consistent. If any of the variables in *x* are endogenous, the entire OLS estimator is inconsistent, not just specific elements. By this construction, one could carry out the Hausman test for $K_2 > 1$ variables by just using one of the elements of *dh*. But, this would not test a different hypothesis; it would just waste the information contained in the other elements of *dh*.

3. This test is not useable for nonlinear models. It is specifically proposed for the linear model with possibly endogenous right hand side variables.

We carried out the Hausman test for the consumption function in Klein's Model I. For the application, *x* is *cons*, *z* is *exog* and *y* is *c*. The result of the test is

```
HAUSMAN |             1
--------+--------------
       1|       7.45221
```

The critical chi squared for two degrees of freedom and 95% significance is 5.99. We conclude on the basis of the test that at least one of *p* and *w* are endogenous in the consumption function.

The second test is the Wu test (also attributed to Durbin and Hausman and reiterated in Davidson and MacKinnon (1993)). The Wu test is a simple variable addition test based on least squares. The test can be carried out by the following steps:

Step 1. For each possibly endogenous variable in the equation, compute the residuals from a regression of that variable on the full set of exogenous variables.

Step 2. Add the residuals to the least squares regression. The test is carried out by testing the joint hypothesis that the coefficients on the added residuals are zero.

Mechanically, there is a much simpler way to carry out this test. The relevant F statistic is computed as

$$\text{F}[K_2, n-K_1-K_2-K_2] = \frac{(ss_{ols} - ss_{augmented})/K_2}{ss_{augmented}/(n-K_1-K_2-K_2)},$$

where ss_{ols} is the sum of squares in the original least squares regression and $ss_{augmented}$ is the sum of squares in the least squares regression to which the K_z elements of **z** that are not contained in $\mathbf{x}_1$ are added to the equation. Note that the denominator degrees of freedom includes the additional K_2 not K_z – the test is whether the K_2 coefficients on the added residuals are zero. Since this is based on OLS regressions, the F statistic is exactly $1/K_2$ times the chi squared statistic that would result if a Wald statistic were used instead.

This test is automated. The command is

REGRESS ; Lhs = y variable ; Rhs = x variables
; Inst = z variables ; Wu test $

Include the full set of instruments in **z** – that includes $\mathbf{x}_1$ plus the additional instrumental variables that are not contained in $\mathbf{x}_1$. These K_Z variables are denoted $\mathbf{z}_2$. *LIMDEP* will sort out internally what variables are contained in $\mathbf{x}_1$, $\mathbf{x}_2$ and $\mathbf{z}_2$ (the part of **z** that is not in $\mathbf{x}_1$).

The following shows in detail how this would be applied to the consumption function.

REGRESS ; Lhs = c
; Rhs = one, p, plag, w
; Inst = one,g,t,wg,a,plag,klag,xlag
; Wu test $

In this setup, $\mathbf{x}_1$ = (*one,plag*), $\mathbf{x}_2$ = (*p,w*), $\mathbf{z}_2$ = (*g,t,wg,a,klag,xlag*). Applying this test to the consumption function set up earlier, we would use

REGRESS ; Lhs = c ; Rhs = cons ; Inst = Exog ; Wu test $

The results are as follows:

```
-----------------------------------------------------------------------------
Ordinary      least squares regression ............
LHS=C         Mean                    =      53.99524
              Standard deviation      =       6.86087
              No. of observations     =            21  Degrees of freedom

Total         Sum of Squares          =       941.430          20
              Standard error of e     =       1.02554
Fit           R-squared               =        .98101  R-bar squared =   .97766
--------+--------------------------------------------------------------------
        |                  Standard             Prob.      95% Confidence
       C|  Coefficient       Error        t    |t|>T*         Interval
--------+--------------------------------------------------------------------
Constant|    16.2366***     1.30270    12.46  .0000     13.6834   18.7898
       P|     .19293**       .09121     2.12  .0495      .01417    .37170
    PLAG|     .08988         .09065      .99  .3353     -.08778    .26755
       W|     .79622***      .03994    19.93  .0000      .71793    .87451
--------+--------------------------------------------------------------------
+-----------------------------------------------------------------------------+
| Wu test for exogeneity of variables in RHS that are not listed in   |
| INST, beginning with P        . F[ 2,     15] =      5.603. P value  |
| for this F statistic is  .0000. (If < .05, reject exogeneity.)      |
+-----------------------------------------------------------------------------+
```

Note that Wu and Hausman are not the same test. Wu is an F test while Hausman is a Wald test, and they are based on different sums of squared residuals. Thus, twice the Wu statistic in the preceding does not produce the Hausman statistic.

E21.3 Autocorrelation with a Lagged Dependent Variable

If you are using **2SLS** to estimate an equation with a lagged endogenous variable and autocorrelation, such as:

$$y_t = \boldsymbol{\beta}'\mathbf{x}_t + \gamma y_{t-1} + \varepsilon_t,$$
$$\varepsilon_t = \rho\varepsilon_{t-1} + u_t.$$

you can use Hatanaka's (1974) efficient estimator, which is asymptotically equivalent to maximum likelihood for normally distributed disturbances, u_t. The procedure is as follows:

Step 1. Use instrumental variables to estimate $[\boldsymbol{\beta},\gamma]$. Any consistent estimator will do. A suitable instrumental variable for the lagged value of y_t might be the lagged value of the prediction of y_t from a regression on $\mathbf{x}_t$ and $\mathbf{x}_{t-1}$.

Step 2. Using the consistent estimator in Step 1, estimate ρ consistently by the autocorrelation of the residuals,

$$e_t = y_t - \mathbf{b}_{IV}'\mathbf{x}_t - c_{IV}y_{t-1}.$$

That is, compute the residuals using actual values, not predictions.

Step 3. Now, use the Cochrane-Orcutt transformation to do GLS based on the original data, but add an additional regressor to the model, e_{t-1}. (The transformation is not applied to the lagged residual.)

Step 4. The efficient estimator of ρ is the original estimator plus the slope on the lagged residual in the regression at Step 3. The asymptotic covariance for this estimate is that provided for the slope in Step 3. I.e., the GLS regression in Step 3 provides the full set of covariances.

This procedure uses the **2SLS** command, not **REGRESS**. The command is

```
2SLS      ; Lhs = y ; Rhs = x ; Inst = full set of instruments
          ; AR1 ; Hatanaka $
```

To use the **2SLS** command builder, click the Autocorrelation button on the Options page to open a dialog box that offers Hatanaka's estimator as an option. (See Figure E21.3.)

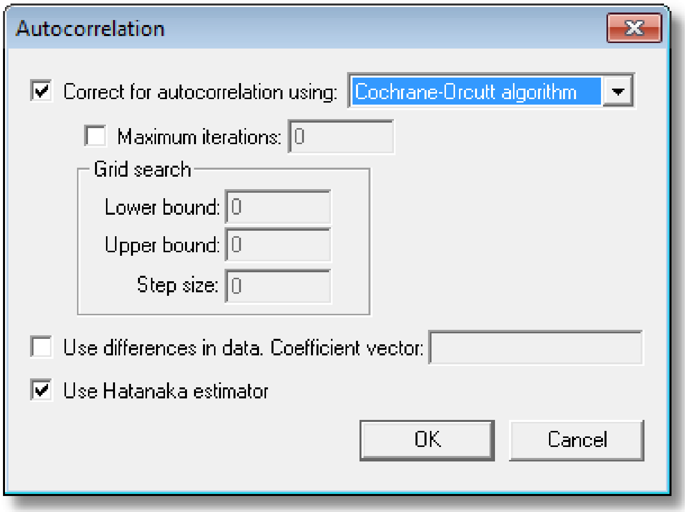

Figure E21.3 Command Builder for Hatanaka Estimator

Note that the set of instruments includes:

- all exogenous variables in *x* on the Rhs,
- *one* if it is included in the Rhs,
- additional instrumental variables.

For estimating a simultaneous equations model with first order autoregressive disturbances, the list of instruments should include the lagged values of all endogenous and exogenous variables in the reduced form. (See Pindyck and Rubinfeld (1991) and Greene (2011).)

For example, for a linear model that contains a constant, two regressors and a lagged dependent variable,

```
CREATE    ; ylag = y[-1]
          ; x1lag = x1[-1]
          ; x2lag = x2[-1] $
SAMPLE    ; 3 - ... end of sample $
2SLS      ; Lhs = y
          ; Rhs = one,x1,x2,ylag
          ; Inst = one,x1,x2,x1lag,x2lag
          ; AR1 ; Hatanaka $
```

Note that we have also begun the sample period for this estimator at observation 3. Since the lagged value of y_{t-1} is needed for the Cochrane-Orcutt transformation, two observations at the beginning of the sample will be incomplete.

E21.4 Alternatives to 2SLS

Two estimators (other than OLS) are proposed as alternatives to 2SLS. The limited information maximum likelihood (LIML) estimator based on assuming the disturbances are normally distributed may have better small sample properties than 2SLS and, unlike 2SLS, is invariant to normalization. The same result is obtained regardless of which variable in a structural equation is labeled the 'dependent' variable. Ackerberg and Devereux's (2009) JIVE estimator is a jackknife estimator that is intended to remedy some of the small sample bias of 2SLS. The 'improved,' IJIVE estimator, as suggested, is an extension.

E21.4.1 LIML

The LIML estimator is derived at length in numerous sources such as Davidson and MacKinnon (2004) and Greene (2011). We note only the mechanics of the computation here. In the single equation in a system, which we write in terms of the full n observations as

$$\mathbf{Y} = \mathbf{Y}\boldsymbol{\gamma} + \mathbf{X}^0\boldsymbol{\beta} + \boldsymbol{\varepsilon},$$

where the set of endogenous variables is $\mathbf{Y}$ and the 'included' exogenous variables are $\mathbf{X}^0$. (In the consumption function in our earlier example, $\mathbf{y}$ is $\mathbf{c}$, $\mathbf{Y}$ is $(\mathbf{p},\mathbf{w})$ and $\mathbf{X}^0$ is $(\mathbf{1},\mathbf{plag})$.). Consider the residuals in the linear regressions of $\mathbf{Y}^0 = (\mathbf{y},\mathbf{Y})$ on $\mathbf{X}^0$,

$$\mathbf{E}^0 = \mathbf{M}^0\mathbf{Y}^0 = (\mathbf{I} - \mathbf{X}^0(\mathbf{X}^{0\prime}\mathbf{X}^0)^{-1}\mathbf{X}^{0\prime})\mathbf{Y}^0.$$

(The residuals are computed column by column then arranged next to each other in $\mathbf{E}^0$.) Then, the covariance matrix estimator (mean squares and cross products) is

$$\mathbf{W}^0 = (1/n)\mathbf{E}^{0\prime}\mathbf{E}^0.$$

Now, repeat the computation using not $\mathbf{X}^0$, but $\mathbf{X}^1$, which is all of the exogenous variables in the system. (In the consumption function example, $\mathbf{X}^1$ would be (**one,g,t,wg,a,plag,klag,xlag**). Note that $\mathbf{X}^1$ contains $\mathbf{X}^0$ plus at least M additional variables, where M is the number of variables in $\mathbf{Y}$. (This number would be $M = 2$ in the consumption function example.) Then, based on this regression,

$$\mathbf{W}^1 = (1/n)\mathbf{E}^{1\prime}\mathbf{E}^1.$$

Define λ = the smallest characteristic root of $(\mathbf{W}^1)^{-1}\mathbf{W}^0$. (The root is real even though the product matrix is asymmetric and greater than one if $\mathbf{X}^1$ contains $\mathbf{X}^0$ plus more than M additional variables.) Now, $\mathbf{W}^0$ and $\mathbf{W}^1$ are partitioned into $w_{yy}{}^0$, $\mathbf{w}_{\mathbf{Y}y}{}^0$ and $\mathbf{W}_{\mathbf{YY}}{}^0$ based on $\mathbf{y}$ and $\mathbf{Y}$, and $\mathbf{W}^1$ likewise. The components of the LIML estimator are computed as

$$\hat{\gamma}_{LIML} = [\mathbf{W}^0_{\mathbf{YY}} - \lambda\mathbf{W}^1_{\mathbf{YY}}]^{-1}\left(\mathbf{w}^0_{\mathbf{Y}y} - \lambda\mathbf{w}^1_{\mathbf{Y}y}\right)$$

$$\hat{\beta}_{LIML} = \left(\mathbf{X}^{0\prime}\mathbf{X}^0\right)\mathbf{X}^{0\prime}\left(\mathbf{y} - \mathbf{Y}^0\hat{\gamma}_{LIML}\right)$$

The asymptotic covariance matrix is estimated using the same matrix as 2SLS save for the computation of the residuals based on the LIML estimator, and replacing 1.0 with λ in the upper left block of the matrix. (See equation (10-56) in Greene (2011, p. 329).)

By construction, $\lambda > 1$ if the number of instruments is greater than the number needed. (In the consumption function example, there are two endogenous variables and eight instrumental variables.) Thus, the system is overidentified by four variables. A test of the overidentifying restrictions is based on

$$c = n(\lambda - 1).$$

The limiting distribution of c is chi squared with degrees of freedom equal to the number of overidentifying restrictions – four in our example.

The LIML estimator is requested with

LIML ; Lhs = y, variables in $\mathbf{Y}^0$
; Rhs = variables in $\mathbf{X}^0$
; Inst = variables in X, including $\mathbf{X}^0$ and at least M more $

The command is otherwise the same as 2SLS in the options, such as residuals, fitted values and hypothesis tests. There is no 'robust' covariance matrix available, since the estimator is based on a specific assumption.

For the consumption function in our example, the estimator would be

LIML ; Lhs = c,p,w
; Rhs = one,plag
; Inst = one,g,t,wg,a,plag,klag,xlag $

The results with a comparison to 2SLS are as follows:

```

E21.4.2 JIVE Estimator

The jackknife instrumental variable estimator (JIVE), developed in Ackerberg and Devereux (2009) (based on Phillips and Hale (1977), Staiger and Stock (1997), Angrist, Imbens and Krueger (1999) and others, is a straightforward modification of 2SLS. Write the 2SLS estimator as a true IV estimator,

$$\mathbf{b}_{2SLS} = \left(\hat{\mathbf{X}}'\mathbf{X}\right)^{-1}\hat{\mathbf{X}}'\mathbf{y}$$

where $\mathbf{X} = (\mathbf{X}_1,\mathbf{X}_2)$ and $\mathbf{X}_2$ is the set of K_2 endogenous variables and $\hat{\mathbf{X}}$ is the set of predictions in the regressions of the columns of $\mathbf{X}$ on all of the instrumental variables, $\mathbf{Z}$, which includes $\mathbf{X}_1$ and some additional variables. In these regressions, the predictions are computed using the least squares coefficients in the linear regressions of each column of $\mathbf{X}$ on $\mathbf{Z}$. The matrix whose columns are the regression coefficients used for the predictions is $\mathbf{P} = (\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X}_2$. (The predictions of $\mathbf{X}_1$ are themselves, $\mathbf{X}_1$.) The JIVE estimator is constructed by using an observations specific set of least squares coefficients to compute each set of predictions. That is, for row i of $\hat{\mathbf{X}}$, to compute the predictions, instead of using the same matrix of coefficients, $\mathbf{P}$, we compute $\mathbf{P}_{(i)}$ by omitting observation *i* from the first step regression – hence the jackknife aspect of the computation. (Ackerberg and Devereux provide a 'one pass' computation that can obviate computing *n* regressions. However, with the sample sizes typically in use for this sort of computation, one would expect the time savings to be trivial.) They also propose an 'improved' estimator, IJIVE, that is obtained by first partialling out $\mathbf{X}_2$ from $\mathbf{X}_1$, $\mathbf{y}$, and the other instruments. (Davidson and MacKinnon (2006 and others) are convinced that this estimator has no moments and stridently argue against its use.)

The estimator is obtained as a modification of 2SLS;

2SLS ; … ; JIVE or IJIVE $

The other features and options of 2SLS remain as earlier. This computation only changes the computation of the coefficient vector and the covariance matrix.

The earlier example is extended here with

LIML ; Lhs = c, p,w ; Rhs = one,plag
; Inst = one,g,t,wg,a,plag,klag,xlag
; JIVE $

E21.5 Nonlinear IV Estimation

Estimation of the parameters of the nonlinear model $y_i = f(\mathbf{x}_i,\boldsymbol{\beta}) + \varepsilon_i$ can be done by nonlinear least squares. (See Amemiya (1987).) If either $\mathbf{x}_i$ is correlated with ε_i or the model is identified by the orthogonality conditions $E[\mathbf{z}_i\varepsilon_i] = \mathbf{0}$, where $\mathbf{z}$ is a set of instrumental variables, then an appropriate estimator is nonlinear instrumental variables.

The nonlinear IV estimator is requested with

NLSQ **; Lhs = the dependent variable**
; Fcn = function specification
; Labels = labels for parameters
; Start = starting values
; Inst = list of instrumental variables $

The command and other options are exactly as described in Chapter E14. The only new feature added here is the set of instrumental variables. This is also a form of GMM estimator. The GMM estimator is described in Section E21.6.

The nonlinear IV procedure involves a set of instrumental variables, $\mathbf{z}_1, \mathbf{z}_2,..., \mathbf{z}_K$. Suppose these are combined in an $n\times K$ matrix $\mathbf{Z}$. Let the vector $\boldsymbol{\varepsilon}$ denote the $n\times 1$ column of residuals $\varepsilon_i = y_i - f(\mathbf{x}_i,\boldsymbol{\beta})$. Then, the nonlinear least squares estimator described in Chapter E14 is found by solving the optimization problem

$$\text{Minimize wrt } \boldsymbol{\beta} \;\; \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\boldsymbol{\varepsilon}(\boldsymbol{\beta}).$$

For the nonlinear instrumental variables estimation problem (NLIV), the estimation criterion is

$$\text{Minimize wrt } \boldsymbol{\beta} \;\; \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\boldsymbol{\varepsilon}(\boldsymbol{\beta}).$$

This replicates two stage least squares for linear functions. You may also combine nonlinear two stage least squares with weighted least squares. In this case, we define a diagonal matrix $\mathbf{W}$ whose diagonal elements are the weights, w_i. The weighted nonlinear IV procedure (NLWIV) is

$$\text{Minimize wrt } \boldsymbol{\beta} \;\; \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{W}\mathbf{Z}(\mathbf{Z}'\mathbf{W}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{W}\boldsymbol{\varepsilon}(\boldsymbol{\beta}).$$

To request the nonlinear instrumental variables estimation method, you will use

; Inst = list of variables in Z

in the **NLSQ** command. Add

; Wts = weighting variable

for the nonlinear weighted instrumental variables estimator.

The number of instruments you provide must be at least as large as the number of parameters that you estimate. For purposes of this calculation, *LIMDEP* ignores the possibility of fixed parameters. Thus, if your model has six parameters, and you fix two of them, you must still provide at least six instrumental variables. Although this may seem like a restriction, it is trivial to work around it, simply by fixing the values in the function definition, and not defining them as parameters in the model formulation.

The asymptotic covariance matrix estimated for the nonlinear instrumental variables estimator is

$$\text{Est.Asy.Var.}[\mathbf{b}] = \hat{\sigma}^2 [\mathbf{G}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{G}]^{-1}$$

where the rows of **G** are the derivatives of $f(\mathbf{x}_i,\boldsymbol{\beta})$ with respect to $\boldsymbol{\beta}$ and

$$\hat{\sigma}^2 = (1/n)\Sigma_i[y_i - f(\boldsymbol{\beta},\mathbf{x}_i)]^2.$$

($1/n$ is replaced with $1/(n$ - #parameters) if you select **; Dfc**.)

To apply the method, we revisit the health care data used in several previous examples. The model is

$$\text{Income} = \exp(\beta_0 + \beta_1 educ + \beta_2 age + \beta_3 healthsatisfaction) + \varepsilon.$$

The model is estimated first by nonlinear least squares. It is believed that health satisfaction (*hsat*) is endogenous. Instruments to be used are marital status, public insurance, addon insurance and children in the household. (One might question the endogeneity of the insurance purchases.) The initial ordinary (nonlinear) least squares estimates are obtained first with

```
NLSQ        ; Lhs = hhninc
            ; Fcn = Exp(b0+b1*educ+b2*age+b3*hsat)
            ; Labels = b0,b1,b2,b3
            ; Start = -1,0,0,0  $
```

The nonlinear IV estimator is invoked with

```
NLSQ        ; Lhs = hhninc
            ; Fcn = Exp(b0+b1*educ+b2*age+b3*hsat)
            ; Labels = b0,b1,b2,b3
            ; Start = -1,0,0,0
            ; Inst = one,educ,age,married,public,addon,hhkids $
```

We are interested in the partial effects of education on income.

```
PARTIALS    ; Function = Exp(b0+b1*educ+b2*age+b3*hsat)
            ; Labels = b0,b1,b2,b3
            ; Effects: educ & age = 25(5)60 ; Plot $
```

Results are as follows:

```

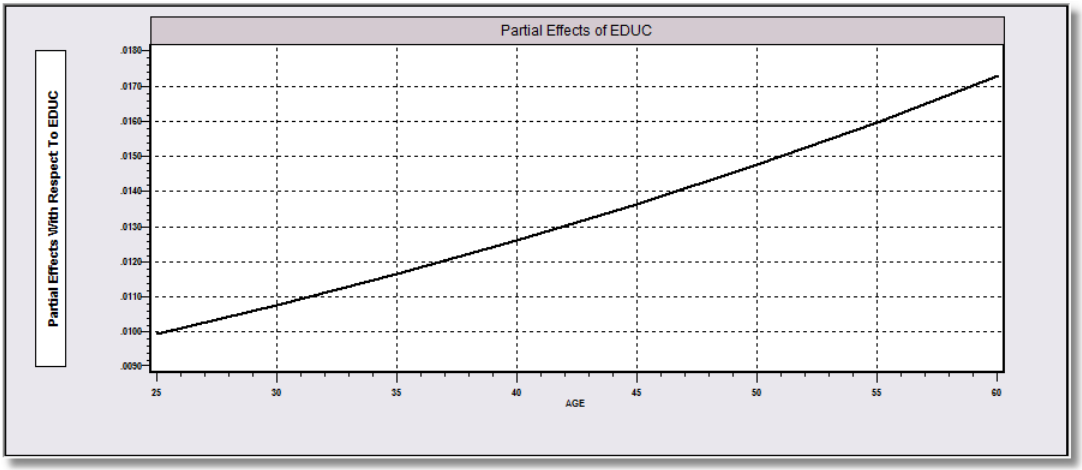

Figure E21.4 Partial Effects in Nonlinear Regression

E21.6 NLSQ/GMM Estimation

LIMDEP can be used for formal GMM estimation of econometric models. Although the methodology is common to all of them, we provide several approaches. The nonlinear least squares estimator presented in the preceding section is based on the least squares criterion

$$M(\boldsymbol{\beta}) = \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\boldsymbol{\varepsilon}(\boldsymbol{\beta})$$

which minimizes the simple sum of squares of a set of residuals. As noted earlier, different weighting schemes and the use of instrumental variables extends this to more general GMM interpretations. A somewhat more general estimator results from using instrumental variables, with

$$M(\boldsymbol{\beta}) = \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\boldsymbol{\varepsilon}(\boldsymbol{\beta}).$$

The yet more general estimation criterion,

$$M(\boldsymbol{\beta}) = \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\boldsymbol{\varepsilon}(\boldsymbol{\beta})$$

allows for instrumental variables and a weighting matrix, $\boldsymbol{\Omega}$. Depending on the choice of the weighting matrix, this will produce GMM estimators of various sorts. Finally, consider the less structured GMM criterion:

$$q = \bar{\mathbf{m}}'\Sigma\, \bar{\mathbf{m}}$$

where $$\bar{\mathbf{m}} = \frac{1}{n}\sum_{i=1}^{n}\mathbf{m}_i(\boldsymbol{\beta},\mathbf{x}_i)$$

based on a set of L ‘orthogonality conditions,’

$$E[\mathbf{m}_i(\boldsymbol{\beta},\mathbf{x}_i)] = \mathbf{0}.$$

E21.6.1 GMM Estimation of Single Equation Nonlinear Models

LIMDEP’s **NLSQ** command can be used for obtaining GMM estimates of the parameters in an equation. (Reference is made to Hansen (1982) or Pagan and Vella (1989) for details on the method.) The following will briefly present the relevant background, then give the command structure.

Let $\boldsymbol{\beta}$ be the vector of parameters being estimated. The estimation criterion is

$$M(\boldsymbol{\beta}) = \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\boldsymbol{\varepsilon}(\boldsymbol{\beta})$$

where $\boldsymbol{\varepsilon}(\boldsymbol{\beta})$ is the column of residuals in the form

$$\varepsilon_i(\boldsymbol{\beta}) = y_i - f(\mathbf{x}_i,\boldsymbol{\beta}),$$

and $\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z}$ is the expected value of

$$\mathbf{W} = (1/n)\Sigma_i\mathbf{z}_i\varepsilon_i^2\mathbf{z}_i'.$$

This matrix must be estimated using the starting values provided for the estimator. Each column of the matrix $\mathbf{Z}$ contains the observations derived from the orthogonality conditions

$$E[\varepsilon_i(\boldsymbol{\beta})z_{ik}] = 0$$

or, in a more compact vector notation,

$$E[\boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{z}_k] = 0 \text{ for the column, and}$$

$$E[\boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}] = \mathbf{0} \text{ for the entire set of variables.}$$

The matrix $\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z}$ is the ‘optimal weighting matrix,’ such that

$$\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z} = \mathrm{E}[(1/n)\mathbf{Z}'\boldsymbol{\varepsilon}(\boldsymbol{\beta})\boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}].$$

After estimation, the estimated asymptotic covariance matrix for this estimator is given by

$$\text{Est.Asy.Var.}[\mathbf{b}] = [\mathbf{G}'\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{G}]^{-1},$$

where each row of $\mathbf{G}$ is $\partial\varepsilon_i(\boldsymbol{\beta})/\partial\boldsymbol{\beta}'$.

Note in $(1/n)\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z}$ that if the disturbances in the model are uncorrelated and homoscedastic, the appropriate matrix to use would simply be $\mathbf{Z}'\mathbf{Z}$. The scalar, σ^2, would be irrelevant. In this instance, GMM estimation reduces simply to nonlinear instrumental variables. Thus, the criterion reduces precisely to that given earlier. But, if the disturbances are heteroscedastic and/or autocorrelated, then the nonscalar matrix $\boldsymbol{\Omega}$ presents a new difficulty. Consider, first, the case of heteroscedasticity. In this case, estimation of $\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z}$ is exactly analogous to computation of the White estimator for heteroscedastic disturbances in the classical regression case. (See Chapter E10.) Given a set of consistent estimates for the elements of $\mathbf{W}$, this is at least straightforward. But, if the disturbances are autocorrelated as well, then there are nonzero off diagonal elements in $\boldsymbol{\Omega}$. If a finite lag length can be specified (i.e., a truncated or finite moving average representation), then the Newey-West estimator (see Chapter E11) can be used, instead. *LIMDEP* uses this approach. The consistent estimator needed to compute the elements of $\mathbf{W}$ must be provided as the starting values for the estimator. One approach would be to estimate the model ignoring the heteroscedasticity and/or autocorrelation just to get the consistent (albeit, inefficient) estimates to use as starting values.

The foregoing is applied with the **NLSQ** command. The basic format would be:

```
NLSQ        ; Labels = list
            ; Start = set of values
            ; Fcn = expression for the residual y(i) - f(.)
            ; Inst = list of instruments, z(k) $
and         ; Pds = 0
```

to request the White estimator

or **; Pds = L** (e.g., **Pds = 5**)

to use the Newey-West estimator. Note that to request the heteroscedasticity estimator, **; Pds = 0** must be provided. This is not the default. The **; Pds** specification requests the computation of a nonscalar **W**; the number of periods (zero or positive) dictates how the computation is to be done. *Also, note that for GMM estimation, you are not providing the name of a Lhs variable.*

In the **NLSQ** command, for GMM estimation, you specify the residual, not just the function, and you do not name the Lhs variable. This is an important difference in the command. For example, to fit the function

$$f(x_i,\boldsymbol{\beta}) = \text{Exp}(\beta_1 + \beta_2 x)$$

use the following commands:

For nonlinear least squares:

; Lhs = y
; Fcn = Exp(b1 + b2*x)

For nonlinear instrumental variables:

; Lhs = y
; Fcn = Exp(b1 + b2 *x)
; Inst = the list of IVs

For GMM:

; Fcn = y - Exp(b1 + b2*x)
; Inst = the list of IVs
; Pds = 0 or the number

E21.6.2 Technical Note on Optimization

The **NLSQ** command maintains all the accounting information to ensure that the nonlinear optimization problem is analyzed as a regression. You can also compute nonlinear least squares coefficients using the **MINIMIZE** command. This will produce the same estimates, but it will not produce the same estimated asymptotic covariance matrix for the coefficients. **MINMIZE** simply accumulates the estimated Hessian of the criterion function, but does not scale it to account for the disturbance variance. Consider the example of a linear regression, using the Grunfeld data used earlier (Greene (2011, Table F10.4)):

```
REGRESS     ; Lhs = i ; Rhs = one,f,c $
NLSQ        ; Lhs = i ; Labels = b1,b2,b3 ; Start = 0,0,0 ;
            ; Fcn = b1+b2*f+b3*c
            ; Dfc $
MINIMIZE    ; Fcn = (i - b1 - b2*f - b3*c)^2
            ; Labels = b1,b2,b3 ; Start = 0,0,0 $
```

All three produce the same coefficients, and the first two produce the same asymptotic covariance matrix. In the first two cases, that covariance matrix is the conventional Est.Var[$\mathbf{b}_{LS}$] = $s^2(\mathbf{X}'\mathbf{X})^{-1}$. But, for the third estimation problem, the estimated asymptotic covariance matrix is computed as

$$\text{Est.Asy.Var}[\mathbf{b}_{MINIMIZE}] = \left[\sum_{i=1}^{n}(-2e_i\mathbf{x}_i)(-2e_i\mathbf{x}_i)'\right]^{-1}$$

This matrix is the BHHH estimator for the function specified. There is no definite relationship between the two matrices; it depends on the data. For the way it is specified above, in large samples, the covariance matrix for the **MINIMIZE** command would resemble $(1/4s^4)$ times that from **NLSQ**, but that should not be used as any kind of rule of thumb.

The essential point in this result is that the **MINIMIZE** command does not directly specify that the problem is a least squares problem or a regression model. From the point of view of the program, there is nothing to distinguish this from any other optimization problem. The **NLSQ** command requests not only a particular kind of optimization, but also a particular arrangement of and interpretation of the results.

E21.7 General Specifications of the GMM Estimator

A somewhat more general form of the GMM estimation procedure departs from a set of 'orthogonality conditions,'

$$E[m_{il}(\boldsymbol{\beta},\mathbf{x}_i)] = 0,\ l = 1,\ldots,L$$

where $\boldsymbol{\beta}$ is the vector of parameters to be estimated, $\mathbf{x}_i$ is a set of variables that is assumed to be in the set of information that defines the 'moment condition,' and $m_{il}(.)$ is one of L expectations that the model specifies to equal zero. The GMM estimator is obtained by finding the estimator, $\mathbf{b}$, that makes the empirical moment,

$$\overline{m}_l = \frac{1}{n}\sum_{i=1}^{n} m_{il}(\mathbf{b},\mathbf{x}_i)$$

mimic the population expectation as closely as possible.

Note the following about the GMM estimator:

- If there are L functionally independent conditions specified and $K = L$ parameters to be estimated, it will generally be possible to find a $\mathbf{b}$ that makes the empirical moments match the population expectations.

- If $L > K$, then it will generally not be possible to make the moments all equal zero, and instead, we will have to minimize some criterion which makes the moments 'close' to zero. This is the GMM estimation problem.

- If $L < K$, then there are more parameters to be estimated than there are moment conditions specified, and, since they are functionally independent, the L moment conditions will not be sufficient to identify the parameters, and estimation will be impossible.

E21.7.1 GMM Estimation

Collect the L moment specifications in the column vector

$$\overline{\mathbf{m}} = \frac{1}{n}\sum_{i=1}^{n}\mathbf{m}_i(\boldsymbol{\beta},\mathbf{x}_i)$$

The GMM estimator is the minimum distance estimator which minimizes the quadratic form

$$q = \overline{\mathbf{m}}'\ \boldsymbol{\Sigma}\ \overline{\mathbf{m}}$$

for some choice of positive definite matrix $\boldsymbol{\Sigma}$. Different choices of $\boldsymbol{\Sigma}$ will produce different estimators. At this point, we turn to formulating the command for the GMM estimator. A brief application will be shown next, then the remaining details of using the estimator will be given. Some technical details will follow.

The essential command structure for the GMM estimator is

GMME **; Fn1** = definition of the first moment condition
; Fn2 = definition of the second moment condition
; ... up to 50 orthogonality conditions
; Labels = the symbols used for the parameters,
; Start = starting values for the optimization **$**

This basic command – note that **Σ** is not specified, requests minimization of the simple sum of squares. The default specification, therefore, is **Σ** = **I**. The number of parameters may not exceed the number of functions. The function definitions can make use of all the tools discussed earlier for specifying nonlinear regressions. They may also specify instrumental variables, as shown in the examples below.

Example 1:

Suppose $y_1...,y_n$ are a sample of n independent observations from the gamma distribution,

$$f(y) = \frac{\lambda^P}{\Gamma(P)} e^{-\lambda y} y^{P-1}, \; y \geq 0, \; \lambda, P > 0.$$

Then, the following expectations hold

$$E[y] = P/\lambda,$$

$$E[y^2] = P(P+1)/\lambda^2,$$

$$E[1/y] = \lambda/(P\text{-}1), \; P > 1,$$

$$E[\log y] = \Psi(P) - \log\lambda,$$

where $\Psi(P)$ is the Psi function, $d\log\Gamma(P)/dP$. Any two moments could be used for estimation of the parameters. To use the two which, it turns out, define the maximum likelihood estimator, consider the first and the fourth. The command would be

GMME ; Fn1 = y - p/lambda
; Fn2 = Log(y) - Psi(p) + Log(lambda)
; Start = ... the starting values
; Labels = p,lambda $

Example 2: (From Ruud (2000)

Hansen and Singleton’s classic (1982) paper on consumption and asset pricing suggests the moment equations

$$E\left[z_{tj} \left\{ \left(\frac{1+r_t}{1+\delta} \right) \left(\frac{C_t}{C_{t-1}} \right)^{\gamma-1} - 1 \right\} \middle| t-1 \right] = 0$$

for a set of instrumental variables z_{tj} where t indexes periods, C_t is consumption, r_t is return, and δ and γ are the parameters to be estimated. Ruud suggests using the instrumental variables obtained by differentiating the function in brackets with respect to 1/(1+δ) and γ, which produces,

$$z_{t1} = (1+r_{t-1})\left(\frac{C_{t-1}}{C_{t-2}}\right)^{\gamma-1} \text{ and } z_{t2} = z_{t1} \times \log\left(\frac{C_{t-1}}{C_{t-2}}\right)$$

We could set this up for estimation as follows:

```
SAMPLE    ; 1 - whatever is appropriate $
CREATE    ; ct1 = c / c[-1]
          ; lagct1 = cc1[-1]
          ; If(_obsno > 2) loglag = Log(lagct1)
          ; r1 = 1+r
          ; lagr1 = r1[-1] $
SAMPLE    ; 3 - whatever is appropriate
GMME      ; Labels = delta,gamma
          ; Start = 0,0
          ; Fn1 = (r/(1+delta) * ct1^(gamma-1) - 1) * lagr1 * ctl^(gamma-1)
          ; Fn2 = (r/(1+delta) * ct1^(gamma-1) - 1) * lagr1 * ctl^(gamma-1) * loglag $
```

We note, this can be made simpler to specify and to estimate by slightly reparameterizing the function. Let θ = 1/(1+δ) and τ = γ - 1. Making the substitutions, we would obtain the same results with

```
GMME      ; Labels = delta,gamma
          ; Start = 0,0
          ; Fn1 = (r1 * theta * ct1^tau - 1) * lagr1 * ctl^tau
          ; Fn2 = (r1 * theta * ct1^tau - 1) * lagr1 * ctl^tau * loglag $
WALD      ; Fn1 = 1/theta - 1
          ; Fn2 = tau + 1  $  (We do this to see our original parameters.)
```

E21.7.2 The Weighting Matrix

The GMM estimator defined above is consistent regardless of what positive definite matrix **Σ** is used in the minimization. (Indeed, if the problem is 'exactly identified,' that is, if there are the same number of equations as parameters), then, as has been widely documented elsewhere, the identical solution will be obtained for all matrices **Σ**. However, in terms of the efficiency of the estimator, not all choices are the same – in this discussion, we now consider only 'overidentified' problems, in which there are more equations than parameters. You may specify any matrix you like to be used in the optimization by adding

; Sigma = the name of the matrix

to the command. The name given must be that of a positive definite matrix with number of rows and columns equal to the number of moment equations.

E21.7.3 The Optimal Weighting Matrix

As noted, you may specify any matrix you wish for the weighting matrix in the criterion function. For GMM estimation, the 'optimal' weighting matrix is

$$\mathbf{\Sigma^*} = \{\mathrm{Var}[\bar{\mathbf{m}}]\}^{-1}$$

This matrix can be estimated if one has in hand any consistent estimator of the model parameters. Thus, let **b** be that estimator. Then, the estimator would be

$$\mathbf{S}^* = (1/n)(1/n)\sum_{i=1}^{n}\mathbf{m}_i(\mathbf{b},\mathbf{x}_i)\mathbf{m}_i(\mathbf{b},\mathbf{x}_i)'$$

A natural way to proceed, then, would be to use two steps:

Step 1. Use the default **Σ** = **I** to obtain the initial consistent estimates of the parameters.

Step 2. After computing **S***, redo the estimation while specifying **Σ** to be the inverse of this estimate.

When you use the **GMME** command, *LIMDEP* automatically saves **S*** for you as a matrix named *sigma*. So, to do the two steps, you would proceed as follows: The first step in GMM obtains consistent estimates. The weighting matrix is **I**.

```
GMME     ; Fn1 = definition of the first moment condition
         ; Fn2 = definition of the second moment condition
         ; ... up to 50 orthogonality conditions
         ; Labels = the symbols used for the parameters,
         ; Start = starting values for the optimization  $
```

Then, compute optimal weighting matrix as inverse of covariance matrix of moments

```
MATRIX   ; optimalw = <sigma> $
```

The second step has the same estimation problem, now with the optimal weighting matrix.

```
GMME     ; Fn1 = definition of the first moment condition
         ; Fn2 = definition of the second moment condition
         ; ... up to 50 orthogonality conditions
         ; Labels = the symbols used for the parameters,
         ; Start = starting values for the optimization
         ; Sigma = optimalw $
```

E21.7.4 Other Options

GMME is an optimization command that is largely the same as **NLSQ** and **MINIMIZE**. All other options that are available for the nonlinear optimization procedures, including output display and convergence are useable here as well. Moreover, the full range of specification options are available for defining the moment equations; that is, all functions, using quadrature, linear, bilinear, and quadratic forms, use of namelists, and so on, may all be used as they are in other optimization problems.

E21.7.5 Application

The following is Example 1 suggested earlier. It is based on 20 observations on a random variable '*y*' to which we fit a gamma distribution with parameters λ and P. (See Example 13.5 in Greene (2011).) The data are

$$\mathbf{y}' = 20.5, 31.5, 47.7, 26.2, 44.0, 8.28, 30.8, 17.2, 19.9, 9.96,\\ 55.8, 25.2, 29.0, 85.5, 15.1, 28.5, 21.4, 17.7, 6.42, 84.9$$

We first obtain the maximum likelihood estimates by maximizing the log likelihood function directly:

```
MAXIMIZE    ; Fcn = p*Log(l) - Lgm(p) - l*y + (p-1)*Log(y)
            ; Labels = l,p
            ; Start = .1,2 $
```

The GMM estimator based on the first and fourth moments will replicate the maximum likelihood estimator.

```
GMME        ; Labels =  l,p
            ; Start = .1,2
            ; Fn1 =  p/l - y  ? (changed sign of this for convenience.)
            ; Fn2 =  Log(y) - Psi(p) + Log(l) $
```

Note, however, that the asymptotic covariance matrix will differ – a finite sample difference – because of the different formulas used to do the computations. It seems useful to pursue that difference here, as we can derive the results in full detail for this simple problem. We use the BHHH estimator for the asymptotic covariance matrix for the MLE. For the gamma model above,

$$\partial \log L/\partial \lambda = \Sigma_i (P/\lambda - y)$$

$$\partial \log L/\partial P = \Sigma_i (\log\lambda - \Psi(P) + \log y)$$

Note that the first order conditions for the MLE are $n\bar{\mathbf{m}} = \mathbf{0}$. Let $\mathbf{M}$ be the 20×2 matrix whose ith row is the derivative shown above for the ith observation. Then, the estimator of the asymptotic covariance matrix for the MLE is

$$\text{Est.Asy.Var[MLE]} = (\mathbf{M}'\mathbf{M})^{-1}.$$

For the GMM estimator, $\mathbf{\Sigma} = \mathbf{I}$ while $\mathbf{G}$ turns out to be a sum of constants, so the n disappears;

$$\mathbf{G} = \begin{bmatrix} -P/\lambda^2 & 1/\lambda \\ 1/\lambda & -\Psi'(P) \end{bmatrix}$$

Inserting these in the formula for the asymptotic covariance matrix of the GMM estimator, we obtain after canceling

$$\text{Est.Asy.Var}[GMM] = (\mathbf{G}'\mathbf{G})^{-1}\mathbf{G}'\mathbf{M}'\mathbf{M}\mathbf{G}(\mathbf{G}'\mathbf{G})^{-1}$$

As can be seen, this differs from the formula for the MLE. Since $\mathbf{G}'\mathbf{G}$ and $(1/n)\mathbf{M}'\mathbf{M}$ converge to the same matrix, we see that the difference is due to finite sample variation.

Finally, we obtain the full GMM estimator, using all four moment equations, and two steps to obtain the efficient estimator at the second step.

This is the maximum likelihood estimator.

E21.7.6 Technical Details for the GMM Estimator

The underlying theory for the GMM estimator is well documented in the current literature, including the current textbooks such as Greene (2011), Ruud (2000), and Hayashi (2000), so it will be omitted here, and only final results will be shown.

The estimation criterion used is

$$q = \frac{1}{2}\,\bar{\mathbf{m}}'\boldsymbol{\Sigma}\bar{\mathbf{m}}$$

(The 1/2 is purely for convenience - it allows the 2 to disappear from the derivatives.)

NOTE: The output displayed by the program reports 2q, not q. That is, your final results will report the value of the quadratic form, not one half times it.

The first order conditions for minimizing q are

$$\frac{\partial q}{\partial \boldsymbol{\beta}} = \mathbf{G}' \boldsymbol{\Sigma} \, \bar{\mathbf{m}} = \mathbf{0},$$

where $$\mathbf{G} = \frac{\partial \bar{\mathbf{m}}}{\partial \boldsymbol{\beta}'}$$

There are L equations and K parameters and $L \geq K$. Thus, $\mathbf{G}$ is an $L \times K$ matrix of partial derivatives. (Note, as well, that $\mathbf{G}$ is a sample mean.) If there are K moment equations used to identify the K parameters, then assuming that $\boldsymbol{\Sigma}$ is positive definite and that the moment equations are functionally independent so that $\mathbf{G}$ has an inverse, then we can premultiply the first order condition by $(\mathbf{G}' \boldsymbol{\Sigma})^{-1}$ and obtain the simpler necessary condition, $\bar{\mathbf{m}} = \mathbf{0}$. The solution to this is independent of $\boldsymbol{\Sigma}$, which establishes the earlier claim that $\boldsymbol{\Sigma}$ is irrelevant to the solution to an exactly identified problem.

The asymptotic covariance matrix is computed using the estimated parameters, and

$$\text{Est.Var}[\mathbf{b}] = [\mathbf{G}' \boldsymbol{\Sigma} \mathbf{G}]^{-1} \mathbf{G}' \boldsymbol{\Sigma} \mathbf{S}^* \boldsymbol{\Sigma} \mathbf{G} [\mathbf{G}' \boldsymbol{\Sigma} \mathbf{G}]^{-1}$$

where $\mathbf{S}^*$ was defined earlier. If you have specified the optimal weighting matrix, $\boldsymbol{\Sigma} = (\mathbf{S}^*)^{-1}$, then the estimated variance reduces to the familiar result,

$$\text{Est.Var}[\mathbf{b}] = [\mathbf{G}' (\mathbf{S}^*)^{-1} \mathbf{G}]^{-1}$$

If the model is exactly identified, then q is minimized at zero. (See the example above.) If not, then q will be positive. The theoretical result that $2q$ will have a limiting chi squared distribution with degrees of freedom equal to the number of overidentifying restrictions (equations minus parameters) can be used to test restrictions in this framework. (The multiplier, 2, appears because in our formulation of the problem, we initially divided by 2.) For two nested models, with $q0$ being the unrestricted one and $q1$ embodying the restrictions, $2(q1 - q0)$ can be used to test the restrictions – refer this statistic to the chi squared table with degrees of freedom equal to the number of restrictions.

E22: 2SLS for Panel Data

E22.1 Introduction

This chapter will present estimation of linear models for panel data by two stage least squares and instrumental variables. It combines the results in Chapters E16-18 (panel data models) and E21 (instrumental variables estimation).

E22.2 Application

The data used in the application below were analyzed in Cornwell and Rupert (1988). (See Baltagi (2005), page 122 for further analysis.) Unfortunately, the data are not available at the archive site for the journal. They were downloaded from the website for Baltagi's text, http://www.wiley.com/legacy/wileychi/baltagi/supp/WAGES.xls. These data are a microeconomic panel data set of observations on 595 individuals for seven years. Variables in the data set are:

exp	=	work experience
wks	=	weeks worked
occ	=	occupation, 1 if blue collar
ind	=	1 if manufacturing industry
south	=	1 if resides in south
smsa	=	1 if resides in a city (SMSA)
ms	=	1 if married
fem	=	1 if female
union	=	1 if wage set by union contract
ed	=	years of education
blk	=	1 if individual is black
lwage	=	log of wage

The model estimated below is

$$\log wks_{it} = \beta_1 + \beta_2 lwage_{it} + \beta_3 occ_{it} + \beta_4 fem_{it} + \beta_5 ed_{it} + \varepsilon_{it} + u_i$$

The instrumental variables used for the *lwage* variable are *union* membership and *south*, both dummy variables.

E22.3 2SLS Estimation with Fixed Effects

A basic estimator for a fixed effects model with one endogenous variable on the Rhs is obtained as follows:

```
SETPANEL    ; Group = id variable ; Pds = count variable to create $
REGRESS     ; Lhs = endogenous variable
            ; Rhs = all instruments
            ; Panel
            ; Keep = fittedy
            ; Output = 5 $
REGRESS     ; Lhs = dependent variable
            ; Rhs = endogenous variable, other variables
            ; Panel
            ; Inst = fittedy $
```

The list of instrumental variables includes only the predicted value for the one variable for which instruments are needed. The command can be extended to models with more than one endogenous variable on the right hand side, as well by producing a fitted value for each one, including the more than one endogenous variables at the beginning of the Rhs list, and including the corresponding list of fitted values in the Inst list. Note, the Rhs list should not include *one*.

The following computes the 2SLS estimates for the *logwks* equation in the application

```
CREATE      ; i = Trn(7,0) $
SETPANEL    ; Group = i ; Pds = ti $
REGRESS     ; Lhs = lwage
            ; Rhs = one,occ,fem,ed,union,south
            ; Panel
            ; Keep = fittedy
            ; Output = 5 $
REGRESS     ; Lhs = logwks
            ; Rhs = lwage, occ,fem,ed
            ; Panel
            ; Inst = fittedy $
```

```

E22.4 IV Estimators for Panel Data

Two stage least squares for panel data estimators is extended to include random effects. In the preceding section, it is shown how you may include predicted values of the regressors in the right hand side of the equation. The estimator then adjusts the computation of variance estimators for the presence of the fitted value. The extension described here adds a full two stage least squares treatment for other panel data models. The essential model is

$$y_{it} = \alpha_i + \boldsymbol{\beta_1}'\mathbf{x}_{1,it} + \boldsymbol{\beta_2}'\mathbf{x}_{2,it} + \varepsilon_{it}.$$

In the different specifications, α_i may be a fixed effect, a random effect, or unspecified. (The chosen estimator is robust to either.) Variables in $\mathbf{x}_{2,it}$ are assumed to be correlated with ε_{it}. A set of instrumental variables, $\mathbf{z}_{it}$ is provided. Five estimators are supported: conventional two stage least squares, fixed effects, first differences, random effects and group means. The estimator is the linear estimator for these panel data settings, using instrumental variables rather than OLS, GLS, or FGLS. Let $\mathbf{X}_i$ denote the K_1+K_2 columns in the structural variables, and let $\mathbf{Z}_i$ denote the K_1+K_z instrumental variables – note, presumably, some of the variables in $\mathbf{Z}_i$ are those in $\mathbf{x}_{1,it}$ and there must be at least K_2 additional instrumental variables in $\mathbf{Z}_i$ so that the model is identified. The matrices have T_i rows or observations. Then, the various estimators of $\boldsymbol{\beta} = (\boldsymbol{\beta}_1{}',\boldsymbol{\beta}_2{}')'$ are

Two Stage Least Squares (2SLS)

$$\hat{\boldsymbol{\beta}}_{2S} = \left[\sum_{i=1}^{N} \hat{\mathbf{X}}_i{}'\mathbf{X}_i\right]^{-1} \left[\sum_{i=1}^{N} \hat{\mathbf{X}}_i{}'\mathbf{y}_i\right]$$

where $\hat{\mathbf{X}}_i = \mathbf{Z}_i(\mathbf{Z}_i{}'\mathbf{Z}_i)^{-1}\mathbf{Z}_i{}'\mathbf{X}$

Fixed Effects (FE)

$$\hat{\boldsymbol{\beta}}_{FE} = \left[\sum_{i=1}^{N} \mathbf{Z}_i' \mathbf{M}_i^0 \mathbf{X}_i\right]^{-1} \left[\sum_{i=1}^{N} \mathbf{Z}_i' \mathbf{M}_i^0 \mathbf{y}_i\right]$$

where $\mathbf{M}_i^0$ is the $T_i \times T_i$ matrix that creates deviations from means.

First Differences (FD)

$$\hat{\boldsymbol{\beta}}_{FD} = \left[\sum_{i=1}^{N} (\mathbf{Z}_i' \mathbf{D}_i')(\mathbf{D}_i\mathbf{X}_i)\right]^{-1} \left[\sum_{i=1}^{N} (\mathbf{Z}_i' \mathbf{D}_i')(\mathbf{D}_i\mathbf{y}_i)\right]$$

where $\mathbf{D}_i$ is the $(T_i\text{-}1) \times T_i$ matrix that creates first differences. The first observation is lost.

Random Effects (RE)

$$\hat{\boldsymbol{\beta}}_{RE} = \left[\sum_{i=1}^{N} \mathbf{Z}_i' \hat{\boldsymbol{\Omega}}_i^{-1} \mathbf{X}_i\right]^{-1} \left[\sum_{i=1}^{N} \mathbf{Z}_i' \hat{\boldsymbol{\Omega}}_i^{-1} \mathbf{y}_i\right]$$

where $\boldsymbol{\Omega}_i^{-1}$ is the $T_i \times T_i$ matrix that creates partial deviations from means for the two step FGLS estimator. The variance components are computed using the simple two stage least squares estimator and the fixed effects estimator.

Group Means (MEANS)

$$\hat{\boldsymbol{\beta}}_{MEANS} = \left[\sum_{i=1}^{N} (\mathbf{Z}_i' \mathbf{a}_i')(\mathbf{a}_i\mathbf{X}_i)\right]^{-1} \left[\sum_{i=1}^{N} (\mathbf{Z}_i' \mathbf{a}_i')(\mathbf{a}_i\mathbf{y}_i)\right]$$

where $\mathbf{a}_i$ is a $1 \times T_i$ vector with all elements equal to $1/T_i$; it creates a group mean vector.

Some of these estimators (2SLS, RE, MEANS) are inconsistent under the fixed effects assumption. All are consistent under the random effects assumption, but some (2SLS, FE) are inefficient. The fixed effects and first difference estimators are always consistent. Also, the treatment of the constant term differs from one to the next. The estimator will sort this out, as can be seen in the example below.

Commands

The command for this estimator is

2SLS ; Lhs = dependent variable
; Rhs = set of independent variables
; Inst = full list of instruments

plus, for any of the panel data estimators,

; Pds = the usual panel data setup, balanced or not
; Panel

and exactly one of the following

; Fixed Effects
; Random Effects
; Differences to use first differences
; Means to use group means $

Options **; Keep**, **; Res** and **; Covariance Matrix** operate as usual. With **; Fixed Effects**, **; Par** saves the *alphafe* matrix containing the estimated constant terms. If the model contains time invariant variables, as in the example below, the fixed effects estimator uses generalized inverses. This will be noted in the results. But don't expect good results.

We fit the model by conventional 2SLS and then using the four estimators detailed above.

```
2SLS    ; Lhs = logwks
        ; Rhs = one,lwage,occ,fem,ed
        ; Inst = one,occ,fem,south,union,ed $
2SLS    ; Lhs = logwks
        ; Rhs = one,lwage,occ,fem,ed
        ; Inst = one,occ,fem,south,union,ed
        ; Panel ; Fixed effects $
2SLS    ; Lhs = logwks
        ; Rhs = one,lwage,occ,fem,ed
        ; Inst = one,occ,fem,south,union,ed
        ; Panel ; Random Effects $
2SLS    ; Lhs = logwks
        ; Rhs = one,lwage,occ,fem,ed
        ; Inst = one,occ,fem,south,union,ed
        ; Panel ; Differences $
2SLS    ; Lhs = logwks
        ; Rhs = one,lwage,occ,fem,ed
        ; Inst = one,occ,fem,south,union,ed
        ; Panel ; Means $
```

(Some superfluous results and results that are repeated in the outputs are omitted.)

E23: Hausman-Taylor and Arellano-Bond Estimators

E23.1 Introduction

This chapter will detail estimation of several linear models for panel data. The essential structure for most of them is an 'effects' model,

$$y_{it} = \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}$$

in which variation across groups (individuals) or time is captured in simple shifts of the regression function – i.e., changes in the intercepts. These models are the *fixed effects* (FE) and *random effects* (RE) models. Several variations on this structure can be analyzed with this estimator, including both one and two factor models, models of autocorrelation, and simultaneous equations models. This chapter also presents some major extensions including multifactor random effects models, the Hausman and Taylor estimator for random effects and the Arellano, Bond and Bover estimator for dynamic panel data models.

E23.2 The Hausman and Taylor Estimator for Random Effects

Hausman and Taylor's (1981) estimator for the random effects model is provided to overcome one of the major shortcomings of the REM, the possible correlation between the independent variables and the random effects. The following will sketch the technical aspects; the user is referred to their paper for full details.

The random effects model is formulated with the possibility that there may be time invariant independent variables. We thus write it in this form:

$$y_{it} = \boldsymbol{\beta}_1'\mathbf{x}_{1it} + \boldsymbol{\beta}_2'\mathbf{x}_{2it} + \boldsymbol{\gamma}_1'\mathbf{f}_{1i} + \boldsymbol{\gamma}_2'\mathbf{f}_{2i} + \varepsilon_{it} + u_i, \text{ where } \boldsymbol{\beta} = (\boldsymbol{\beta}_1',\boldsymbol{\beta}_2')' \text{ and } \boldsymbol{\gamma} = (\boldsymbol{\gamma}_1',\boldsymbol{\gamma}_2')'$$

where

$$E[u_i] = 0,\ \mathrm{Var}[u_i] = \sigma_u^2\ \ \mathrm{Cov}[\varepsilon_{it},u_i] = 0,$$

$$\mathrm{Var}[\varepsilon_{it} + u_i] = \sigma^2 = \sigma_\varepsilon^2 + \sigma_u^2,$$

$$\mathrm{Corr}[\varepsilon_{it} + u_i,\varepsilon_{is} + u_i] = \rho = \sigma_u^2 / \sigma^2.$$

There are four sets of variables in the model,

	Uncorrelated with u_i	Correlated with u_i
Time varying	$\mathbf{x}_{1it}$ is KX_1 variables	$\mathbf{x}_{2it}$ is KX_2 variables
Time invariant	$\mathbf{f}_{1i}$ is KF_1 variables	$\mathbf{f}_{2i}$ is KF_2 variables

Note that as stated, the model already embodies an important assumption. The formulation assumes that you can distinguish a set of variables $\mathbf{x}_1$ that is uncorrelated with u_i. In *LIMDEP*'s formulation of the model, any of the remaining three sets of variables are optional; your model may include any or all of these remaining three sets, but it must include set $\mathbf{x}_1$. *For identification purposes, KX_1 must be at least as large as KF_2 (KF_2 may be zero).* At the outset, we note that if your model contains neither $\mathbf{x}_2$ nor $\mathbf{f}_2$, then you should not use this estimator, as you can use the ordinary random effects estimator.

By construction, any OLS or GLS estimators of this model are inconsistent when KX_2 or KF_2 are positive (that is, when the model contains variables that are correlated with the random effects). Hausman and Taylor have proposed an instrumental variables estimator that uses only the information within the model (i.e., as already stated). The strategy for estimation is based on the following logic. First, by taking deviations from group means, we find that

$$y_{it} = \boldsymbol{\beta}_1'(\mathbf{x}_{1it} - \overline{\mathbf{x}}_{1i}) + \boldsymbol{\beta}_2'(\mathbf{x}_{2it} - \overline{\mathbf{x}}_{2i}) + \varepsilon_{it} - \overline{\varepsilon}_i$$

which implies that $\boldsymbol{\beta}$ can be consistently estimated by least squares, in spite of the correlation between $\mathbf{x}_2$ and u. This is the familiar, fixed effects, least squares dummy variable estimator. Now, in the original model, Hausman and Taylor show that the group means can be used as (KX_1+KX_2) instrumental variables for estimation of $(\boldsymbol{\beta},\boldsymbol{\gamma})$. Since $\mathbf{f}_1$ is uncorrelated with the disturbances, it can likewise serve as a set of KZ_1 instrumental variables. That leaves a necessity for KF_2 instrumental variables. The authors show that the group means for $\mathbf{x}_1$ can serve as these remaining instruments, and the model will be identified so long as KX_1 is greater than or equal to KF_2. As before, feasible GLS is better than OLS, and available. Likewise, FGLS is an improvement over simple IV estimation of the model, which is consistent but inefficient.

The authors propose the following set of steps:

Step 1. Use consistent but inefficient estimators of $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ to estimate the variance components.

Step 2. Use weighted FGLS with instrumental variables to take full advantage of the known information about the variances at a second step.

The specific procedure is as follows:

Step 1. Obtain the LSDV (fixed effects) estimator of $\boldsymbol{\beta} = (\boldsymbol{\beta}_1',\boldsymbol{\beta}_2')'$ based on $\mathbf{x}_1$ and $\mathbf{x}_2$. The residual variance estimator from this step is a consistent estimator of σ_ε^2.

Step 2. Form the within groups residuals from this regression at Step 1, e_{it}. Stack the group means of these residuals in a full sample length data vector. Thus, $e_{it}^* = \overline{e}_i$, $i = 1,...,T_i$, i = 1,...,N. These group means are used as the dependent variable in a two stage least squares regression on $\mathbf{f}_1$ and $\mathbf{f}_2$ with instrumental variables $\mathbf{f}_1$ and $\mathbf{x}_1$. (Note the identification requirement that KX_1, the number of columns in $\mathbf{x}_1$ be at least as large as KF_2, the number of columns in $\mathbf{f}_2$.) This provides a consistent estimator of $\boldsymbol{\gamma}$. The residual variance in this regression is a consistent estimator of $\sigma^{*2} = \sigma_u^2 + Q\sigma_\varepsilon^2$ where $Q = \text{plim}(1/N)\Sigma_i(1/T_i)$. (This is just $1/T$ in a balanced sample, but we do not require this.) From this estimator and the estimator of σ_ε^2 in Step 1, we deduce an estimator of σ_u^2.

Step 3. The final step is a weighted instrumental variable estimator. The transformation of y_{it} and $(\mathbf{x}_{1it},\mathbf{x}_{2it},\mathbf{f}_{1i},\mathbf{f}_{2i})$ is

$$v_{it}^* = v_{it} - (1 - \theta_i)\,\overline{v}_i \text{ where } \theta_i = \sqrt{\frac{\sigma_\varepsilon^2}{\sigma_\varepsilon^2 + T_i\sigma_u^2}}$$

where v_{it} denotes any of the aforementioned variables and $\overline{v}_i$ denotes a group mean. Note in the case of the time invariant variables, the group mean is the original variable, and the transformation just multiplies the variable by θ_i. The instrumental variables are $\mathbf{x}_{1it} - \overline{\mathbf{x}}_{1i}$, $\mathbf{x}_{2it} - \overline{\mathbf{x}}_{2i}$, $\mathbf{z}_{1i}$ and $\overline{\mathbf{x}}_{1i}$. Note for the fourth set of instruments, the group mean is repeated for each member of the group.

In order to implement this estimator with *LIMDEP*, several steps are required, but the final, most complicated one has been completely automated. The program below shows the set of steps. Most of the steps for this estimator use familiar parts of the program. *The final* **REGRESS** *command contains the important settings which specifically request the Hausman and Taylor estimator.*

This is a program template for application of the Hausman and Taylor estimator for the random effects model.

1. Define four sets of variables. Note, any of *x*2, *f*1, or *f*2 may contain no variables. In this case, in the **CALC** command, set the associated count to zero. Be sure to define the compound namelists appropriately as well. If the model contains a constant term, include one in *f*1.

```
CREATE or otherwise set up group ID.  We call this i $
SETPANEL    ; Group = i ; Pds = ti $
NAMELIST    ; x1 = ... the set of variables  $
NAMELIST    ; x2 = ... the set of variables  $
NAMELIST    ; f1 = ... one, the set of variables $
NAMELIST    ; f2 = ... the set of variables  $
NAMELIST    ; x = x1,x2 ; f = f1,f2 ; exog = x1,f1 ; all = x1,x2,f1,f2 $
CREATE      ; y = the dependent variable $
CALC        ; kx1 = Col(x1) ; kx2 = Col(x2) ; kf1 = Col(f1) ; kf2 = Col(f2) $
```

2. Compute the LSDV estimator based only on [**x1**,**x2**] to produce β and σ_ε^2. The panel specification may be by **; Pds = number** or **; Str = variable.**

```
REGRESS     ; Lhs = y ; Rhs = x ; Fixed ; Panel  $
MATRIX      ; bw = b $
CALC        ; s2e = ssqrd$
```

3. Form within groups residuals, then get the group means, expanded to the full sample length. This is a special command created for this purpose. Panel specification should now be the one created automatically by the regression above. This command also creates the estimate of *Q* and calls it *avg_ti*. See Step 4 below. (It can be done with **CREATE**, but we need *Q* as well so we use the regression.)

```
CREATE      ; dwit = y - x'bw $
CREATE      ; dwi = Group Mean(dwit, Pds = ti) $
```

4. Regress these group means on [**f1**,**f2**] with instruments [**f1**,**x1**] to estimate γ and σ_*^2. (This is just 2SLS.) Then get the variance components estimator.

```
2SLS        ; Lhs = dwi ; Rhs = f ; Inst = exog $
CALC        ; s2s = ssqrd ; s2u = s2s - avg_ti*s2e $
```

5. This is the Hausman and Taylor procedure which has been automated. The model is set up as usual for the random effects model. The **; Start** specification requests the estimator. This must provide six values, exactly as shown below.

```
REGRESS     ; Lhs = y ; Rhs = all ; Panel ; Random
            ; Start = kx1,kx2,kf1,kf2,s2e,s2u $
```

To illustrate the Hausman and Taylor estimator, we will fit a log wage equation using the Cornwell and Rupert data examined in the previous section. The model is the one specified by Cornwell and Rupert,

$$\begin{aligned}\log wage_{it} = \; & \beta_{1,1}wks_{it} + \beta_{1,2}south_{it} + \beta_{1,3}smsa_{it} + \beta_{1,4}ms_{it} \\ & + \beta_{2,1}exp_{it} + \beta_{2,2}exp_{it}^2 + \beta_{2,3}occ_{it} + \beta_{2,4}ind_{it} + \beta_{2,5}union_{it} \\ & + \gamma_{1,1} + \gamma_{1,2}fem_i + \gamma_{1,4}blk_i \\ & + \gamma_{2,1}ed_i + \varepsilon_{it} + u_i\end{aligned}$$

We take weeks worked and union membership to be endogenous in the model. The following commands adapt the Hausman and Taylor routine to this specification. Results follow. We note, this is precisely the model specified by Cornwell and Rupert, and these are their data. Our results resemble theirs, but are not close enough to 'match' within rounding error. One possible explanation is that the estimator depends crucially on the two variance estimators, and there are numerous ways to estimate them. Cornwell and Rupert do not document how they did this computation.

? [Specific for this application]

```
CREATE      ; i = Trn(7,0) $
SETPANEL    ; Group = i ; Pds = ti $
NAMELIST    ; x1= wks,south,smsa,ms $
NAMELIST    ; x2= exp,exp*exp,occ,ind,union $
NAMELIST    ; f1 = one,fem,blk $
NAMELIST    ; f2 = ed $
NAMELIST    ; x = x1,x2
            ; f  = f1,f2
            ; exog = x1,f1
            ; all = x1,x2,f1,f2 $
```

? [Generic for estimation of Hausman and Taylor]

```
CREATE    ; y = lwage $

E23.3 Arellano, Bond, and Bover's Estimator for Dynamic Panel Data Models

This estimator is for the dynamic random effects model

$$\begin{aligned} y_{it} &= \alpha y_{i,t-1} + \boldsymbol{\beta}_1'\mathbf{x}_{1it} + \boldsymbol{\beta}_2'\mathbf{x}_{2it} + \boldsymbol{\gamma}_1'\mathbf{f}_{1i} + \boldsymbol{\gamma}_2'\mathbf{f}_{2i} + \varepsilon_{it} + u_i \\ &= \alpha y_{i,t-1} + \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\gamma}'\mathbf{f}_i + \varepsilon_{it} + u_i \\ &= \alpha y_{i,t-1} + \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\gamma}'\mathbf{f}_i + v_{it} \\ &= \boldsymbol{\delta}'\mathbf{w}_{it} + v_{it}. \end{aligned}$$

where the terms in the equation are the same as in the Hausman and Taylor (HT) model. Subscripts '1' denote variables that are uncorrelated with u_i while subscripts '2' indicate variables that are correlated with u_i. This model differs by its inclusion of the lagged dependent variable. In principle, one could include additional lags, but our formulation includes only one. Note, also, that variables $\mathbf{f}_i$ are time invariant. If there is a constant term in the model, it is part of $\mathbf{f}_{1i}$.

E23.3.1 Technical Background

Instrumental variables estimation of the model without the lagged dependent variable is discussed in the previous section on the HT estimator. The Arellano et al. (ABB) estimator uses GMM instead. The HT approach is consistent in this setting, but ABB show that efficiency gains are available by using a larger set of moment conditions. In order to present the command structure for this estimator, it is necessary to lay out first some of the mathematical formulation of the ABB estimator. Let

$$\mathbf{w}_{it} = [y_{i,t\text{-}1},\ \mathbf{x}_{1it}',\ \mathbf{x}_{2it}',\ \mathbf{f}_{1i}',\ \mathbf{f}_{2i}']'$$

$$= (1 \ + KX_1 + KX_2 + KF_1 + KF_2) \times 1 = K{\times}1 \text{ vector}$$

and $$\mathbf{W}_i = \begin{bmatrix} \mathbf{w}_{i1}' \\ \mathbf{w}_{i2}' \\ \vdots \\ \mathbf{w}_{iT_i}' \end{bmatrix} = \text{ the full set of Rhs data for group } i \text{, and } \mathbf{y}_i = \begin{bmatrix} y_{i1} \\ y_{i2} \\ \vdots \\ y_{iT_i} \end{bmatrix}$$

Note that $\mathbf{W}_i$ is, in principle, a $T_i{\times}K$ matrix. However, owing to the lagged dependent variable, only T_i-1 observations are available. To avoid a cumbersome, cluttered notation, we leave this distinction embedded in the notation for the moment. Later, when necessary, we will make it explicit. It will reappear in the formulation of the instrumental variables. A total of T_i-1 observations will be available for constructing the IV estimators. (Users with very short panels, i.e., two or three observations, are warned at this point that this estimator requires at least three periods of data to be useable, but four or more will be preferable.)

We now form the matrix of instrumental variables. Readers are referred to Hausman and Taylor (1981), Arellano et al. (1991, 1995, 1998), Ahn and Schmidt (1995) and Amemiya and MaCurdy (1995) for discussion of the various possibilities. We will form a matrix $\mathbf{Z}_i$ consisting of T_i-1 rows constructed the same way for T_i-2 observations and a final row that will be different, as discussed below. The matrix will be of the form

$$\mathbf{Z}_i = \begin{bmatrix} \mathbf{z}_{i1}' & \mathbf{0}' & \cdots & \mathbf{0}' \\ \mathbf{0}' & \mathbf{z}_{i2}' & \cdots & \mathbf{0}' \\ \vdots & \vdots & \ddots & \vdots \\ \mathbf{0}' & \mathbf{0}' & \cdots & \mathbf{m}_i' \end{bmatrix}.$$

The instrumental variables contained in $\mathbf{z}_{it}'$ can include the following from within the model:

(Z Type 0) $\mathbf{x}_{it}$	(i.e., current values of the time varying variables)
(Z Type 1) $\mathbf{x}_{it}$ and $\mathbf{x}_{i,t\text{-}1}$	(i.e., current and one lag of the time varying variables)
(Z Type 2) $\mathbf{x}_{i1},...,\mathbf{x}_{iTi}$	(i.e., all current, past and future values of the time varying variables)
(Z Type 3) $\mathbf{x}_{i1},...\mathbf{x}_{i,t}$	(i.e., all current and past values of the time varying variables)

The time invariant variables that are uncorrelated with u_i, that is $\mathbf{f}_{1i}$, are always appended at the end of the nonzero part of each row. We should note, it may seem that including $\mathbf{x}_2$ in the instruments would be invalid. However, we will be using deviations from group means. While the original variables are correlated with u_i, by construction, the group mean deviations are not. The issue of correlation between the transformed lagged y_{it} and the deviations of ε_{it} is discussed in the papers cited.

The final row of $\mathbf{Z}_i$ is important to the construction. Two possibilities are provided:

(M Type 1) $\mathbf{f}_{1i}'$ and $\overline{\mathbf{x}}_{1i}$ (produces the Hausman and Taylor estimator)

(M Type 2) $\mathbf{f}_{1i}'$ and $\mathbf{x}_{1i,1}', \mathbf{x}_{1i,2}',..., \mathrm{x}_{1i,Ti}$ (Amemiya and MaCurdy).

Note that the **m** variables are exogenous time invariant variables, $\mathbf{f}_{1i}$, and the exogenous time varying variables, either condensed into the single group mean or in the raw form, with the full set of T_i observations.

As Ahn and Schmidt show, there are potentially huge numbers of additional orthogonality conditions in this model owing to the relationship between first differences and second moments. We do not consider those. As it stands, the number of instrumental variables contained in $\mathbf{Z}_i$ is potentially enormous even in a moderately sized model. The matrix $\mathbf{Z}_i$ could be huge. Consider the Z Type 3 and M Type 2 forms in a model with 10 time varying right hand side variables and suppose T_i is 15. Then, there are 15 rows and roughly 15×(10×15) or 2,250 columns. (This makes one wonder about the practicality of the Ahn and Schmidt estimator which involves potentially thousands of instruments in a model containing only a handful of parameters. The order of the computation grows with the square of T_i.)

To construct the estimator, we will require a transformation matrix, $\mathbf{H}_i$ constructed as follows. Let **i** denote a $T_i \times 1$ column of ones. Then,

$$\mathbf{M}_i = \mathbf{I} - (1/T_i)\mathbf{i}\,\mathbf{i}'$$

This is the matrix that creates deviations from means. Let $\mathbf{M}_{i1}$ denote the first T_i-1 rows of this matrix. Then, finally,

$$\mathbf{H}_i = \begin{bmatrix} \mathbf{M}_{i1} \\ \dfrac{1}{T_i}\mathbf{i}' \end{bmatrix}$$

Thus, $\mathbf{H}_i$ replaces the last row of $\mathbf{M}_i$ with a row with all elements equal to $1/T_i$. The effect is as follows: if $\mathbf{q}_i$ is T_i observations on a variable, then $\mathbf{H}_i\mathbf{q}_i$ produces $\mathbf{q}_i$* in which the first T_i-1 observations are converted to deviations from group means and the last observation is the group mean.

Finally, for purposes of GMM estimation, consider three candidates for the covariance matrix of $\mathbf{v}_i = (v_{i1},v_{i2},...,v_{iTi})$

($\mathbf{\Omega}$ Type 1) $\mathbf{\Omega} = \sigma_\varepsilon^2\mathbf{I}$ (uncorrelated, misspecified by construction)

($\mathbf{\Omega}$ Type 2) $\mathbf{\Omega} = \sigma_\varepsilon^2\,\mathbf{I} + \sigma_u^2\mathbf{i}\,\mathbf{i}'$ (variance components, random effects)

($\mathbf{\Omega}$ Type 3) $\mathbf{\Omega} = E[\mathbf{v}_i\mathbf{v}_i']$ (robust, unrestricted, $E[\boldsymbol{\varepsilon\varepsilon}'] = \mathbf{\Sigma} \neq \sigma^2\,\mathbf{I}$)

We leave aside for the moment the problem of computing an estimator of $\mathbf{\Omega}$. The ABB estimator of δ is a two step GMM estimator in which the two steps are defined by which form of $\mathbf{\Omega}$ is used. In the first step, the consistent, but inefficient estimator based on $\mathbf{\Omega}$ Type 1 is used to obtain an estimator of δ that enables estimation of the appropriate $\mathbf{\Omega}$. At the second step, the more efficient estimator based on $\mathbf{\Omega}$ Type 2 or 3 is used. (Note, again, this is not going to be 'fully' efficient because there remain moment conditions based on first differences and higher moments that are not being used - see Ahn and Schmidt (1995).) The ABB estimator is

$$\hat{\delta} = \left[\left(\sum_{i=1}^{N} (\mathbf{W}_i'\mathbf{H}_i')\mathbf{Z}_i\right)\left(\sum_{i=1}^{N} \mathbf{Z}_i'(\mathbf{H}_i\mathbf{\Omega}_i\mathbf{H}_i')\mathbf{Z}_i\right)^{-1}\left(\sum_{i=1}^{N} \mathbf{Z}_i'(\mathbf{H}_i\mathbf{W}_i)\right)\right]^{-1} \times$$
$$\left(\sum_{i=1}^{N} (\mathbf{W}_i'\mathbf{H}_i')\mathbf{Z}_i\right)\left(\sum_{i=1}^{N} \mathbf{Z}_i'(\mathbf{H}_i\mathbf{\Omega}_i\mathbf{H}_i')\mathbf{Z}_i\right)^{-1}\left(\sum_{i=1}^{N} \mathbf{Z}_i'(\mathbf{H}_i\mathbf{y}_i)\right)$$

The estimator of the asymptotic covariance matrix for this estimator is the inverse matrix in square brackets. The two step estimator is computed as follows:

Step 1. Computation of $\hat{\delta}$ based on $\mathbf{\Omega} = \sigma_\varepsilon^2\mathbf{I}$. (Note, σ_ε^2 is not necessary. It falls out of the matrix product. After Step 1, a set of residuals $\hat{\mathbf{v}}_i$ is computed. Two estimators of $\mathbf{\Omega}$ are now available. You may provide specific values for σ_ε^2 and σ_u^2. If so, then Type 2 is computed. (In this case, the first step is actually superfluous, but results will be reported nonetheless.) Otherwise,

$$\hat{\mathbf{\Omega}} = \frac{1}{N}\sum_{i=1}^{N} \mathbf{H}_i\,\hat{\mathbf{v}}_i\,\hat{\mathbf{v}}_i\,\mathbf{H}_i'$$

Step 2. Recompute the estimator using the new estimator of $\mathbf{\Omega}$.

E23.3.2 Command

The command for this procedure is as follows: Note that the entire estimator is self contained, unlike the HT estimator of the previous section. Use

SETPANEL	**; … $**
REGRESS	**; Lhs = dependent variable**
	; Rhs = variables in x_1 then
	variables in x_2 then
	variables in f_1 (including one if needed) then
	variables in f_2
	; Start = kx_1, kx_2, kf_1, kf_2
	; Panel
	; DPD (for dynamic panel data) $

If your model contains a constant term, include it in the list for $\mathbf{f}_1$. This procedure allows unbalanced panels, but it is quite intricate to do so. The panel data specification,

; Pds = count variable

assumes each group starts with the first period. If this is not the case, use

; Date = date variable, first - last

for example,

; Date = year, 1980 - 1987

to specify starting and ending points in the sample. All dates must fall in that interval. This allows you to change starting dates for specific observation groups with balanced or unbalanced panels. Your date variable, *year* in the example above, will provide the dates for the specific observation. We would note, in spite of the additional flexibility this allows, you *should not* use this estimator with panels that have gaps in them. The lagged values of the variables cannot be placed properly if the data set contains gaps. Results will be unpredictable, and almost certainly unusable.

Some of the four sets of variables may not be present in your model. You will indicate this by placing zeros in the **; Start** list. Thus, for example, if you have no exogenous time invariant variables, you will set KF_1 to zero. (We note, like many of these, the setup is much more complicated than the command it requires.)

NOTE: The model is assumed to contain a lagged dependent variable. Do not include this on your Rhs. It will be added to your model. If your model does not contain a lagged dependent variable, you should be using the HT estimator described in the previous section.

With the command as given, the default settings for the different arrangements are

Instruments: *Z* Type 1, present and a single lagged value
M Type 1, Hausman and Taylor, group means, not the original data

Covariances: $\mathbf{\Omega}$ Type 3, computed after the first step

You can change the first of these by using

; Pattern = Z Type, M Type if desired

where the specifications are in the following table:

		M Type = last row of $\mathbf{Z}_i$	
Z Type = instruments		1 = means	2 = all data
0	$\mathbf{x}_t$, $\mathbf{f}_1$	**0**	**0, A**
1	$\mathbf{x}_t$, $\mathbf{x}_{t-1}$, $\mathbf{f}_1$	**1**	**1, A**
2	$\mathbf{x}_t$, $\mathbf{x}_{t-1}$,...,$\mathbf{x}_1$, $\mathbf{f}_1$	**P**	**P, A**
3	$\mathbf{x}_T$, $\mathbf{x}_{T-1}$,...,$\mathbf{x}_1$, $\mathbf{f}_1$	**A**	**A, A**

For example, to use all previous values and the Amemiya/MaCurdy form of the last row of Z_i, you would use

; Pattern = P, A

Note the following for this estimator:

- *Z* Type 3 may only be used with a balanced panel with a fixed starting date.

- This estimator has no handler for missing data. You must set up the sample without missing values before invoking the estimator.

- You may use **; Model = kx1,kx2,kf1,kf2** instead of **; Start = kx1,kx2,kf1,kf2**. This change in format is just for convenience. Both forms are retained to maintain compatibility with earlier versions.

- Time dummy variables can be included in the model if desired – they must be created separately. However, they are likely to be problematic when constructing the instruments. They can proliferate.

This estimator generates huge numbers of moment conditions, particularly if you use the '*A*' pattern – that is, ALL moment conditions in the sample. For example, suppose that $T_i = 10$, $KX_1 = 3$, $KX_2 = 1$, $KF_1 = 2$ (including *one*) and $KF_2 = 1$, which does not seem like a large model. Then, the number of moment conditions (columns in $\mathbf{Z}_i$) is

KZ = 8 periods of lagged data after the one dropped initially ×
(8 groups of available exogenous variables × 4 variables in $\mathbf{x}_1$ and $\mathbf{x}_2$ + 2 variables in $\mathbf{f}_1$) +
the number of variables in the last row, which might be $KX_1+KF_1 = 5$ for *M* Type 1
= 277 columns

This does not seem like a large model, but it is. The problem is that the number of columns proliferates with the square of the number of periods. The Ahn and Schmidt (1995) approach would add roughly 10(10(9)/2 + 8) = 530 additional columns to $\mathbf{Z}_i$ for a total approaching 900, for the purpose of estimating eight parameters! A matrix with 900 columns might, in itself, present no obvious obstacle. However, note that the center matrix in the computation of $\hat{\delta}$ is square with this number of rows, so in order to compute the Ahn and Schmidt estimator, one would have to manipulate a 900×900 inverse matrix. Ahn and Schmidt do not mention this practical burden.

Arellano and Bond (1998) mention briefly the possibility that $\mathbf{Z}_i$ may have many columns, and one might have to drop some of them (some 'less informative instruments'). We begin this paring by dropping the Ahn and Schmidt estimator. Then, *Z* Type 1 is used to produce a fairly small set of instruments. Given that the model is already vastly overidentified, it seems that Type 1, a single lagged value of the exogenous variables, ought to be sufficient. For the model size considered here, this would produce an order of 9(5+5) + 5 or 95 columns in $\mathbf{Z}_i$. This is still very large, but manageable. The end result of this discussion is that this estimator is practical only when T_i is relatively small, and best with small T_i and quite large *N*. We recommend using only the default pattern, '1,' that is, a single lagged value.

Finally, if you wish to specify the **Ω** Type 2, GLS estimator, then you must provide values for σ_u^2 and σ_ε^2, in that order, after KF_2 in the **; Start** specification (which will now contain six values instead of four.) You might use a prior GLS estimator to estimate the variance components in your model. The resulting command for the DPD estimator would be

REGRESS ; Lhs = dependent variable
; Rhs = all independent variables
; Pds = the value
; Panel
; DPD
; Start = kx1,kx2,kf1,kf2,s2u,s2e $

There are no other options for this model other than those already mentioned. After estimation, you may use

; List to display fitted values
; Keep = name to retain fitted values
; Res = name to retain residuals

all as usual for regression estimators.

E23.3.3 A Test Statistic for the Specification

Bhargava and Sargan (1983) propose a test statistic for the specification of the model. This is computed as part of the results for the estimator. See the results below. The computation is

$$\chi^2[KZ - Kmodel] = \left(\sum_{i=1}^{N} (\hat{\mathbf{v}}_i'\mathbf{H}_i')\mathbf{Z}_i\right)\left(\sum_{i=1}^{N}\mathbf{Z}_i'(\mathbf{H}_i\mathbf{\Omega}_i\mathbf{H}')_i\mathbf{Z}_i\right)^{-1}\left(\sum_{i=1}^{N}\mathbf{Z}_i'(\mathbf{H}_i\hat{\mathbf{v}}_i)\right)$$

The statistic has a limiting chi squared distribution with degrees of freedom equal to the number of overidentifying restrictions (moment conditions). As noted earlier, in these models, there are typically few parameters and very many moments, so that the degrees of freedom is likely to be quite large.

E23.3.4 Technical Notes

The earlier result lays out the computation of the estimator and the asymptotic covariance matrix. A detail to be added concerns the precise form of the matrices of instrumental variables. Your data for this estimator are assumed to consist of groups of T_i observations,

$$Data_{it} = y_{it},\ \mathbf{x}_{1it},\ \mathbf{x}_{2it}, \mathbf{f}_{1i}, \mathbf{f}_{2i}, t = 1,...,T_i.$$

That is, each data group contains T_i rows. We assume that the first row contains known initial values for all variables, but since there is no y_{i0} in the data set, the model applies to observations two through T_i. The general form of the model is

$$y_{it} = \alpha y_{i,t-1} + \beta_0 + \boldsymbol{\beta}_1'\mathbf{x}_{1it} + \boldsymbol{\beta}_2'\mathbf{x}_{2it} + \boldsymbol{\gamma}_1'\mathbf{f}_{1i} + \boldsymbol{\gamma}_2'\mathbf{f}_{2i} + \varepsilon_{it} + u_i, t = 2,...,T_i.$$

The matrices of instruments are assembled as follows: (Note that any of $\mathbf{x}_{2it}$, $\mathbf{f}_{1i}$ and $\mathbf{f}_{2i}$ may not actually be present in your model. First, define the vector placed in the last row.

$$\mathbf{m}_i' = [\,\bar{\mathbf{x}}_{i1}{}'\ \ \mathbf{f}_{1i}'\,] \qquad \text{for } M \text{ Type 1} \qquad (KM = KF_1 + KX_1)$$

or
$$\mathbf{m}_i' = [\mathbf{x}_{1i2}, \ldots, \mathbf{x}_{1iT(i)}\ \mathbf{f}_{1i}'] \qquad \text{for } M \text{ Type 2} \qquad (KM = KF_1 + (T_i - 1)KX_1)$$

Type 1 uses the group mean, including only the observations used in the computation of the coefficients (i.e., dropping the first observation in each group) – this is $(1 \times KX_1{+}KF_1)$. Type 2 uses the original data that would be used to compute the group mean, so this vector has $(T_i\text{-}1) \times KX_1{+}KF_1$ elements.

The matrices of instrumental variables contain T_i - 1 rows, once again, assuming that the first row of data contains only initial values. Rows 1 to T_i - 2 are built up from the data set, while the last row contains only $\mathbf{m}_i'$ and zeros. The particular forms of these matrices are as follows, where we illustrate with a model in which T_i = 4. This will be sufficiently general to extend to other cases. With T_i = 4, there are three observations to use for estimation in each group, as one is lost for the lagged dependent variable. In the following, let $\mathbf{x}_{it}'$ denote $[\mathbf{x}_{1it}{}', \mathbf{x}_{2it}{}']$, the full set of time varying right hand side variables. Then,

Z Type 0, current data only:

$$\begin{bmatrix} \mathbf{x}_{i1}' & \mathbf{f}_{1i}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{x}_{i2}' & \mathbf{f}_{1i}' & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{m}_i' \end{bmatrix}$$

This matrix has number of columns equal to $(T_i\text{-}2)\times[(KX_1{+}KX_2) + KF_1] + KM$.

Z Type 1, current and one period lagged data:

$$\begin{bmatrix} \mathbf{x}_{i1}' & \mathbf{x}_{i2}' & \mathbf{f}_{1i}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{x}_{i2}' & \mathbf{x}_{i3}' & \mathbf{f}_{1i}' & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{m}_i' \end{bmatrix}$$

This matrix has number of columns equal to $(T_i\text{-}2)\times[2(KX_1{+}KX_2) + KF_1] + KM$.

Z Type 2, current past and future data:

$$\begin{bmatrix} \mathbf{x}_{i1}' & \mathbf{x}_{i2}' & \mathbf{x}_{i3}' & \mathbf{x}_{i4}' & \mathbf{f}_{1i}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{x}_{i1}' & \mathbf{x}_{i2}' & \mathbf{x}_{i3}' & \mathbf{x}_{i4}' & \mathbf{f}_{1i}' & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{m}_i' \end{bmatrix}$$

This matrix has number of columns equal to $(T_i\text{-}2)\times[T_i(KX_1{+}KX_2) + KF_1] + KM$.

Z Type 3, current and lagged data:

$$\begin{bmatrix} \mathbf{x}'_{i1} & \mathbf{x}'_{i2} & \mathbf{f}'_{1i} & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{x}'_{i1} & \mathbf{x}'_{i2} & \mathbf{x}'_{i3} & \mathbf{f}'_{1i} & \mathbf{0}' \\ \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{0}' & \mathbf{m}'_i \end{bmatrix}$$

This matrix has number of columns equal to $[T_i \times (T_i\text{-}1)/2\ -\ 1](KX_1+KX_2) + (T_i\text{-}2)KF_1 + KM$.

The matrix $\mathbf{W}_i$ consists of T_i - 1 rows of the right hand side data for the observations in group i.

E23.3.5 An Application

To illustrate the Arellano, Bond and Bover estimator, we extend the Cornwell and Rupert log wage equation examined in the previous section. The model is now

$$\begin{aligned} \log wage_{it} = \; & \alpha \log wage_{i,t-1} \\ & + \beta_{1,1} wks_{it} + \beta_{1,2} south_{it} + \beta_{1,3} smsa_{it} + \beta_{1,4} ms_{it} \\ & + \beta_{2,1} exp_{it} + \beta_{2,2} exp_{it}^2 + \beta_{2,3} occ_{it} + \beta_{2,4} ind_{it} + \beta_{2,5} union_{it} \\ & + \gamma_{1,1} + \gamma_{1,2} fem_i + \gamma_{1,4} blk_i \\ & + \gamma_{2,1} ed_i + \varepsilon_{it} + u_i \end{aligned}$$

The commands used to specify the model are

```
CREATE      ; i = Trn(7,0) $
SETPANEL    ; Group = i ; Pds = ti $
NAMELIST    ; x1= wks,south,smsa,ms $
NAMELIST    ; x2= exp,exp*exp,occ,ind,union $
NAMELIST    ; f1 = one,fem,blk $
NAMELIST    ; f2 = ed $
NAMELIST    ; x = x1,x2 $
NAMELIST    ; f  = f1,f2 $
NAMELIST    ; exog = x1,f1 $
NAMELIST    ; all = x1,x2,f1,f2 $
CALC        ; kx1 = Col(x1) ; kx2 = Col(x2)
            ; kf1 = Col(f1) ; kf2 = Col(f2) $
REGRESS     ; Lhs = lwage
            ; Rhs = all
            ; Start = kx1,kx2,kf1,kf2
            ; Panel
            ; DPD
            ; List $
```

Results are given for the first step IV and the second step GMM estimators. The **; List** request generates an extremely long list. We show only a few lines of this. One would normally not use this option with a large sample such as this one. Finally, the initial, one step instrumental variable estimates are shown last. They would appear at the beginning of the displayed results when the program is used.

E24: Linear Systems of Regression Equations – SURE and 3SLS

E24.1 Introduction

This chapter and Chapter E25 present methods of estimating the parameters of the regression system

$$y_1 = f_1(\mathbf{x}_1,\boldsymbol{\beta}) + \varepsilon_1$$

$$y_2 = f_2(\mathbf{x}_2,\boldsymbol{\beta}) + \varepsilon_2$$

$$\ldots$$

$$y_M = f_M(\mathbf{x}_M,\boldsymbol{\beta}) + \varepsilon_M$$

or

$$\mathbf{y} = \mathbf{f}(\mathbf{X},\boldsymbol{\beta}) + \boldsymbol{\varepsilon},.$$

We assume $E[\boldsymbol{\varepsilon}|\text{all } \mathbf{x}] = \mathbf{0}$

and $E[\boldsymbol{\varepsilon\varepsilon}'|\text{all } \mathbf{x}] = \boldsymbol{\Sigma}.$

As stated, the model is a possibly nonlinear system of seemingly unrelated regressions. However, for some settings (e.g., the linear model of Section E24.4), the **x** vectors on the right hand sides of the equations may include endogenous variables, y_j, from other equations. That is, we also accommodate systems of simultaneous equations. The linear models also allow autocorrelation of the disturbances. Systems of nonlinear equations are shown in Chapter E25.

E24.2 Linear SURE Models Estimated by GLS

The seemingly unrelated linear regression equations (**SURE**) model is:

$$\mathbf{y}_1 = \mathbf{X}_1\boldsymbol{\beta}_1 + \boldsymbol{\varepsilon}_1,$$

$$\mathbf{y}_2 = \mathbf{X}_2\boldsymbol{\beta}_2 + \boldsymbol{\varepsilon}_2,$$

$$\ldots$$

$$\mathbf{y}_M = \mathbf{X}_M\boldsymbol{\beta}_M + \boldsymbol{\varepsilon}_M.$$

$$E[\boldsymbol{\varepsilon}_i|\mathbf{X}_1,\ldots] = \mathbf{0},$$

$$E[\boldsymbol{\varepsilon}_i\boldsymbol{\varepsilon}_j'|\mathbf{X}_1,\ldots] = \sigma_{ij}\mathbf{I}.$$

There are M, up to 20, equations. There are n observations in total. There must be the same number of observations for all equations. The disturbances across equations are allowed to be freely correlated. The parameter vector obtained by stacking $\boldsymbol{\beta}_m$ may have up to 150 parameters.

Collect the M disturbances for a particular observation in a column vector

$$\boldsymbol{\varepsilon}_t = [\varepsilon_{t1},\varepsilon_{t2}, \ldots \varepsilon_{tM}]'.$$

The model specifies $E[\boldsymbol{\varepsilon}_t|\mathbf{X}_1,\ldots] = \mathbf{0}$, $E[\boldsymbol{\varepsilon}_t \boldsymbol{\varepsilon}_t' |\mathbf{X}_1,\ldots] = \boldsymbol{\Sigma}.$

The estimator also allows for first order autocorrelation,

$$\varepsilon_{i,t} = \rho_i \varepsilon_{i,t\text{-}1} + u_{i,t}.$$

There are two estimators for this model in *LIMDEP*. The two step (or iterative) feasible GLS procedure (FGLS) uses Zellner's technique. The second is maximum likelihood, which is suitable for constrained, singular systems, such as translog demand systems. This is presented in Section E24.3.

E24.2.1 Command for SURE Estimation

The command for the GLS estimator for a system of regression equations is:

SURE **; Lhs = y1, y2, ..., ym** (your list of Lhs variables)
; Eq1 = list of Rhs variables for first equation
; Eq2 = list of Rhs variables for second equation
; ...
; EqM = list of Rhs variables for Mth equation $

HINT: This application is a convenient one for namelists. Namelists will be particularly useful if all of the equations share a set of variables. See Chapter R6 for details.

HINT: If all equations have the same set of Rhs variables *and if there are no linear constraints imposed*, then SURE is the same as equation by equation ordinary least squares. If linear constraints are imposed, this is no longer true.

E24.2.2 Options for the Generalized Least Squares Procedure

If no further specifications are given on the command, the procedure is allowed to iterate to convergence. This is a globally concave problem for which convergence is guaranteed unless the data are very badly conditioned. You can restrict the number of iterations with

; Maxit = maximum iterations

To use Zellner's efficient two step estimator for the system, that is, using the OLS residuals to estimate $\mathbf{\Sigma}$, use

; Maxit = 0

To obtain equation by equation OLS estimates, use

; Maxit = 99

Linear constraints may be imposed on the coefficients in the same way as described for the single equation, linear regression model in Chapter E8. The parameters of the equations are stacked as $\boldsymbol{\beta} = [\boldsymbol{\beta}_1', \boldsymbol{\beta}_2', ..., \boldsymbol{\beta}_M']'$, then the constraints are imposed as if this were a single equation model. For example, the following is a part of the model estimated in our example below:

SURE **; Lhs = igm,ic**
; Eq1 = one,fgm,cgm
; Eq2 = one,fc,cc
; CLS: b(4) - b(1) = 0, b(5) - b(2) = 0, b(6) - b(3) = 0 $

The linear restriction imposes cross equation equality of the corresponding pairs of coefficients. (With this restriction imposed, the model is the TSCS model presented in Chapter E15.) (The new specification of restrictions and hypothesis tests shown in Chapter E8, using the variable names, is not useable here because the program has no way to know which equation to use if a variable appears in more than one equation.)

With restrictions imposed, you will see two full sets of output. The initial set, without the restrictions imposed, is presented in full. Then, the restricted least squares estimates are presented.

TECHNICAL NOTE: The restricted GLS estimator is *not* the maximum likelihood estimator, even if it is allowed to iterate to convergence. The RGLS estimator is computed using the restricted least squares formula, *after* the unrestricted estimates are obtained. Therefore, the RGLS estimator is a function of the unrestricted estimator, not an iterative estimator in its own right.

Autocorrelation may be of two forms:

Model 1: $\varepsilon_{i,t} = \rho_i \varepsilon_{i,t\text{-}1} + u_{i,t}$ (equation specific autocorrelation)

Model 2: $\varepsilon_{i,t} = \rho\varepsilon_{i,t\text{-}1} + u_{i,t}$ (common autocorrelation).

Model 2 differs in that the same correlation coefficient is used for all equations. For these estimators, simply add

; Model = 1

or **; Model = 2**

to the command. The autocorrelation coefficients are estimated by using $r_i = 1 - DW_i/2$, where DW_i is the Durbin-Watson statistic computed using the single equation, equation by equation ordinary least squares residuals. If you specify **; Model = 2**, the common estimate is the simple (unweighted) average of the M individual estimates.

The estimated **Σ** is a 'weighting' matrix which greatly influences the final results. You can specify your own, rather than allowing *LIMDEP* to use the second step OLS residuals to form one. To specify a particular **Σ** matrix, use

; Sigma = name of matrix
; Maxit = 1

The setting of the maximum iterations at 1 is needed to prevent *LIMDEP* from recomputing **Σ** at another iteration. If necessary, you may also weight observations with

; Wts = weighting variable

The estimated disturbance covariance matrix, **S** is not displayed in the final output unless you request it with

; List

Note that this is not the same as a request for a listing of the fitted values.

Because this is a multiple equation estimator, it does not produce a set of fitted values or residuals. But, these are simple to obtain just by extracting the coefficients from the saved results and using **CREATE** with each parameter vector to create the linear function of the variables.

E24.2.3 Model Output for the GLS Estimator

Initial results include a trace of the log likelihood function for the iterations. Then, for each equation, the usual sorts of regression results, including fit measures, coefficient estimates, etc. are given. If the model is fit with a correction for autocorrelation, the diagnostic statistics include the autocorrelation coefficient estimated using the OLS residuals and the Durbin-Watson statistic and estimated autocorrelation for the corrected GLS residuals. That is, the values displayed are for

$$\hat{u}_{i,t} = e_{i,t} - r_i e_{i,t-1}.$$

The other saved results for this estimator are:

Matrices:	*b*	=	stacked coefficient vector,
	varb	=	estimated asymptotic covariance matrix for **B**,
	sigma	=	**S**, the final sample estimate of $\boldsymbol{\Sigma}$.
Scalars:	*logl*	=	log likelihood
		=	$-(MT/2)[1 + \log 2\pi + \log \det(\mathbf{S})]$,
	traceofs	=	trace(**S**).

In addition, this model creates a coefficient matrix named *b_sure* that is built up from the separate coefficient vectors, into a matrix whose each column corresponds to an equation.

Consider a small example using the Grunfeld data:

$$I_{it} = \alpha_1 + \alpha_2 C_{it} + \varepsilon_{1t},$$

$$F_{it} = \beta_1 + \beta_2 Year_t + \varepsilon_{2t}.$$

```
SAMPLE      ; 1-200 $
SURE        ; Lhs = i,f
            ; Eq1 = one,c
            ; Eq2 = one,year $
```

The estimates for the two equations using the 200 observations will be

```
Criterion function for GLS is log-likelihood.

The additional matrix created, *b_sure*, will be as follows:

	1	2
1	81.8294	-1168.17
2	0.232336	0
3	0	1.15703

Figure E24.1 Coefficient Matrix

Note that although it is clear from the specification of the model, the matrix, itself, contains no internal information to identify which variable corresponds to each row. The set of variables is constructed by moving through the equation lists, in order, and assembling the union of all of the sets of names in the order in which they occur in the stacked list.

The labels for the *Last Model* estimated are constructed from the equation specification. Each name is constructed as the first three characters from the name of the Lhs variable, then an underscore, then the first four characters of the Rhs variable. In the example,

SURE ; Lhs = igm,ic ; Eq1 = one,fgm,cgm ; Eq2 = one,fc,cc $

the set of labels would be [**igm_one, igm_fgm, igm_cgm, ic_one, ic_fc, ic_cc**]. (See Section R9.7.3 for use of the *Last Model*.)

There are no residuals or fitted values produced internally. But, you can retrieve these from the other results. In most cases, this will involve some setup that is specific to the model at hand.

E24.2.4 The Translog System

The translog function and some related models are estimated in various forms in the setting of multivariate regressions. Normally, the restrictions in the model are cross equation equality restrictions not usually viewed as testable, but as part of the model. Christensen and Greene's (1976) homothetic translog cost function provides an example. The model is:

$$
\begin{aligned}
\log(c/p_f) &= \alpha + \beta\log y + \gamma(\log y)^2/2 + \delta_k\log(p_k/p_f) + \delta_l\log(p_l/p_f)\\
&\quad + \theta_{kk}\log(p_k/p_f)^2/2 + \theta_{ll}\log(p_l/p_f)^2/2 + \theta_{kl}\log(p_k/p_f)\log(p_l/p_f) + \varepsilon_c,\\
s_k &= \delta_k + \theta_{kk}\log(p_k/p_f) + \theta_{kl}\log(p_l/p_f) + \varepsilon_k,\\
s_l &= \delta_l + \theta_{kl}\log(p_k/p_f) + \theta_{ll}\log(p_l/p_f) + \varepsilon_l,
\end{aligned}
$$

where c = cost,
y = output,
s_k = cost share of capital,
s_l = cost share of labor,
p_k, p_l, and p_f are the unit prices for capital, labor, and fuel, respectively.

The restriction of linear homogeneity in the input prices is imposed by normalizing cost and the other prices by the price of fuel. Using the obvious mnemonics for the variables in the model, and assuming that all variables are in log form, the commands for estimating a model such as this would be:

```
SURE     ; Lhs = cost,sk,sl
         ; Eq1 = one,y,y2,lpkf,lplf,lpkf2,lpkl2,lpkfplf
         ; Eq2 = one,lpkf,lplf
         ; Eq3 = one,lpkf,lplf
         ; CLS: b(9)  - b(4) = 0,   ? δk  in 1st and 2nd equation
                b(10) - b(6) = 0,   ? θkk in 1st and 2nd equation
                b(11) - b(8) = 0,   ? θkl in 1st and 2nd equation
                b(12) - b(5) = 0,   ? δl  in 1st and 3rd equation
                b(13) - b(8) = 0,   ? θkl in 1st and 3rd equation
                b(14) - b(7) = 0    $ θll in 1st and 3rd equation
```

This imposes all of the necessary constraints across the second and third equations. It is generally observed that very large gains in efficiency often follow when the cross equation restrictions are imposed. This underscores the substantial collinearity in the unrestricted equation and raises the question of whether it can be estimated at all. In practical terms, if the data in the unrestricted equations are so collinear that the model cannot be estimated, then the restricted estimates will not be computable either. Ultimately, they are functions of the unrestricted estimates. But, for systems such as the translog model, this problem is circumvented by the estimator described in the next section.

As specified above, one is not guaranteed to obtain the same parameter estimates if a different variable is chosen as the numeraire. This is normally handled by obtaining maximum likelihood estimates, rather than two step GLS estimates. As noted earlier, using **SURE** in the fashion specified above does not produce maximum likelihood estimators, even with iteration. The problem is easily solved using the direct maximum likelihood estimator described in Section E24.3.

E24.2.5 Generalized Least Squares

In Chapter E15, a Time Series/Cross Section model was fit using 20 years of data for five firms. The following continues that example by relaxing the constraint of equal parameter vectors across equations. The model commands are as follows: (We begin by transforming the first 100 observations in the raw data set to the 20 observations used here.) First, move the data up to the first 20 rows of the data set.

```
CREATE     ; igm = i       ; fgm = f       ; cgm = c
           ; ich  = i[+20] ; fch  = f[+20] ; cch  = c[+20]
           ; ige  = i[+40] ; fge  = f[+40] ; cge  = c[+40]
           ; iwe  = i[+60] ; fwe  = f[+40] ; cwe  = c[+40]
           ; ius  = i[+80] ; fus  = f[+40] ; cus  = c[+40] $
SAMPLE     ; 1-20 $
NAMELIST   ; xgm = one,fgm,cgm ; xch = one,fch,cch
           ; xge  = one,fge,cge ; xwe = one,fwe,cwe
           ; xus  = one,fus,cus ; y = igm,ich,ige,iwe,ius $
```

Fit the basic model by iterated FGLS.

SURE ; Lhs = y
; Eq1 = xgm ; Eq2 = xch ; Eq3 = xge ; Eq4 = xwe ; Eq5 = xus $

Estimate the model with autocorrelation, with separate coefficients for each equation.

SURE ; Lhs = y
; Eq1 = xgm ; Eq2 = xch ; Eq3 = xge ; Eq4 = xwe ; Eq5 = xus
; Model = 1 $

Constrained FGLS imposes cross equation equality of coefficient vectors

SURE ; Lhs = y
; Eq1 = xgm ; Eq2 = xch ; Eq3 = xge ; Eq4 = xwe ; Eq5 = xus
; CLS: b(4)-b(1) = 0, b(7)-b(1) = 0, b(10)-b(1) = 0, b(13)-B(1) = 0,
b(5)-b(2) = 0, b(8)-b(2) = 0, b(11)-b(2) = 0, b(14)-B(2) = 0,
b(6)-b(3) = 0, b(9)-b(3) = 0, b(12)-b(3) = 0, b(15)-B(3) = 0 $

The listing below shows parts of the output from these commands. In the first, the full set of results is shown for the set of equations. For the autocorrelation model, the results which have changed are listed. Finally, in the constrained model, only one coefficient vector is estimated, so only the diagnostic statistics are shown. Some superfluous lines of results are omitted in each case.

The first is the base case, iterated FGLS estimates.

```
Criterion function for GLS is log-likelihood.
Iteration    0, GLS            =   -473.1602
Iteration    1, GLS            =   -469.5564

The figure below plots the residuals equation by equation for the five equations. This is a counterpart to the first 100 points in the figure at the end of Chapter E15. As can be seen by comparing the two figures, the restriction of identical coefficients in the two equations brings a considerable change in the fit of some of the equations.

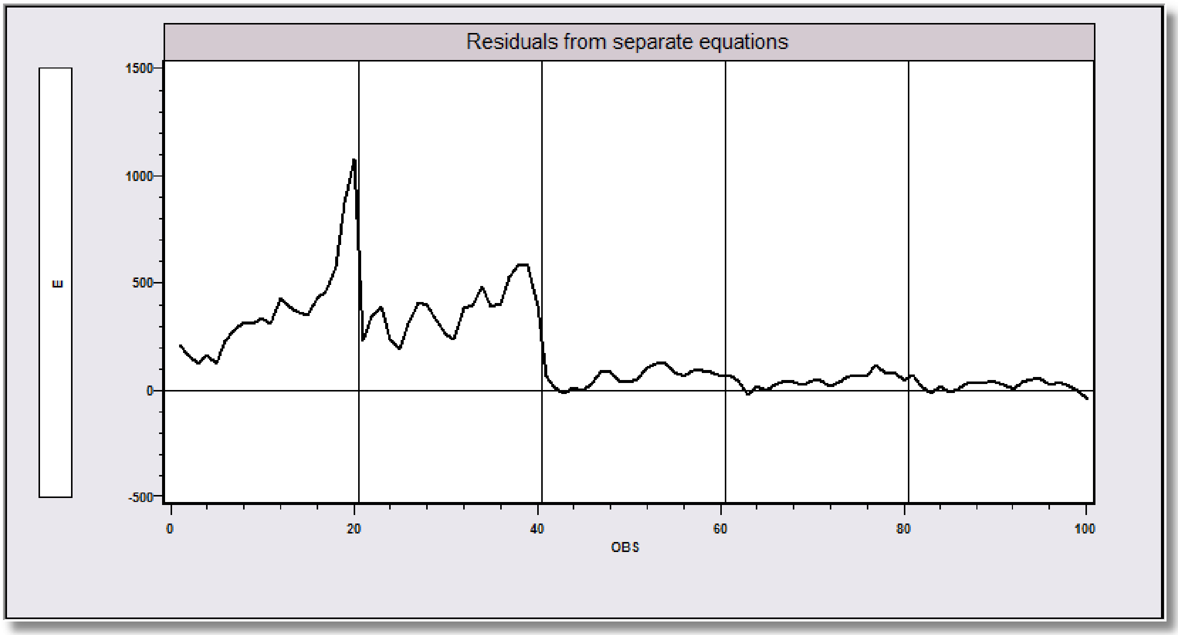

Figure E24.2 Plot of Residuals from Separate Equations

E24.2.6 Technical Details for Generalized Least Squares

The generalized least squares (GLS) approach to estimation is based on the 'stacked' system,

$$\begin{bmatrix} \mathbf{y}_1 \\ \mathbf{y}_2 \\ \vdots \\ \mathbf{y}_M \end{bmatrix} = \begin{bmatrix} \mathbf{X}_1 & \mathbf{0} & \cdots & \mathbf{0} \\ \mathbf{0} & \mathbf{X}_2 & \cdots & \mathbf{0} \\ \vdots & \vdots & \cdots & \vdots \\ \mathbf{0} & \mathbf{0} & \cdots & \mathbf{X}_M \end{bmatrix} \begin{bmatrix} \boldsymbol{\beta}_1 \\ \boldsymbol{\beta}_2 \\ \vdots \\ \boldsymbol{\beta}_M \end{bmatrix} + \begin{bmatrix} \boldsymbol{\varepsilon}_1 \\ \boldsymbol{\varepsilon}_2 \\ \vdots \\ \boldsymbol{\varepsilon}_M \end{bmatrix}$$

or $\quad \mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\varepsilon},$

where $\quad \mathrm{E}[\boldsymbol{\varepsilon}] = \mathbf{0}$

and $\quad \mathrm{E}[\boldsymbol{\varepsilon}\boldsymbol{\varepsilon}'] = \boldsymbol{\Sigma}\otimes\mathbf{I}.$

The GLS estimator is

$$\hat{\boldsymbol{\beta}} = [\mathbf{X}'(\boldsymbol{\Sigma}^{-1}\otimes\mathbf{I})\mathbf{X}]^{-1}[\mathbf{X}'(\boldsymbol{\Sigma}^{-1}\otimes\mathbf{I})\mathbf{y}].$$

The feasible GLS (FGLS) estimator is obtained in two steps. At the first, single equation ordinary least squares is used one equation at a time to compute $\mathbf{b}_i$. Then, $\mathbf{b}_i$ is used to obtain residuals $\mathbf{e}_i$, which are used to compute

$$s_{ij} = \mathbf{e}_i'\mathbf{e}_j / T.$$

FGLS is then computed using this estimator of **Σ**. The estimated asymptotic covariance matrix is the estimate of the inverse matrix in brackets above. If desired, the estimator can then be allowed to iterate to convergence. Convergence is checked at the *i*th iteration using $\text{Max}(|b_k(i)/b_k(i\text{-}1) - 1|) <$ 1.d-9. That is, the largest absolute percentage change in any parameter from one iteration to the next must be less than 1.d-9.

The GLS procedure is based exactly on the textbook formulas. In computing the estimate of **Σ**, we do not make any corrections for degrees of freedom. But, results given with the initial output from the regressions for each equation provide the values needed if you wish to make the correction later. The model results do not include the correlation matrix for the residuals. Since the covariance matrix is kept as *sigma* this can also be computed later. The commands would be:

```
SURE        ; ... $
MATRIX      ; se = Diag (sigma) ; se = Isqr(se) * sigma * Isqr(se) $
```

NOTE: With no constraints imposed, this iterative SURE estimator converges to the maximum likelihood estimator. This is not the case if there are constraints imposed. We will return to this subject below.

In the autocorrelation model, the parameters are estimated twice. In the first pass, the model is fit with no autocorrelation. The autocorrelation coefficients are then estimated using $r_j = 1 - ½DW_j$. In the next pass, the models are fit using the Prais-Winsten transformation – the first observation is transformed by $\sqrt{1-r_j^2}$, not dropped, as it would be for the Cochrane-Orcutt estimator.

E24.3 Maximum Likelihood Estimation of Constrained Linear Systems

The **SURE** command will produce feasible GLS estimates for the multivariate regression model. It can also be allowed to iterate in order to produce maximum likelihood estimates. This does the intended job if there are no restrictions on the parameters. But, if you use the iterated GLS estimator, then impose linear restrictions, (as we did in the previous example) the restricted estimator will be a hybrid of the GLS and MLE, as *LIMDEP* will take the unconstrained MLE and apply the constrained GLS formula to it to get the constrained estimator. Although the unconstrained estimator is MLE, this is not the way to get the constrained MLE. If you have a restricted model, you can use one of the following procedures:

Use **SURE**'s FGLS procedure, with the restrictions, and limit the number of iterations to one. This will obtain the constrained two step GLS estimator (see, e.g., Greene (2011) or Johnston and DiNardo (1997)). But, if you are estimating a translog model or other singular system of demand equations in which you have dropped an equation to achieve nonsingularity, these estimates will not be invariant to which equation you drop. Use the MLE procedure described below.

The following is for models in which the constraints are equalities of the parameters across (or within) equations. (See Greene (2011).) (For other types, use constrained FGLS.) Consider, for example, the following model:

	Variable			
Equation	*one*	x_1	x_2	x_3
y_1	a_1	a_2	a_3	a_4
y_2	a_3		b_1	
y_3	a_4			c_1

This model has eight parameters with two equalities. We view the set of parameters as arranged in a 'parameter matrix,' such as the one in the box above. It has number of rows equal to the number of equations and number of columns equal to the total number of independent variables (including *one*) in the model. The fact that not all variables appear in all equations shows up as empty cells (or zeros) in the matrix. Note the arrangement which implies that each column of the parameter matrix applies to one of the independent variables, and each row corresponds to an equation, or dependent variable.

E24.3.1 Command for ML Estimation of Constrained SURE Systems

To set up such a model, you must inform *LIMDEP* of the dimensions of the problem, what the nonzero values in the parameter matrix are and where they are. Your command does that as follows:

```
SURE        ; Lhs     = list of dependent variables
            ; Rhs     = full list of independent variables
            ; Labels  = the labels to use for the parameters
            ; Pattern = the parameter matrix $
```

Note the following aspects of this command:

- Dimensions of the problem: The number of rows in the parameter matrix equals the number of variables in your Lhs list. The number of columns in the matrix equals the number of variables in your Rhs list.

- The Labels are the names you want to use for the parameters in the model. These may be any symbols with up to five characters. (Anything over five is truncated.) The one exception is that you may not use the '*' character in a label.

- The Pattern is simply a listing of the rows of the parameter matrix, with labels and zeros, moving rowwise through the matrix and separating values with commas. As will be obvious from the examples, the best way to set this up is, literally, to lay out the matrix in the command.

- You may use n*0, e.g., 10*0, where 'n' is from 2 to 50 to provide a string of zeros.

The full command for the example above would be:

```
SURE      ; Lhs     = y1,y2,y3
          ; Rhs     = one,x1,x2,x3
          ; Pattern = a1, a2, a3, a4,
                      a3, 0,  b1, 0,
                      a4, 0,  0,  c1
          ; Labels  = a1, a2, a3, a4, b1, c1 $
```

Note that the pattern matrix automatically (and visually) imposes any equality constraints on the parameters within or across equations. For example, the fact that *a*3 is used in two places in the matrix ensures that this constraint will be imposed.

For laying out the parameter matrix, it will often help to arrange the Rhs list and Pattern list exactly above one another in correspondence. For example, the command for the translog model given earlier, using the same variable names, would be

```
SURE      ; Lhs     = cost,sk,sl
          ; Labels  = a,    cy,    dk,    dl,     tkk,    tll,     tkl,  cyy
          ; Rhs     = one,  lpkf,  lplf,  lpkf2,  lplf2,  lpkfplf, y,    y2
          ; Pattern = a,    dk,    dl,    tkk,    tll,    tkl,     cy,   cyy
                      dk,   tkk,   tkl,           5*0
                      dl,   tkl,   tll,           5*0  $
```

There are no other options for this model.

E24.3.2 Model Output for the Maximum Likelihood Estimator

Model output for the constrained MLE consists of an initial trace of

1. log likelihood function,
2. log determinant of **S**,
3. $\mathbf{g}'\mathbf{H}^{-1}\mathbf{g}$, where **g** = gradient and **H** = Hessian.

We use the last of these as the convergence criterion. This is a scale free measure, which is invariant to the sample size. (See Chapter R9.) Since the likelihood is globally concave, convergence will be fast and monotonic. Moreover, the entire optimization is based on the moments of **X** and **Y** (sums of squares and cross products), so the amount of computation is independent of the sample size. The one pass through the data to obtain the moment matrices will be the only significant amount of time spent.

Remaining output is a display of the pattern matrix and a list of the coefficient estimates, standard errors, and t ratios. The final display is the maximum likelihood estimator of **E**. Results kept by this estimator are the same as for the GLS estimator. The coefficient vector kept is the unconstrained parameter vector, *b* and the estimated asymptotic covariance matrix, *varb*. As before, *sigma* is the estimate of the disturbance covariance matrix. For example, in the first illustration above, the parameter matrix has eight nonzero cells, but only six free parameters. The parameter vector, *b*, would be the six values $[a_1,a_2,a_3,a_4,b_1,c_1]$. Finally, the *Last Model* labels are the ones you provide in your **; Labels** list. A coefficient matrix, *b_sur_ml* is constructed from the estimated parameter vector in the same fashion as described earlier for the GLS estimator.

E24.3.3 Application

The data below will be used to fit a translog cost/demand system. The data are from Berndt and Wood (1975). The authors estimated a model of production in the U.S. manufacturing sector for 1947-1971. The four factors are capital (*K*), labor (*L*), energy (*E*) and materials (*M*). Quantities are denoted '*Q*' while price indices are denoted '*P*.' The output quantity is denoted '*Y*' in the model below. The reader is referred to Greene (2011) or Berndt and Wood (1975) for details on the translog model. For convenience, denote by *k*, *l*, and *e*, the logs of the normalized prices, as in $k = \log(PK/PM)$, and so on. Let *y* denote ln*Y*, *c* denote log(*Total Cost*/*PM*), and S_i denote the cost shares. The equations of the full model are:

$$c = \alpha + \beta_k k + \beta_l l + \beta_e e + \beta_y y + \theta_{yy} y^2 + \delta_k ky + \delta_l ly + \delta_e ey$$
$$+ \gamma_{kk} k^2/2 + \gamma_{kl} kl + \gamma_{ke} ke + \gamma_{ll} l^2/2 + \gamma_{le} le + \gamma_{ee} e^2/2 + \varepsilon_c,$$
$$S_k = \beta_k + \gamma_{kk} k + \gamma_{kl} l + \gamma_{ke} e + \delta_k y + \varepsilon_k,$$
$$S_l = \beta_l + \gamma_{kl} \mathrm{k} + \gamma_{ll} l + \gamma_{le} e + \delta_l y + \varepsilon_l,$$
$$S_k = \beta_k + \gamma_{ke} k + \gamma_{le} l + \gamma_{ee} e + \delta_e y + \varepsilon_e.$$

There are a total of 30 parameters in the model, but 15 constraints leave only 15 free parameters to be estimated.

The following results provide estimates of the full model first. We then test the hypothesis of the cross equation restrictions in the share equations by estimating them as a system without the cost equation, and with and without the cross equation equality restrictions. A likelihood ratio test is used to test the hypothesis (such as it is – without the assumption of the restrictions, the share equations have no theoretical basis).

```
CREATE        ; cost      =  pk*qk + pl*ql + pe*qe + pm*qm
              ; sk        =  pk*qk/cost
              ; sl        =  pl*ql/cost
              ; se        =  pe*qe/cost
              ; sm        =  pm*qm/cost
              ; c         =  Log(cost/pm)

E24.3.4 Technical Details

The maximum likelihood estimator uses Newton's method. Let **Y** denote the $n \times M$ matrix of data on the M Lhs variables specified and let **X** denote the counterpart for the K Rhs variables. All computations are based on moments of the data, so after a single pass through the data set to accumulate $\mathbf{Y}'\mathbf{Y}$, $\mathbf{X}'\mathbf{Y}$, and $\mathbf{X}'\mathbf{X}$, iterations are extremely rapid. Let $\mathbf{\Pi}$ denote the $K \times M$ parameter matrix. $\mathbf{\Pi}$ is the transpose of the matrix defined in the **; Pattern** specification of the **SURE** command. Let **E** denote the $n \times M$ matrix of disturbances. Each row of **E** is the M disturbances for the M equations for the ith observation, $\boldsymbol{\varepsilon}_t$. Then,

$$\mathbf{\Sigma} = E[(1/n)\mathbf{E}'\mathbf{E}].$$

The model is

$$\mathbf{Y} = \mathbf{X\Pi} + \mathbf{E}$$

Let **P** denote any estimate of $\mathbf{\Pi}$. Then, the residuals are

$$\mathbf{U} = \mathbf{Y} - \mathbf{XP}.$$

The sample estimate of $\mathbf{\Sigma}$ will always be

$$\mathbf{W} = (1/n)\mathbf{U}'\mathbf{U}.$$

The concentrated log likelihood function for this model is

$$\begin{aligned}\log L^* &= \text{a constant} - ½ \log \det[(1/n)(\mathbf{Y}\text{-}\mathbf{X\Pi})'(\mathbf{Y}\text{-}\mathbf{X\Pi})] \\ &= \text{a constant} - ½ \log \det(\mathbf{\Omega}).\end{aligned}$$

Note that $\mathbf{\Omega}$ is not equal to $\mathbf{\Sigma}$, though $E[\mathbf{\Omega}]$ equals $\mathbf{\Sigma}$. Finally, define the following matrices:

$$\mathbf{S_{xx}} = (1/n)\mathbf{X}'\mathbf{X}, \ \mathbf{S_{xy}} = (1/n)\mathbf{X}'\mathbf{Y}, \text{ and } \mathbf{S_{yy}} = (1/n)\mathbf{Y}'\mathbf{Y}.$$

For the model being estimated, note that $\mathbf{\Pi}$ has a number of zeros in it, and many of the elements are equal to each other. We will impose these constraints later.

$$\partial \log L^*/\partial\mathbf{\Pi} = (1/n)\mathbf{X}'\mathbf{E}\mathbf{\Omega}^{\mathbf{-1}} = \mathbf{G}^*.$$

Defining $\boldsymbol{\pi}$ to be the column vector obtained by stacking the columns of $\mathbf{\Pi}$, we have

$$\partial^2 \log L^*/\partial\boldsymbol{\pi}\partial\boldsymbol{\pi}' = \mathbf{\Omega}^{-1}\otimes\mathbf{S_{xx}} = \mathbf{H}^*.$$

Let $\boldsymbol{\gamma}$ = vector of Q nonzero elements in $\boldsymbol{\pi}$.

In order to implement Newton's method, we assemble a column vector from $\mathbf{G}^*$ by extracting the elements corresponding to nonzero elements of $\mathbf{\Pi}$. Denote this vector $\mathbf{g}$. Likewise, extract the relevant elements from $\mathbf{H}^*$ into a matrix $\mathbf{H}$ of much smaller dimension. (Rows and columns of $\mathbf{H}^*$ corresponding to zeros in $\mathbf{\Pi}$ are discarded. To impose the equality constraints in $\mathbf{\Pi}$, define $\boldsymbol{\beta}$ to be the unique, free parameters in the model. Thus, there are, say, J elements in $\boldsymbol{\beta}$. There are, say, Q elements in $\boldsymbol{\gamma}$, and $Q \geq J$. Several elements in $\boldsymbol{\gamma}$ may equal the same element of $\boldsymbol{\beta}$. Define the matrix $\mathbf{K}$ such that

$$\mathbf{K}_{ij} = 1 \text{ if } \gamma_i = \beta_j \text{ and 0 otherwise.}$$

Therefore, $\mathbf{K}$ has L rows and J columns. Every row contains a single one and J-1 zeros. Finally

$$\partial \log L^*/\partial\boldsymbol{\beta} = \mathbf{K}'\mathbf{g}$$

and

$$\partial^2 \log L^*/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' = \mathbf{K}'\mathbf{HK}.$$

These give the necessary elements for the Newton iterations.

E24.4 Instrumental Variables (3SLS) Estimation of a Set of Linear Equations

The setup for three stage least squares (3SLS) is identical to that for the GLS (not the maximum likelihood) estimator for the SURE model as shown in Section E25.2. The only change is the addition of a set of instrumental variables to the command. The command is

```
3SLS    ; Lhs  = y1,y2,...,ym
        ; Eq1  = list of Rhs variables in first equation
        ; Eq2  = list of Rhs variables in second equation
        ...
        ; EqM  = list of Rhs variables in Mth equation (up to 20 equations)
        ; Inst = complete list of exogenous variables $
```

The list of exogenous variables should include all of the exogenous variables appearing on the right hand sides of the equations of the model (only once in the list) and may include any other variables as well.

This estimator is obtained by first regressing all variables on the right hand side of each equation on all of the variables in the list of instruments and retaining the fitted values. Any variable in an Eqn list which appears in the Inst list as well is reproduced exactly since in this event, this first stage regression produces a perfect fit with a coefficient of one on that variable and zeros for all the others. Thereafter, the procedure is identical to the SURE procedure. Note, the fitted variables are not actually created; only the necessary sample moments using the fitted values where appropriate are physically retained for the computations.

After estimation, the disturbance covariance matrix is estimated using the original variables, not the fitted ones. This procedure can be allowed to iterate by specifying

```
        ; Maxit = maximum
```

If you do not provide this, the default is one iteration. To obtain Zellner's three stage least squares estimator, use

```
        ; Maxit = 0
```

Do note, iterated 3SLS does not bring gains in efficiency and does not produce an MLE. Moreover, iterated 3SLS frequently differs dramatically from 2SLS.

Application to Klein's Model I

We continue the example of Section E21.2 with

```
3SLS    ; Lhs = c,i,wp
        ; Eq1 = cons ; Eq2 = invs ; Eq3 = wage
        ; Inst = exog
        ; Maxit = 0 $
```

The iteration produces the trace:

```
Iteration    0, maximum |Δb/b|=    1.000000
Iteration    1, maximum |Δb/b|=    6.218180
```

The model output is as follows:

```
Criterion function is max(abs(%chg in b(i))).
Iteration    0, 3SLS          =    1.000000
Iteration    1, 3SLS          =    6.218180

E25: Nonlinear Systems of Regression Equations

E25.1 Introduction

This chapters present methods of estimating the parameters of the regression system

$$y_1 = f_1(\mathbf{x}_1,\boldsymbol{\beta}) + \varepsilon_1$$

$$y_2 = f_2(\mathbf{x}_2,\boldsymbol{\beta}) + \varepsilon_2$$

$$\ldots$$

$$y_M = f_M(\mathbf{x}_M,\boldsymbol{\beta}) + \varepsilon_M$$

or

$$\mathbf{y} = \mathbf{f}(\mathbf{X},\boldsymbol{\beta}) + \boldsymbol{\varepsilon},.$$

We assume $E[\boldsymbol{\varepsilon}|\text{all } \mathbf{x}] = \mathbf{0}$ and $E[\boldsymbol{\varepsilon\varepsilon}'|\text{all } \mathbf{x}] = \boldsymbol{\Sigma}$.

As stated, the model is a possibly nonlinear system of seemingly unrelated regressions. However, for some settings, the **x** vectors on the right hand sides of the equations may include endogenous variables, y_j, from other equations. That is, we also accommodate systems of simultaneous equations.

The system may contain up to 50 equations and up to 150 unique parameters. As defined, there is a single parameter vector, $\boldsymbol{\beta}$, to be estimated, though subsets of parameters can appear in each equation, and this is just a notational convenience. Estimates of the elements of $\boldsymbol{\Sigma}$ are also obtained.

The estimation procedures available for this model are:

- Nonlinear OLS, equation by equation (NLOLS): $\boldsymbol{\Sigma} = \text{diag}(\sigma_1,\ldots,\sigma_M)$
- Nonlinear equation by equation instrumental variables (NL2SLS)
- Nonlinear GLS (NLSUR): $\boldsymbol{\Sigma}$ = a full positive definite matrix
- Nonlinear GLS with instrumental variables (NL3SLS)
- Multiple equation GMM

The cases in which $\boldsymbol{\Sigma}$ is diagonal and there are no cross equation restrictions or equalities will replicate the nonlinear least squares and nonlinear instrumental variables equations estimators described earlier. The reasons that you might use this estimator in these cases are, first, estimating the equations jointly, even if uncorrelated, will be faster and, second, with this estimator, you can impose cross equation restrictions.

E25.2 Nonlinear Systems – The NLSUR Command

The essential command for the nonlinear system shown above is

NLSUR ; Lhs = ... the list of dependent variables
; Fn1 = ... the first equation
; Fn2 = ... the second equation
...
; FnM = ... the last equation (up to 20 equations)
; Labels = ... a list of labels for the parameters
; Start = ... the starting values for the iterations $

This setup is for a full, unrestricted Σ, which is estimated as part of the estimation process. The setup for the functions is exactly that shown in Section E14.3. All of the elements, functions, etc., shown there apply fully to these equation definitions. Note, as well that the parameters defined by the labels may appear anywhere in any equation, without restriction. That is, there is no presumption that any particular parameter applies to or belongs in any specific equation. Every equation is assumed to involve some or all of the parameters.

NOTE: The recursion feature and user supplied derivatives feature, both described in Section E14.5 are *not* supported for the **NLSUR** command.

The command shown above specifies a set of Lhs variables. The estimation criterion function will be based on the implied residuals,

$$e_j = y_j - Fn_j$$

(for example, the sums of squares). You may, instead, use the functions to define the 'residuals' directly, and omit the Lhs definition. This will be useful in specifying the GMM estimator, in which the orthogonality conditions may involve functions more complicated than a simple residual. For present purposes, then, let $\varepsilon_j(\boldsymbol{\beta})$ denote the residual defined above if you have included a **; Lhs** specification in your command. Otherwise, $\varepsilon_j(\boldsymbol{\beta})$ is $Fn_j(\boldsymbol{\beta})$. Let 't' index the T sample observations where needed. Let

$\boldsymbol{\varepsilon}_t(\boldsymbol{\beta})$ = the column vector of M residuals for observation t.

Let $\mathbf{E}_j(\boldsymbol{\beta})$ = the column vector of T residuals for equation j.

To specify the different estimation criteria, your command should appear as follows: (Since the criteria are all quadratic, the multiplication of each by ½ removes an inconvenient 2 from the derivatives. There is no other significance to this scaling.)

NOTE: Any of the following may include **; Wts = a weighting variable**, in which case, all sums of observations are computed using this weighting variable.

E25.2.1 OLS Estimation, Equation by Equation (NLOLS)

Include **; Sigma = I** in your command. In this case, the estimation criterion is

$$F = \tfrac{1}{2}\,\Sigma_i \boldsymbol{\varepsilon}_i{}'\boldsymbol{\varepsilon}_i = \tfrac{1}{2}\,\Sigma_i\Sigma_m \varepsilon_{im}{}^2 = \tfrac{1}{2}\,\Sigma_m \mathbf{E}_m(\boldsymbol{\beta})'\mathbf{E}_m(\boldsymbol{\beta}).$$

This is the sum of the sums of squares for each equation. If there are no cross equation equalities (i.e., no parameter name appears in more than one equation), then this is the same as using **NLSQ** once for each equation. If, in addition, all equations are linear, this will be the same as **REGRESS**, equation by equation.

```
NLSUR    ; Lhs    = ... the list of dependent variables
         ; Fn1    = ... the first equation
         ; Fn2    = ... the second equation
         ...
         ; FnM    = ... the last equation (up to 20 equations)
         ; Labels = ... a list of labels for the parameters
         ; Start  = ... the starting values for the iterations
         ; Sigma  = I  $
```

E25.2.2 Weighted Least Squares, Equation by Equation (NLWLS)

Include **; Sigma = D** in your command for a 'diagonal' disturbance covariance matrix. The estimation criterion is the weighted sum of squares,

$$F = \tfrac{1}{2}\,\Sigma_m (1/\sigma_m{}^2)\mathbf{E}_m(\boldsymbol{\beta})'\mathbf{E}_m(\boldsymbol{\beta}).$$

This is a groupwise heteroscedastic regression model. If there are no cross equation equalities, this will, once again, be the same as **NLSQ** equation by equation. If, in addition, the equations are all linear, this will be the same as model (S1,R0) in the **TSCS** model.

```
NLSUR    ; Lhs    = ... the list of dependent variables
         ; Fn1    = ... the first equation
         ; Fn2    = ... the second equation
         ...
         ; FnM    = ... the last equation (up to 20 equations)
         ; Labels = ... a list of labels for the parameters
         ; Start  = ... the starting values for the iterations
         ; Sigma  =  D  $
```

E25.2.3 IV Estimation, Equation by Equation (NL2SLS)

Include **; Sigma = I** and **; Inst = list of instrumental variables** in the command. Then,

$$F = ½ \Sigma_m \mathbf{E}_m(\beta)'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{E}_m(\beta).$$

This is the sum of the 2SLS criteria for the *M* equations. If there are no cross equation equalities, this will be the same as using **NLSQ ; Inst = ...** once for each equation. If, in addition, all equations are linear, this is the same as 2SLS equation by equation.

```
NLSUR    ; Lhs    = ... the list of dependent variables
         ; Fn1    = ... the first equation
         ; Fn2    = ... the second equation
         ...
         ; FnM    = ... the last equation (up to 20 equations)
         ; Labels = ... a list of labels for the parameters
         ; Start  = ... the starting values for the iterations
         ; Sigma  = I
         ; Inst   = list of instrumental variables $
```

(There must be at least as many instrumental variables as there are parameters in the model.)

E25.2.4 Weighted IV Estimation, Equation by Equation (WNL2SLS)

Include **; Sigma = D** and **; Inst = list of instrumental variables** in the command. Then,

$$F = ½ \Sigma_m (1/\sigma_m^2)\mathbf{E}_m(\beta)'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{E}_m(\beta).$$

This is the sum of the 2SLS criteria for the *M* equations, each weighted by its own variance. This is, once again, a groupwise heteroscedastic model. If there are no cross equation equalities, this would be the same as using **NLSQ ; Inst = ...** once for each equation. If all equations are linear, it is the same as 2SLS, equation by equation.

```
NLSUR    ; Lhs    = ... the list of dependent variables
         ; Fn1    = ... the first equation
         ; Fn2    = ... the second equation
         ...
         ; FnM    = ... the last equation (up to 20 equations)
         ; Labels = ... a list of labels for the parameters
         ; Start  = ... the starting values for the iterations
         ; Sigma  = D
         ; Inst   = list of instrumental variables $
```

E25.2.5 Nonlinear GLS Estimation (NLSURE)

The command is the one shown at the beginning of this section. I.e., no specification of *sigma*. (This is the default model.) The estimation criterion is

$$F = \tfrac{1}{2}\, \Sigma_m \Sigma_n \sigma^{mn} \mathbf{E}_m(\boldsymbol{\beta})' \mathbf{E}_n(\boldsymbol{\beta}),$$

where σ^{ij} is the ijth element of $\boldsymbol{\Sigma}^{-1}$. This is the nonlinear counterpart to the SURE estimator of Sections E24.2 and E24.3. If all equations are linear and there are no constraints, this will be the same as the SURE estimator in Section E24.2. If there are cross equation equality constraints, it is the MLE of Section E24.3.

```
NLSUR     ; Lhs    = ... the list of dependent variables
          ; Fn1    = ... the first equation
          ; Fn2    = ... the second equation
          ...
          ; FnM    = ... the last equation (up to 20 equations)
          ; Labels = ... a list of labels for the parameters
          ; Start  = ... the starting values for the iterations $
```

(There must be at least as many instrumental variables as there are parameters in the model.)

E25.2.6 Nonlinear IV Systems Estimation (NL3SLS)

Specify only **; Inst = list of instrumental variables** but do not specify **; Sigma**. In this case, the estimation rule is

$$F = \tfrac{1}{2}\, \Sigma_m \Sigma_n \sigma^{mn} \mathbf{E}_m(\boldsymbol{\beta})' \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1} \mathbf{Z}' \mathbf{E}_n(\boldsymbol{\beta}).$$

This is the nonlinear counterpart to the 3SLS estimator described in Section E24.4.

```
NLSUR     ; Lhs    = ... the list of dependent variables
          ; Fn1    = ... the first equation
          ; Fn2    = ... the second equation
          ...
          ; FnM    = ... the last equation (up to 20 equations)
          ; Labels = ... a list of labels for the parameters
          ; Start  = ... the starting values for the iterations
          ; Inst   = list of instrumental variables $
```

E25.2.7 GMM Estimation (GMM)

Include **; Inst = list of instrumental variables** and **; Pds = number for weighting matrix** in the command. The number of periods is needed to compute the weighting matrix for GMM estimation. The estimation criterion for GMM estimation is

$$F = ½ \Sigma_m \Sigma_n \mathbf{E}_m(\boldsymbol{\beta})'\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Omega}_{mn}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{E}_n(\boldsymbol{\beta})$$

where $$\boldsymbol{\Omega}_{mn} = \mathbf{E}[(1/T)\Sigma_t \varepsilon_{tm}\varepsilon_{tn}\mathbf{z}_t\mathbf{z}_t'].$$

Note that the full $\boldsymbol{\Omega}$ contains M^2 blocks, none of which are assumed to be empty. This matrix must be estimated using the starting values.

```
NLSUR   ; Lhs    = ... the list of dependent variables
        ; Fn1    = ... the first equation
        ; Fn2    = ... the second equation
        ...
        ; FnM    = ... the last equation (up to 20 equations)
        ; Labels = ... a list of labels for the parameters
        ; Start  = ... the starting values for the iterations
        ; Inst   = list of instrumental variables
        ; Pds    = number of periods for Newey-West (may be 0) $
```

E25.2.8 Weighting Observations in Equation Systems

You may, if you wish, superimpose a weighting scheme on all of the preceding with

; Wts = weighting variable

This is the usual weighting procedure, but there is no assumption that the weights are observation specific variances; they may just be replication factors, or any other form of weight that you wish to apply. In any event, weights are still scaled to sum to N unless you suppress this with **; Wts = ...,Noscale**. Note, however, that the way that weights will be applied depends on the estimation criterion. In all cases, the weight is applied to the term in a sum. Thus, in NLOLS, with **; Wts** in use, the criterion becomes $½ \Sigma_i w_i \Sigma_m \varepsilon_{im}^2$, whereas in the various IV procedures, which are not simple sums of terms such as this, the weights are applied to the summations in the moment matrices. To consider an example, let **W** denote a diagonal matrix with your weights on the diagonal. In NL2SLS, the estimation criterion becomes

$$F = ½\Sigma_m \mathbf{E}_m(\boldsymbol{\beta})'\mathbf{WZ}(\mathbf{Z}'\mathbf{WZ})^{-1}\mathbf{Z}'\mathbf{WE}_m(\boldsymbol{\beta}).$$

(Of course, we do not actually create the diagonal matrix internally.) The other estimators are constructed likewise.

E25.2.9 Model Specifications for the NLSUR Procedure

This is the full list of general specifications that are applicable to this model estimator.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, BFGS is the default.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays **S** in the output.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.
; Fix = list fixes the named parameters at the starting values.

Note that with **; Maxit = 0**, this is not necessarily an LM test at all, since the disturbances in these models are not assumed to be normally distributed, and, even if they were, the estimation criteria listed above are not the log likelihood functions in most cases. As such, **; Maxit = 0** is best viewed as a useful descriptive device that allows you to examine your model for a fixed set of parameters. (Note, as well, that **; Maxit = 0** is the same as **; Fix All**, but provides more useful information.)

E25.3 Output and Saved Results from NLSUR

The output from this procedure is largely the same as that from **NLSQ**. The saved results are:

Matrices:	*b*	= the estimated parameter vector
	varb	= asymptotic covariance matrix
	sigma	= estimate of **Σ**
Scalars:	*kreg*	= the number of parameters in the model
	nreg	= the number of observations
	logl	= the value of the criterion function

Last Model: The labels are those in your **; Labels** list

Last Function: None

Results from the procedure will include the initial table reporting the procedure used, the number of iterations completed, and so on. *The 'log likelihood' reported is actually the minimized criterion function, not a true log likelihood.* This is followed by the table of estimates, estimated standard errors, and so on. If you have specified a **; Lhs** list, an additional table will give a listing of the Lhs variables, means and standard deviations, and sum of squared residuals and an R^2 for each equation.

NOTE: This R^2 is not bounded in [0,1] because the fitting criterion is not linear ordinary least squares with a constant term.

When you provide a set of Lhs variables for an NLSURE model, the diagnostic output will also include McElroy's R^2 measure for the system. This is computed as

$$R_m^2 = \sum_s \sum_t \sigma^{st} (1/n) \sum_{i=1}^{n} (y_{is} - \bar{y}_s)(y_{it} - \bar{y}_t) = \text{tr}(\mathbf{S}^{-1}\mathbf{V}_{\mathbf{y}})$$

where $\mathbf{V}_y$ is the sample covariance matrix for the Lhs variables.

There are no residuals or fitted values from this procedure. The parameters are retrievable, however, so you can construct these with **CREATE**.

E25.4 Application

To illustrate use of this estimator, we will estimate a system of linear equations. The procedure does not differentiate between linear and nonlinear systems, so this illustrates the full procedure. We have in hand the first 100 observations in the Grunfeld data used in Chapter E15.

```
SAMPLE      ; 1-100$
CREATE      ; igm= i        ; fgm= f        ; cgm = c
            ; ich  = i[+20] ; fch  = f[+20] ; cch  = c[+20]
            ; ige  = i[+40] ; fge  = f[+40] ; cge  = c[+40]
            ; iwe = i[+60] ; few = f[+60] ; cwe  = c[+60]
            ; ius  = i[+80] ; fus  = f[+80] ; cus  = c[+80] $
NAMELIST    ; xgm = one,fgm,cgm
            ; xch  = one,fch,cch
            ; xge  = one,fge,cge
            ; xwe = one,fwe,cwe
            ; xus  = one,fus,cus
            ; y = igm,ich,ige,iwe,ius $
SAMPLE      ; 1-20 $
NLSUR       ; Lhs = y
            ; Fn1 = b0'xgm ; Fn2=b0'xch ; Fn3=b0'xge ; Fn4=b0'xwe ; Fn5=b0'xus
            ; Start = 0,0,0 ; Labels = b0,b1,b2 ; Sigma = I $
NLSUR       ; Lhs = y
            ; Fn1 = b0'xgm ; Fn2=b0'xch ; Fn3=b0'xge ; Fn4=b0'xwe ; Fn5=b0'xus
            ; Start = 0,0,0 ; Labels = b0,b1,b2 ; Sigma = D $
NLSUR       ; Lhs = y
            ; Fn1 = b0'xgm ; Fn2=b0'xch ; Fn3=b0'xge ; Fn4=b0'xwe ; Fn5=b0'xus
            ; Start = 0,0,0 ; Labels = b0,b1,b2 $
```

The equations are linear, with cross equation equality restrictions. The three commands will reestimate models (S0,R0), (S1,R0), and (S2,R0), from Section E15.3, respectively. Note that, as discussed in the next section, the estimated standard errors differ from those given previously. Moreover, in the more complex models, the parameter estimates differ slightly as well. This is due, in part to the convergence rule used for **NLSURE**, which does not use the actual second derivatives and, thus, does not find the exact minimizer of the criterion, as **TSCS** does and, second, because **NLSUR** does not necessarily converge to exactly the same estimate of $\mathbf{\Sigma}$.

The first set of results is equivalent to pooled least squares. The OLS results are shown as well. Note that although the parameter estimates are identical, the standard errors are noticeably different. The reason for this difference is the method of computation of the covariance matrix in the NLSUR case. The routine minimizes

$$F = \Sigma_i \mathbf{e}(\boldsymbol{\beta})'\mathbf{e}(\boldsymbol{\beta})/2 = (1/2)\Sigma_i \Sigma_m e_{im}(\boldsymbol{\beta})^2$$

where each derivative vector is five (for this case, M in general) by one. The covariance matrix used is then based on

$$\text{BHHH} = \{\Sigma_i \Sigma_m [e_{im}(\boldsymbol{\beta})]^2 \mathbf{x}_{im}\mathbf{x}_{im}'\}^{-1}.$$

This matrix will be approximately equal to $(1/\sigma^2)(\mathbf{X'X})^{-1}$ under the assumption that the disturbances have the common variance σ^2 and that they are independent of the pseudoregressors. Since it is known from the specification that you have specified **I** as the covariance matrix, this matrix is then scaled by the square of an estimator of this common variance; in this case that will be $(\sigma^2)^2$. In large samples, this will give the same answer as the more familiar estimator. But, in a finite sample, such as the one of 20 observations here, the results will differ noticeably.

Note, as well, the diagnostic about unusually fast convergence that appears with the output. The reason that this estimation converged so quickly is that the equations are linear. The routine has not examined the equation specifications to discover this, so the warning is the routine one that shows up when a nonlinear optimization problem reaches convergence more quickly than expected.

```
Note: DFP and BFGS usually take more than 4 or 5
iterations to converge.  If this problem was not
structured for quick convergence, you might want
to examine results closely. If convergence is too
early, tighten convergence with, e.g., ;TLG=1.D-9.
Normal exit:   5 iterations. Status=0, F=    831549.4

The second set of results is based on an assumption that the system is groupwise heteroscedastic. In this case, the results differ from the results of the TSCS approach only in that there is a slight difference in the diagonal covariance matrix used in estimation. Note, to make these comparable, the TSCS procedure must be iterated. The results are shown below.

```
Note: DFP and BFGS usually take more than 4 or 5
iterations to converge.  If this problem was not

E25.5 Technical Details

The various estimation criteria listed above will replicate other settings when certain restrictions are in place. For example, NLOLS with no cross equation restrictions in place and linear equations is the same as TSCS. In these cases, the estimator will usually produce the same parameter estimates, but may produce slightly, or in a small sample, noticeably different standard errors. The reason is that the linear estimators (**REGRESS, TSCS, 2SLS**) use (in principle) the actual second derivatives matrices of their estimation criteria. But, **NLSUR** always uses the outer products of the first derivatives to accumulate its estimate of the asymptotic covariance matrix. These will normally be reasonably close to each other, but, as noted, in a finite sample, they can differ.

For estimation of the systems in which $\boldsymbol{\Sigma}$ is not $\sigma^2\mathbf{I}$, we use a straightforward two level iteration. The procedure is as follows:

Step 1. At entry, set $\boldsymbol{\Sigma}$ either to $\mathbf{I}$ or to the matrix you supply with **; Sigma = name**.

Step 2. Obtain the parameter estimates conditioned on this estimate of $\boldsymbol{\Sigma}$.

Step 3. Use the parameter estimates to recompute $\boldsymbol{\Sigma}$.

Step 4. Assess convergence based on the log determinant of the estimated $\boldsymbol{\Sigma}$. If the change is less than 10^{-4}, exit. If there are more than 20 iterations on $\boldsymbol{\Sigma}$, exit on maximum iterations. Else, return to Step 2.

E26: Models for Binary Choice

E26.1 Introduction

We define models in which the response variable being described is inherently discrete as qualitative response (QR) models. This and the next several chapters will describe *LIMDEP*'s qualitative dependent variable model estimators. The simplest of these are the binomial choice models, which are the subject of this chapter and Chapters E27-E29. This will be followed by the progressively more intricate formulations such as bivariate and multivariate probit, multinomial logit, ordered choice and models for count data. *LIMDEP* supports a large variety of models and extensions for the analysis of binary choice. The parametric model formulations, probit, logit, extreme value (complementary log log) etc. are treated in Chapter E27. Panel data models for binary choice appear in Chapters E30 and E31. Semi- and nonparametric models appear in Chapter E32.

There are numerous references for practitioners using the binary choice modeling framework. Four which are widely used are Maddala (1983), Greene (2011), Long (1997) and DeMaris (2004). Another recent source is for binary choice modeling is Greene and Hensher (2010, Chapters 1-4).

E26.2 Modeling Binary Choice

A binomial response may be the outcome of a decision or the response to a question in a survey. Consider, for example, survey data which indicate political party choice, mode of transportation, occupation, or choice of location. We model these in terms of probability distributions defined over the set of outcomes. There are a number of interpretations of an underlying data generating process that produce the binary choice models we consider here. All of them are consistent with the models that *LIMDEP* estimates, but the exact interpretation is a function of the modeling framework.

E26.2.1 Underlying Processes

Consider a process with two possible outcomes indicated by a *dependent variable*, y, labeled for convenience, $y = 0$ and $y = 1$. We assume, as well, that there is a set of measurable *covariates*, x, which will be used to help explain the occurrence of one outcome or the other. Most models of binary choice set up in this fashion will be based upon an *index function*, $\boldsymbol{\beta}'\mathbf{x}$, where $\boldsymbol{\beta}$ is a vector of parameters to be estimated. The modeling of discrete, binary choice in these terms, is typically done in one of the following frameworks:

Random Utility Approach

The respondent derives utility

$$U_0 = \boldsymbol{\beta}_0'\mathbf{x} + \varepsilon_0 \text{ from choice 0, and } U_1 = \boldsymbol{\beta}_1'\mathbf{x} + \varepsilon_1 \text{ from choice 1,}$$

in which ε_0 and ε_1 are the individual specific, random components of the individual's utility that are unaccounted for by the measured covariates, **x**. The choice of alternative 1 reveals that $U_1 > U_0$, or that

$$\varepsilon_0 - \varepsilon_1 < \boldsymbol{\beta}_1'\mathbf{x} - \boldsymbol{\beta}_0'\mathbf{x}.$$

Let $\varepsilon = \varepsilon_0 - \varepsilon_1$ and let $\boldsymbol{\beta}'\mathbf{x}$ represent the difference on the right hand side of the inequality – **x** is the union of the two sets of covariates, and $\boldsymbol{\beta}$ is constructed from the two parameter vectors with zeros in the appropriate locations if necessary. Then, the binary choice model applies to the probability that $\varepsilon \leq \boldsymbol{\beta}'\mathbf{x}$, which is the familiar sort of model shown in the next paragraph. This is a convenient way to view migration behavior and survey responses to questions about economic issues.

Latent Regression Approach

A latent regression is specified as

$$y^* = \boldsymbol{\beta}'\mathbf{x} + \varepsilon.$$

The observed counterpart to y^* is

$$y = 1 \text{ if and only if } y^* > 0.$$

This is the basis for most of the binary choice models in econometrics, and is described in further detail below. It is the same model as the reduced form in the previous paragraph. Threshold models, such as labor supply and reservation wages lend themselves to this approach.

Conditional Mean Function Approach

We assume that y is a binary variable, taking values 0 and 1, and formulate a priori that $\text{Prob}[y=1] = F(\boldsymbol{\beta}'\mathbf{x})$, where F is any function of the index that satisfies the axioms of probability,

$$0 \leq F(\boldsymbol{\beta}'\mathbf{x}) \leq 1$$

$$F'(\boldsymbol{\beta}'\mathbf{x}) \geq 0,$$

$$\lim_{z\downarrow -\infty} F(z) = 0, \lim_{z\uparrow +\infty} F(z) = 1.$$

It follows that, $$F(\boldsymbol{\beta}'\mathbf{x}) = 0 \times \text{Prob}[y = 0 \mid \mathbf{x}] + 1 \times \text{Prob}[y = 1 \mid \mathbf{x}]$$

is the conditional mean function for the observed binary y. This may be treated as a nonlinear regression or as a binary choice model amenable to maximum likelihood estimation. This is a useful departure point for less parametric approaches to binary choice modeling.

E26.2.2 Modeling Approaches

This and the next several chapters document three approaches to formulating the binary choice models described above:

Parametric Models – Probit, Logit, Extreme Value, Gompertz, Burr, Arctangent

Most of the material below (and the received literature) focuses on models in which the full functional form, including the probability distribution, are defined a priori. Thus, the probit model which forms the basis of most of the results in econometrics, is based on a latent regression model in which the disturbances are assumed to have a normal distribution. The logit model, in contrast, can be construed as a random utility model in which it is assumed that the random parts of the utility functions are distributed as independent extreme value. The complementary log log model arises as the natural distribution in a setting of counts of occurrences (such as part failures or numbers of arrivals of messages at a receiving center) in which the analyst is interest in modeling not the number of occurrences, but whether none or any events have occurred. The Burr distribution allows asymmetry in the logit framework. Finally, the Arctangent model provides a flexible, interesting functional form.

Semiparametric Models – Maximum Score, Semiparametric Analysis

A semiparametric approach to modeling the binary choice steps back one level from the previous model in that the specific distributional assumption is dropped, while the covariation (index function) nature of the model is retained. Thus, the semiparametric approach analyzes the common characteristics of the observed data which would arise regardless of the specific distribution assumed. Thus, the semiparametric approach is essentially the conditional mean framework without the specific distribution assumed. For the models that are supported in *LIMDEP*, MSCORE and Klein and Spady's framework, it is assumed only that $F(\boldsymbol{\beta}'\mathbf{x})$ exists and is a smooth continuous function of its argument which satisfies the axioms of probability. The semiparametric approach is more general (and more robust) than the parametric approach, but it provides the analyst far less flexibility in terms of the types of analysis of the data that may be performed. In a general sense, the gain to formulating the parametric model is the additional precision with which statements about the data generating process may be made. Hypothesis tests, model extensions, and analysis of, e.g., interactions such as marginal effects, are difficult or impossible in semiparametric settings.

Nonparametric Analysis – NPREG

The nonparametric approach, as its name suggests, drops the formal modeling framework. It is largely a bivariate modeling approach in which little more is assumed than that the probability that y equals one depends on some x. (It can be extended to a latent regression, but this requires prior specification and estimation, at least up to scale, of a parameter vector.) The nonparametric approach to analysis of discrete choice is done in *LIMDEP* with a kernel density (largely based on the computation of histograms) and with graphs of the implied relationship. Nonparametric analysis is, by construction, the most general and robust of the techniques we consider, but, as a consequence, the least precise. The statements that can be made about the underlying DGP in the nonparametric framework are, of necessity, very broad, and usually provide little more than a crude overall characterization of the relationship between a y and an x.

E26.2.3 The Linear Probability Model

One approach to modeling binary choice has been to ignore the special nature of the dependent variable, and use conventional least squares. The resulting model,

$$\text{Prob}[y_i = 1] = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i$$

has been called the linear probability model (LPM). The LPM is known to have several problems, most importantly that the model cannot be made to satisfy the axioms of probably independently of the particular data set in use. Some authors have documented approaches to forcing the LPM on the data, e.g., Fomby, et al., (1984), Long (1997) and Angrist and Pischke (2009). These computations can easily be done with the other parts of *LIMDEP*, but will not be pursued here.

E26.3 Grouped and Individual Data for Binary Choice Models

There are two types of data which may be analyzed. We say that the data are *individual* if the measurement of the dependent variable is physically discrete, consisting of individual responses. The familiar case of the probit model with measured 0/1 responses is an example. The data are *grouped* if the underlying model is discrete but the observed dependent variable is a proportion. In the probit setting, this arises commonly in bioassay. A number of respondents have the same values of the independent variables, and the observed dependent variable is the proportion of them with individual responses equal to one. Voting proportions are a common application from political science.

All of the qualitative response models estimated by *LIMDEP* can be estimated with either individual or grouped data. You do not have to inform the program which type you are using; if necessary, the data are inspected to determine which applies. The differences arise only in the way starting values are computed and, occasionally, in the way the output should be interpreted. Cases sometimes arise in which grouped data contain cells which are empty (proportion is zero) or full (proportion is one). This does not affect maximum likelihood estimation and is handled internally in obtaining the starting values. No special attention has to be paid to these cells in assembling the data set.

E26.4 Variance Normalization

In the latent regression formulation of the model, the observed data are generated by the underlying process

$$y = 1 \text{ if and only if } \boldsymbol{\beta}'\mathbf{x} + \varepsilon > 0.$$

The random variable, ε, is assumed to have a zero mean (which is a simple normalization if the model contains a constant term). The variance is left unspecified. The data contain no information about the variance of ε. Let σ denote the standard deviation of ε. The same model and data arise if the model is written as

$$y = 1 \text{ if and only if } (\boldsymbol{\beta}/\sigma)'\mathbf{x} + \varepsilon/\sigma > 0.$$

which is equivalent to

$$y = 1 \text{ if and only if } \boldsymbol{\gamma}'\mathbf{x} + w > 0.$$

where the variance of w equals one. Since only the sign of y is observed, no information about overall scaling is contained in the data. Therefore, the parameter σ is not estimable; it is assumed with no loss of generality to equal one. (In some treatments (Horowitz (1993)), the constant term in β is assumed to equal one, instead, in which case, the 'constant' in the model is an estimator of $1/\sigma$. This is simply an alternative normalization of the parameter vector, not a substantive change in the model.)

E26.5 The Constant Term in Index Function Models

A question that sometimes arises is whether the binary choice model should contain a constant term. The answer is yes, unless the underlying structure of your model specifically dictates that none be included. There are a number of useful features of the parametric models that will be subverted if you do not include a constant term in your model:

- Familiar fit measures will be distorted. Indeed, omitting the constant term can seriously degrade the fit of a model, and will never improve it.

- Certain useful test statistics, such as the overall test for the joint significance of the coefficients, may be rendered noncomputable if you omit the constant term.

- Some properties of the binary choice models, such as their ability to reproduce the average outcome (sample proportion) will be lost.

Forcing the constant term to be zero is a linear restriction on the coefficient vector. Like any other linear restriction, if imposed improperly, it will induce biases in the remaining coefficients. (Orthogonality with the other independent variables is not a salvation here. Thus, putting variables in mean deviation form does not remove the constant term from the model as it would in the linear regression case.)

E27: Probit and Logit Models: Estimation

E27.1 Introduction

We define models in which the response variable being described is inherently discrete as qualitative response (QR) models. This and the next several chapters will describe *LIMDEP*'s qualitative dependent variable model estimators. The simplest of these are the binomial choice models, which are the subject of this chapter and Chapters E28 and E29. This will be followed by the progressively more intricate formulations such as bivariate and multivariate probit, multinomial logit, ordered choice and models for count data.

LIMDEP supports a large variety of models and extensions for the analysis of binary choice. The parametric model formulations, probit, logit, extreme value (complementary log log) etc. are treated in this chapter. Several model extensions such as models with endogenous variables, and sample selection, are treated in Chapter E29. Panel data models for binary choice appear in Chapters E30 and E31. Semi- and nonparametric models are documented in Chapter E32.

E27.2 Parametric Models for Binary Choice

LIMDEP supports six parametric functional forms for binary choice models. The basic model commands for the six models are:

$$\left.\begin{array}{c}\textbf{PROBIT}\\ \textbf{LOGIT}\\ \textbf{ARCTANGENT}\\ \textbf{GOMPERTZ}\\ \textbf{COMPLOGLOG}\\ \textbf{BURR}\end{array}\right\}\ \textbf{; Lhs = dependent variable ; Rhs = regressors \$}$$

Data on the dependent variable may be either individual or proportions for all six cases.

E27.2.1 Functional Forms for Parametric Models

Six specific parametric model formulations are provided as internal procedures in *LIMDEP* for binary choice models. The probabilities and density functions are as follows:

Probit

$$F = \int_{-\infty}^{\beta'\mathbf{x}_i} \frac{\exp(-t^2/2)}{\sqrt{2\pi}}dt \;=\; \Phi(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \phi(\boldsymbol{\beta}'\mathbf{x}_i)$$

Logit

$$F = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)} \;=\; \Lambda(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)[1 - \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)]$$

Arctangent

$F = (2/\pi)\ \arctan(\exp(\boldsymbol{\beta}'\mathbf{x}_i)),\qquad f = (2/\pi)\{1/[1+(\exp(\boldsymbol{\beta}'\mathbf{x}_i))^2]\}$

Complementary log log

$F = 1 - \exp(-\exp(\boldsymbol{\beta}'\mathbf{x}_i)) = \mathrm{C}(\boldsymbol{\beta}'\mathbf{x}_i),\qquad f = \exp(\boldsymbol{\beta}'\mathbf{x}_i)[1 - \mathrm{C}(\boldsymbol{\beta}'\mathbf{x}_i)]$

Gompertz, or type 1 extreme value

$F = \exp(-\exp(-\boldsymbol{\beta}'\mathbf{x}_i)) = \mathrm{G}(\boldsymbol{\beta}'\mathbf{x}_i),\qquad f = \exp(-\boldsymbol{\beta}'\mathbf{x}_i)\mathrm{G}(\boldsymbol{\beta}'\mathbf{x}_i)$

Burr or Scobit

$$F = \left[\frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)}\right]^{\gamma} = [\Lambda(\boldsymbol{\beta}'\mathbf{x}_i)]^{\gamma},\ \gamma > 0,\qquad f = \gamma[\Lambda(\boldsymbol{\beta}'\mathbf{x}_i)]^{\gamma}\ [1 - \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)]$$

None of these is obviously best for any situation. (The advantage of the probit model becomes overwhelming when the binary choice model is part of a more elaborate, possibly multiple equation structure.) The complementary log log distribution does arise naturally from a complete censoring of the positive values of the Poisson regression model. The first two listed above are symmetric while the latter four are not. The Burr distribution is an extension of the logistic model. The logistic model is the special case of $\gamma = 1$. Plots of the CDFs and PDFs appear below. Since the shape of the Burr distribution depends on γ, we have chosen an intermediate value of 1.5 for purposes of illustration. The program used to produce the figures is shown below as well.

In the upper figure, the two symmetric distributions, probit and logit, cross at zero in the center of the figure. The complementary log log is the higher one; it assigns a smaller probability to the right tail. As the figure at the right shows, the other asymmetric distributions assign higher probability to the right tail. The same effects can be seen in the lower figures, which plot the densities.

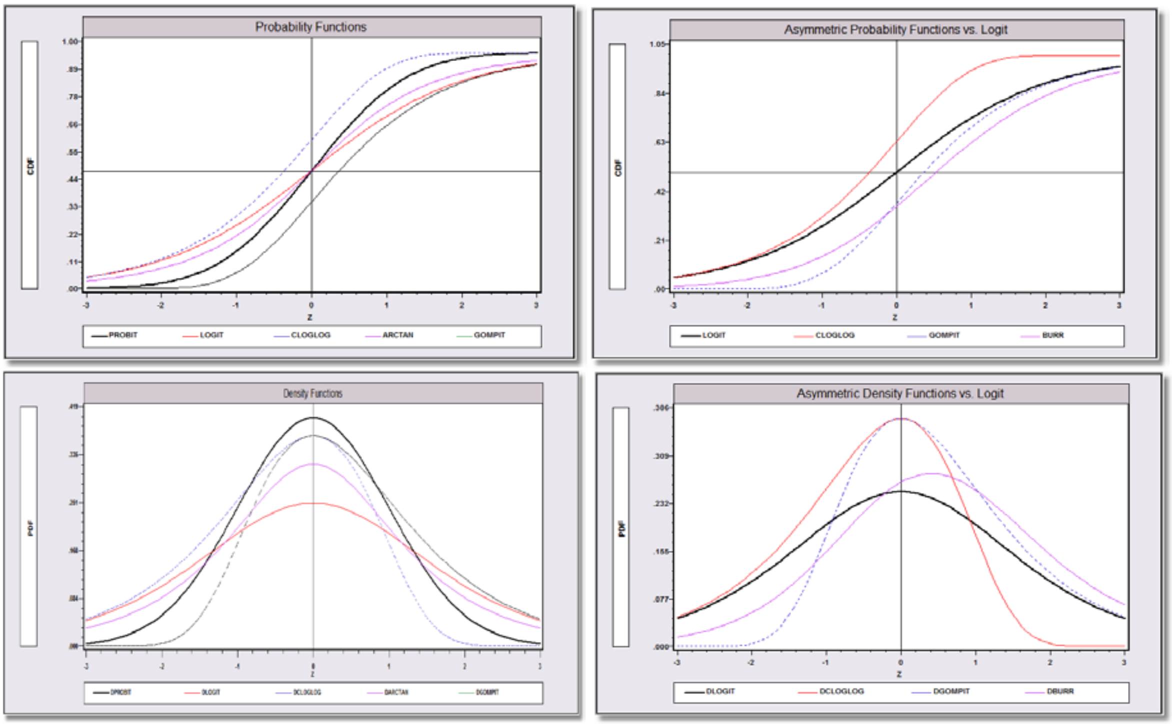

Figure E27.1 Densities and CDFs for Binary Choice Models

E27.2.2 Data Used in Estimation of Parametric Models

The Dependent Variable – Individual or Proportions

Data on the dependent variable for these models may be individual or grouped. The estimation program will check internally, and adjust accordingly where necessary. The log likelihood function is the same for either case. The only special consideration concerns the computation of the starting values for the iterations. If you do not provide your own starting values, they are determined for the individual data case by simple least squares. The OLS estimator is not useful in itself, but it does help to adjust the scale of the coefficient vector for the first iteration. For the grouped data case, however, the initial values are determined by the minimum chi squared, weighted least squares computation. Since this will generally involve logarithms or other transformations which become noncomputable at zero or one, they are not computed for individual data.

Problems with the Independent Variables

There is a special consideration for the independent variables in the binary choice model. If a variable x_k is such that the range of x_k can be divided into two parts and within the two parts, the value of the dependent variable is always the same, then this variable becomes a perfect predictor for the model. The estimator will break down, sometimes by iterating endlessly as the coefficient vector drifts to extreme values. The following program illustrates the effect: The variable *z* is positive when *y* equals one and negative when it equals zero. The estimator exited after 100 iterations, but appears actually to have converged normally – note the derivatives are extremely small. But, a probit model should take less than 10 iterations. Second, note that the log likelihood function is essentially zero, indicative of a perfect fit. The coefficient on *z* is nonsensical, and the standard errors are essentially infinite. All are indicators of a bad data set and/or model. The extreme (perfect) values for the fit measures on the next page underscore the point.

```

In general, for every Rhs variable, *x*, the minimum *x* for which *y* is one must be less than the maximum *x* for which *y* is zero, and the minimum *x* for which *y* is zero must be less than the maximum *x* for which *y* is one. If either condition fails, the estimator will break down. This is a more subtle, and sometimes less obvious failure of the estimator. Unfortunately, it does not lead to a singularity and the eventual appearance of collinearity in the Hessian. You might observe what appears to be convergence of the estimator on a set of parameter estimates and standard errors which might look reasonable. The main indication of this condition would be an excessive number of iterations – the probit model will usually reach convergence in only a handful of iterations – and a suspiciously large standard error is reported for the coefficient on the offending variable, as in the preceding example. You can check for this condition with the command

CALC ; Chk (names of independent variables to check,
name of dependent variable) $

The offending variable in the previous example would be tagged by this check;

CALC ; Chk(x,z,y) $

```
Error   462: 0/1 choice model is inestimable. Bad variable = Z
Error   463: Its values predict 1[Y       = 1] perfectly.
```

This computation will issue warnings when the condition is found in any of the variables listed. (Some computer programs will check for this condition automatically, and drop the offending variable from the model. In keeping with *LIMDEP*'s general approach to modeling, this program does not automatically make functional form decisions. This is up to the analyst.)

Dummy Variables with Empty Cells

A problem similar to the one noted above arises when your model includes a dummy variable that has no observations in one of the other cells of the dependent variable. An example appears in Greene (1993, p. 673) in which the Lhs variable is always zero when the variable ‘Southwest’ is zero. Professor Terry Seaks has used this example to examine a number of econometrics programs. He found that no program which did not specifically check for the failure – only one did – could detect the failure in some other way. All iterated to apparent convergence, though with very different estimates of this coefficient and differing numbers of iterations because of their use of different convergence rules. This form of incomplete matching of values likewise prevents estimation, though the effect is likely to be more subtle. In this case, a likely outcome is that the iterations will fail to converge, though the parameter estimates will not necessarily become extreme.

Here is an example of this effect at work. The probit model looks excellent in the full sample. In the restricted sample, *d* never equals zero when *y* equals zero. The estimator appears to have converged, the derivatives are zero, but the standard errors are huge:

```
SAMPLE    ; 1-100 $
CALC      ; Ran(12345) $
CREATE    ; x = Rnn(0,1) ; d = Rnu(0,1) > .5 $
CREATE    ; y = (-.5 + x + d + Rnn(0,1)) > 0 $
PROBIT    ; Lhs = y ; Rhs = one,x,d $
REJECT    ; y = 0 & d = 0 $
PROBIT    ; Lhs = y ; Rhs = one,x,d $
```

```

You can check for this condition if you suspect it is present by using a crosstab. The command is

CROSSTAB ; Lhs = dependent variable
; Rhs = independent dummy variable $

The 2×2 table produced should contain four nonempty cells. If any cells contain zeros, as in the table below, then the model will be inestimable.

```

```

Missing Values

Missing values in the current sample will always impede estimation. In the case of the binary choice models, if your sample contains missing observations for the dependent variable, you will receive a warning about improper coding of the values of the Lhs variable. This message will be given whenever values of the dependent variable appear to be neither binary (0/1) nor a proportion, strictly between 0 and 1.

```
Probit: Data on Y are badly coded. (<0,1> and <=0 or >= 1).
```

Missing values for the independent variables will also badly distort the estimates. Since the program assumes you will be deciding what observations to use for estimation, and -999 (the missing value code) is a valid value, missing values on the right hand side of your model are not flagged as an error. But, it is obvious that they can seriously affect the results. The second model is computed without the missing values. The true values of the coefficients are both one, which is reflected in the much more reasonable second set of results.

You should use either **SKIP** or **REJECT** to remove the missing data from the sample. (See Chapter R7 for details on skipping observations with missing values.)

E27.3 Model Commands

The model commands for the six binary choice models listed above are largely the same:

PROBIT
LOGIT
ARCTANGENT
GOMPERTZ
COMPLOGLOG
BURR

; Lhs = dependent variable ; Rhs = regressors $

Data on the dependent variable may be either individual or proportions for all six cases. If the data are proportions, the dependent variable gives the proportion of ones. The program deduces the proportion of zeros as one minus this value. You need not make any special note of which. *LIMDEP* will inspect the data to determine which type of data you are using. In either case, you provide only a single dependent variable. As usual, you should include a constant term in the model unless your application specifically dictates otherwise.

The command builder dialog boxes may also be used to construct these commands. The probit, complementary log log, Gompertz and arctangent models are found in Models:Binary Choice/Probit. The Lhs and Rhs variables are specified on the Main page of the dialog box. Then, the Options page offers the various model choices shown in Figure E27.2.

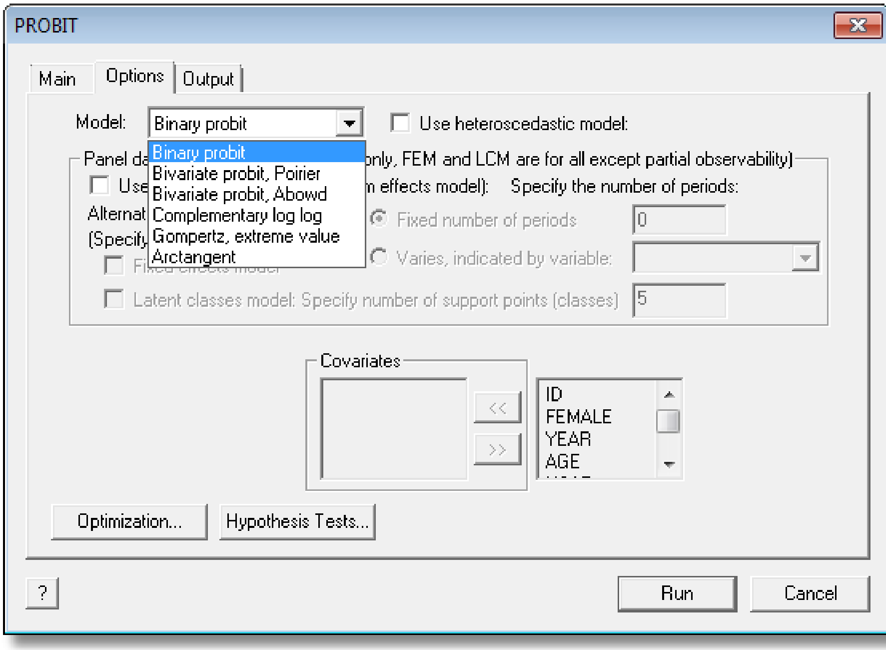

Figure E27.2 Command Builder Options Page for Probit and Other Models

The probit model is the default – no menu selection is necessary. The complementary log log, Gompertz and arctangent models are the last two options in this menu. Note, the command builder generates a probit command of the form

PROBIT	**; Lhs = ... ; Rhs = ...**
and optionally,	**; Model = Comploglog**
or	**; Model = Gompertz**
or	**; Model = Arctangent $**

which is equivalent to the separate commands shown above. The logit model is specified in Models:Binary Choice/Logit. The Burr model is a modification of the logit model and can be selected on the logit model Options page, as shown in Figure E27.3 – the check box is above the Optimization button.

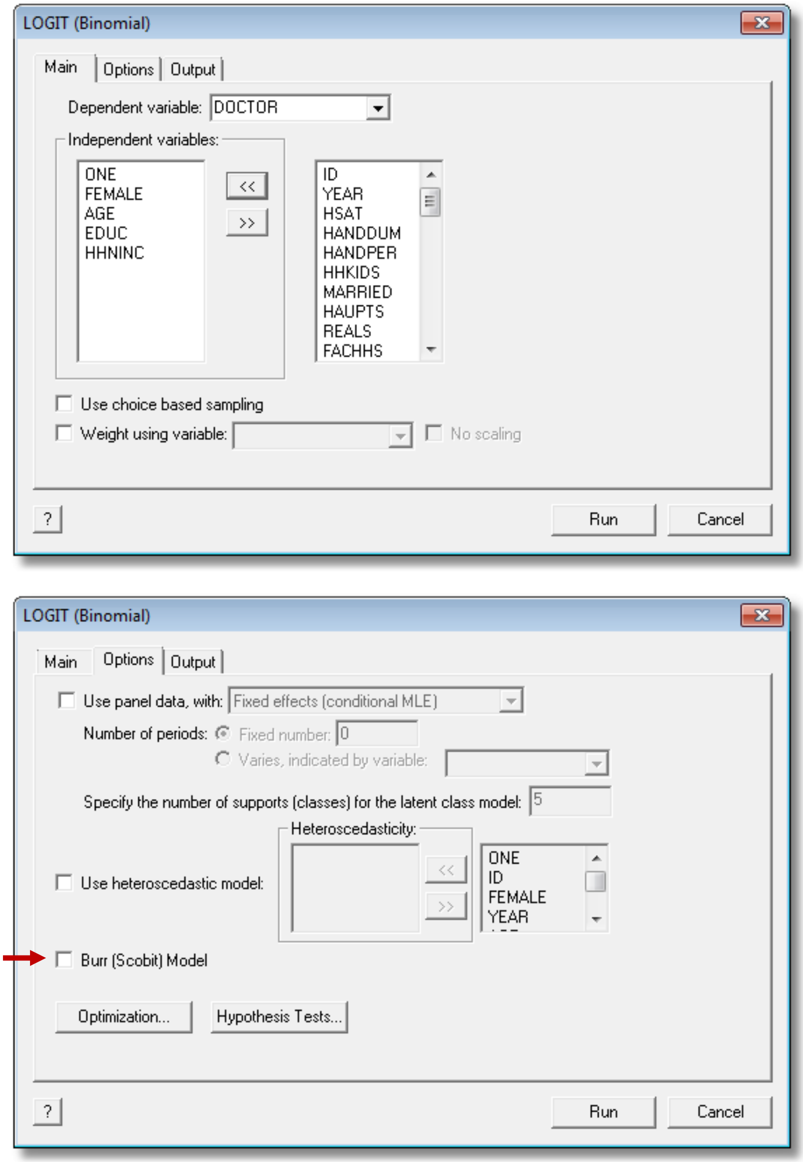

Figure E27.3 Command Builder for Logit Model and Burr Models

All of the standard options for optimization are available. These are discussed in Chapter R26. To reiterate, these are as follows (and operate the same in all model settings):

; Maxit = n	to set maximum iterations (may be 0 to compute LM statistics)
; Start = list	to give starting values (see Section E27.12)
; Tlf [= value]	to control convergence on the function value
; Tlb[= value]	to control convergence on change in parameters
; Tlg[= value]	to control convergence on derivatives weighted by inverse Hessian
; Alg = name	to request a particular algorithm, Newton, DFP, BFGS, etc.
; Output = value	to control the technical output in the displayed results

E27.4 Output

The binary choice models can produce a very large amount of optional output. Computation begins with some type of least squares estimation in order to obtain starting values. With ungrouped data, we simply use OLS of the binary variable on the regressors. If requested, the usual regression results are given, including diagnostic statistics, e.g., sum of squared residuals, and the coefficient 'estimates.' The OLS estimates based on individual data are known to be inconsistent. They will be visibly different from the final maximum likelihood estimates. For the grouped data case, the estimates are GLS, minimum chi squared estimates, which are consistent and efficient. Full GLS results will be shown for this case.

NOTE: The OLS results will not normally be displayed in the output. To request the display, use **; OLS** in any of the model commands.

E27.4.1 Reported Estimates

Final estimates include:

- $\log L$ = the log likelihood function at the maximum,
- $\log L_0$ = the log likelihood function assuming all slopes are zero. If your Rhs variables do not include *one*, this statistic will be meaningless. It is computed as

$$\log L_0 = n[P\log P + (1\text{-}P)\log(1\text{-}P)]$$

where P is the sample proportion of ones.

- McFadden's pseudo R^2 - 1 - $\log L/\log L_0$.
- The chi squared statistic for testing H_0: $\boldsymbol{\beta} = \mathbf{0}$ (not including the constant) and the significance level = probability that χ^2 exceeds test value. The statistic is

$$\chi^2 = 2(\log L - \log L_0).$$

- Akaike's information criterion, $-2(\log L - K)$ and the normalized AIC, = $-2(\log L - K)/n$.
- The sample and model sizes, n and K.
- Hosmer and Lemeshow's fit statistic and associated chi squared and p value. (The Hosmer and Lemeshow statistic is documented in Section E27.8.)

The standard statistical results, including coefficient estimates, standard errors, t ratios, p values and confidence intervals appear next. A complete listing is given below with an example. After the coefficient estimates are given, two additional sets of results can be requested, an analysis of the model fit and an analysis of the model predictions.

We will illustrate with binary logit and probit estimates of a model for visits to the doctor using the German health care data described in Chapter E2. The first model command is

LOGIT ; Lhs = doctor
; Rhs = one,age,hhninc,hhkids,educ,married
; OLS ; Summary
; Output = IC $ (Display all variants of information criteria)

Note that the command requests the optional listing of the OLS starting values and the additional fit and diagnostic results. The results for this command are as follows. With the exception of the table noted below, the same results (with different values, of course) will appear for all five parametric models. Some additional optional computations and results will be discussed later.

E27.4.2 Fit Measures

The model results are followed by a cross tabulation of the correct and incorrect predictions of the model using the rule

$$\hat{y} = 1 \text{ if } F(\hat{\boldsymbol{\beta}}'\mathbf{x}_i) > .5, \text{ and 0 otherwise.}$$

For the models with symmetric distributions, probit and logit, the average predicted probability will equal the sample proportion. If you have a quite unbalanced sample – high or low proportion of ones – the rule above is likely to result in only one value, zero or one, being predicted for the Lhs variable. You can choose a threshold different from .5 by using

; Limit = the value you wish

in your command. There is no direct counterpart to an R^2 in regression. Authors very commonly report the

$$Pseudo - R^2 = 1 - \frac{\log L(\text{model})}{\log L(\text{constants only})}.$$

We emphasize, this is not a proportion of variation explained. Moreover, as a fit measure, it has some peculiar features. Note, for our example above, it is 1 - (-17673.10)/(-18019.55) = 0.01923, yet with the standard prediction rule, the estimated model predicts almost 63% of the outcomes correctly.

```

```

The fit measures are documented in Section E27.8.

The next set of results examines the success of the prediction rule

$$\text{Predict } y_i = 1 \text{ if } P_i > P^* \text{ and 0 otherwise}$$

where P^* is a defined threshold probability. The default value of P^* is 0.5, which makes the prediction rule equivalent to 'Predict $y_i = 1$ if the model says the predicted event $y_i = 1 \mid \mathbf{x}_i$ is more likely than the complement, $y_i = 0 \mid \mathbf{x}_i$.' You can change the threshold from 0.5 to some other value with

; Limit = your *P**

Predictions for Binary Choice Model. Predicted value is 1 when probability is greater than .500000, 0 otherwise. Note, column or row total percentages may not sum to 100% because of rounding. Percentages are of full sample.

Actual Value	Predicted Value 0	Predicted Value 1	Total Actual
0	21 (.6%)	1134 (33.6%)	1155 (34.2%)
1	12 (.4%)	2210 (65.4%)	2222 (65.8%)
Total	33 (1.0%)	3344 (99.0%)	3377 (100.0%)

Crosstab for Binary Choice Model. Predicted probability vs. actual outcome. Entry = Sum[Y(i,j)*Prob(i,m)] 0,1. Note, column or row total percentages may not sum to 100% because of rounding. Percentages are of full sample.

Actual Value	Predicted Probability Prob(y=0)	Predicted Probability Prob(y=1)	Total Actual
y=0	415 (12.3%)	739 (21.9%)	1155 (34.2%)
y=1	739 (21.9%)	1482 (43.9%)	2222 (65.8%)
Total	1155 (34.2%)	2221 (65.8%)	3377 (99.9%)

This table computes a variety of conditional and marginal proportions based on the results using the defined prediction rule. For examples, the 66.697% equals (1482/2222)100% while the 66.727% is (1482/2221)100%.

E27.4.3 Covariance Matrix

The estimated asymptotic covariance matrix of the coefficient estimator is not automatically displayed – it might be huge. You can request a display with

; Covariance Matrix (or ; Printvc)

If the matrix is not larger than 5×5, it will be displayed in full. If it is larger, an embedded object that holds the matrix will show, instead. By double clicking the object, you can display the matrix in a window. An example appears in Figure E27.4 below.

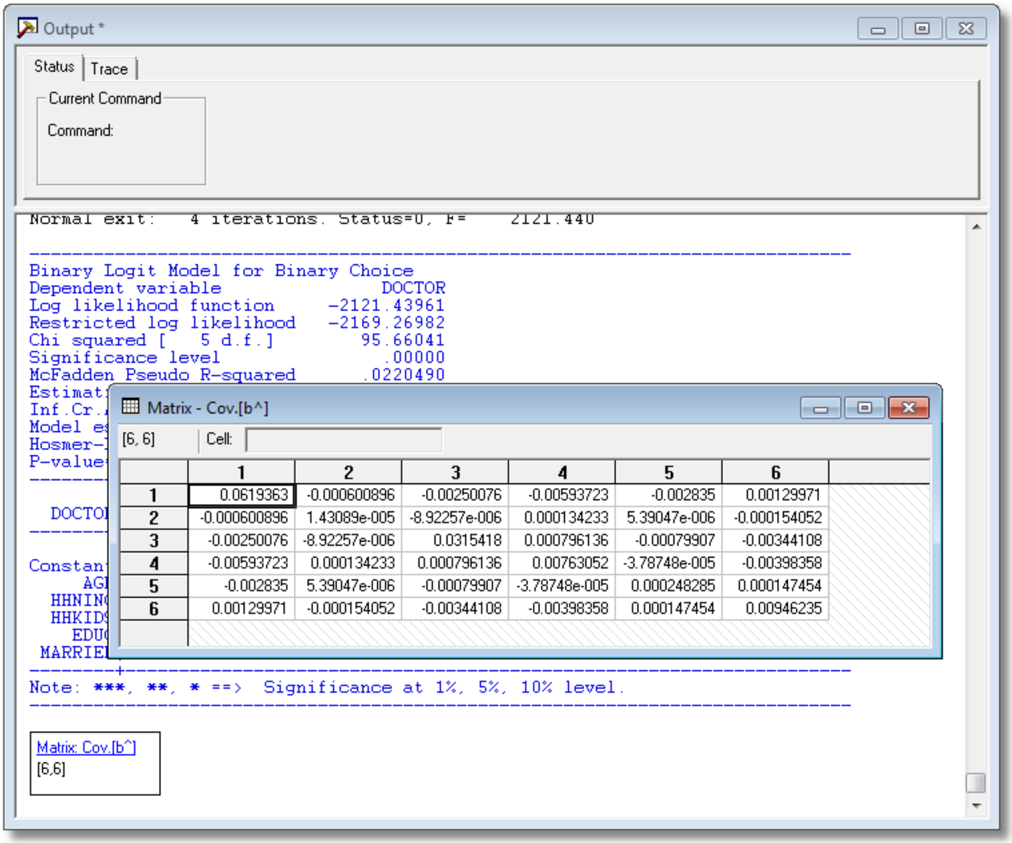

Figure E27.4 Embedded Matrix

E27.4.4 Retained Results and Generalized Residuals

The results saved by the binary choice models are:

Matrices: *b* = estimate of $\boldsymbol{\beta}$ (also contains γ for the Burr model)
varb = asymptotic covariance matrix

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Variables: *logl_obs* = individual contribution to log likelihood
score_fn = generalized residual. See Section E27.9.

Last Model: *b_variables*

Last Function: Prob(y = 1 | $\mathbf{x}$) = $F(\mathbf{b}'\mathbf{x})$. This varies with the model specification.

Models that are estimated using maximum likelihood automatically create a variable named *logl_obs*, that contains the contribution of each individual observation to the log likelihood for the sample. Since the log likelihood is the sum of these terms, you could, in principle, recover the overall log likelihood after estimation with

```
CALC        ; List ; Sum(logl_obs) $
```

The variable can be used for certain hypothesis tests, such as the Vuong test for nonnested models. The following is an example (albeit, one that appears to have no real power) that applies the Vuong test to discern whether the logit or probit is a preferable model for a set of data:

```
LOGIT       ; … $
CREATE      ; lilogit = logl_obs $
PROBIT      ; … $
CREATE      ; liprobit = logl_obs ; di = liprobit - lilogit $
CALC        ; List ; vtest = Sqr(n) * Xbr(di) / Sdv(di) $
```

The 'generalized residuals' in a parametric binary choice model are the derivatives of the log likelihood with respect to the constant term in the model. These are sometimes used to check the specification of the model (see Chesher and Irish (1987)). These are easy to compute for the models listed above – in each case, the generalized residual is the derivative of the log of the probability with respect to $\boldsymbol{\beta}'\mathbf{x}$. This is computed internally as part of the iterations, and kept automatically in your data area in a variable named *score_fn*. The formulas for the generalized residuals are provided in Section E27.12 with the technical details for the models. For example, you can verify the convergence of the estimator to a maximum of the log likelihood with the instruction

```
CALC        ; List ; Sum(score_fn) $
```

E27.5 Robust Covariance Matrix Estimation

The preceding describes a covariance estimator that accounts for a specific, observed aspect of the data. The concept of the 'robust' covariance matrix is that it is meant to account for hypothetical, unobserved failures of the model assumptions. The intent is to produce an asymptotic covariance matrix that is appropriate even if some of the assumptions of the model are not met. (It is an important, but infrequently discussed issue whether the estimator, itself, remains consistent in the presence of these model failures – that is, whether the so called robust covariance matrix estimator is being computed for an inconsistent estimator.) (Chapter R10 provides general discussion of robust covariance matrix estimation.)

E27.5.1 The Sandwich Estimator

A robust covariance matrix estimator adjusts the estimated asymptotic covariance matrix for possible misspecification in the model which leaves the MLE consistent but the estimated asymptotic covariance matrix incorrectly computed. One example would be a binary choice model with unspecified latent heterogeneity. A frequent adjustment for this case is the 'sandwich estimator,' which is the choice based sampling estimator suggested above with weights equal to one. (This suggests how it could be computed.) The desired matrix is

$$\text{Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \left[\sum_{i=1}^{n}\left(\frac{\partial^2 \log F_i}{\partial\hat{\boldsymbol{\beta}}\partial\hat{\boldsymbol{\beta}}'}\right)\right]^{-1}\left[\sum_{i=1}^{n}\left(\frac{\partial \log F_i}{\partial\hat{\boldsymbol{\beta}}}\right)\left(\frac{\partial \log F_i}{\partial\hat{\boldsymbol{\beta}}'}\right)'\right]\left[\sum_{i=1}^{n}\left(\frac{\partial^2 \log F_i}{\partial\hat{\boldsymbol{\beta}}\partial\hat{\boldsymbol{\beta}}'}\right)\right]^{-1}$$

Three ways to obtain this matrix are

; Wts = one ; Choice based sampling
or **; Robust**
or **; Cluster = 1**

The computation is identical in all cases. (As noted below, the last of them will be slightly larger, as it will be multiplied by $n/(n-1)$.)

E27.5.2 Clustering

A related calculation is used when observations occur in groups which may be correlated. This is rather like a panel; one might use this approach in a random effects kind of setting in which observations have a common latent heterogeneity. The parameter estimator is unchanged in this case, but an adjustment is made to the estimated asymptotic covariance matrix. The calculation is done as follows: Suppose the n observations are assembled in G clusters of observations, in which the number of observations in the ith cluster is n_i. Thus,

$$\sum_{i=1}^{G} n_i = n.$$

Let the observation specific gradients and Hessians be

$$\mathbf{g}_{ij} = \frac{\partial \log L_{ij}}{\partial \boldsymbol{\beta}}$$

$$\mathbf{H}_{ij} = \frac{\partial^2 \log L_{ij}}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'}.$$

The uncorrected estimator of the asymptotic covariance matrix based on the Hessian is

$$\mathbf{V}_H = \mathbf{-H}^{-1} = \left(-\sum_{i=1}^{G} \sum_{j=1}^{n_i} \mathbf{H}_{ij}\right)^{-1}$$

Estimators for some models such as the Burr model will use the BHHH estimator, instead. In general,

$$\mathbf{V}_B = \left(\sum_{i=1}^{G} \sum_{j=1}^{n_i} \mathbf{g}_{ij}\mathbf{g}'_{ij}\right)^{-1}$$

Let **V** be the estimator chosen. Then, the corrected asymptotic covariance matrix is

$$\text{Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \mathbf{V}\,\frac{G}{G-1}\left[\sum_{i=1}^{G} \left(\sum_{j=1}^{n_i} \mathbf{g}_{ij}\right)\left(\sum_{j=1}^{n_i} \mathbf{g}_{ij}\right)'\right]\mathbf{V}$$

Note that if there is exactly one observation per cluster, then this is $G/(G\text{-}1)$ times the sandwich estimator discussed above. Also, if you have fewer clusters than parameters, then this matrix is singular – it has rank equal to the minimum of G and K, the number of parameters.

This procedure is described in greater detail in Section E27.5.3. To request the estimator, your command must include

; Cluster = specification

where the specification is either the fixed value if all the clusters are the same size, or the name of an identifying variable if the clusters vary in size. Note, this is not the same as the variable in the Pds function that is used to specify a panel. The cluster specification must be an identifying code that is specific to the cluster. For example, our health care data used in our examples is an unbalanced panel. The first variable is a family *id*, which we will use as follows

; Cluster = id

The results below demonstrate the effect of this estimator. Three sets of estimates are given. The first are the original logit estimates that ignore the cross observation correlations. The second use the correction for clustering. The third is a panel data estimator – the random effects estimator described in Chapter E30 – that explicitly accounts for the correlation across observations. It is clear that the different treatments change the results noticeably.

E27.5.3 Stratification and Clustering

The clustering estimator is extended to include stratum level grouping, where a stratum includes one or more clusters, and weighting to allow finite population correction. We suppose that there are a total of S strata in the sample. Each stratum, 's,' contains C_s clusters. The number of observations in a cluster is N_{cs}. Neglecting the weights for the moment,

$$\text{Variance estimator} = \mathbf{VGV}$$

$$\mathbf{V} = \text{the inverse of conventional estimator of the Hessian}$$

$$\mathbf{G} = \sum_{s=1}^{S} w_s \mathbf{G}_s$$

$$\mathbf{G}_s = \left(\sum_{c=1}^{C_s} \mathbf{g}_{cs}\mathbf{g}'_{cs}\right) - \tfrac{1}{C_s}\mathbf{g}_s\mathbf{g}'_s$$

$$\mathbf{g}_s = \sum_{c=1}^{C_s} \mathbf{g}_{cs}$$

$$\mathbf{g}_{cs} = \sum_{i=1}^{N_{cs}} w_{ics}\mathbf{g}_{ics}$$

where $\mathbf{g}_{ics}$ is the derivative of the contribution to the log likelihood of individual i in cluster c in stratum s. The remaining detail in the preceding is the weighting factor, w_s. The stratum weight is computed as

$$w_s = f_s \times h_s \times d$$

where f_s = 1 or a finite population correction, 1 - C_s/C_s^* where C_s^* is the true number of clusters in stratum s, where $C_s^* \geq C_s$.

h_s = 1 or $C_s/(C_s - 1)$

d = 1 or $(N-1)/(N-K)$ where N is the total number of observations in the entire sample and K is the number of parameters (rows in $\mathbf{V}$).

Use

; Cluster	=	the number of observations in a cluster (fixed) or the name of a stratification variable which gives the cluster an identification. This is the setup that is described above.
; Stratum	=	the number of observations in a stratum (fixed) or the name of a stratification variable which gives the stratum an identification
; Wts	=	the name of the usual weighting variable for model estimation if weights are desired. This defines w_{ics}.
; FPC	=	the name of a variable which gives the number of clusters in the stratum. This number will be the same for all observations in a stratum – repeated for all clusters in the stratum. If this number is the same for all strata, then just give the number.
; Huber		Use this switch to request h_s. If omitted, h_s = 1 is used.
; DFC		Use this switch to request the use of d given above. If omitted, d = 1 is used.

Further details on this estimator may be found in Section E30.3 and Section R10.3.

E27.6 Analysis of Partial Effects

Partial effects in a binary choice model are

$$\frac{\partial E[y\,|\,\mathbf{x}]}{\partial \mathbf{x}} = \frac{\partial F(\boldsymbol{\beta}'\mathbf{x})}{\partial \mathbf{x}} = \frac{dF(\boldsymbol{\beta}'\mathbf{x})}{d(\boldsymbol{\beta}'\mathbf{x})}\boldsymbol{\beta} = F'(\boldsymbol{\beta}'\mathbf{x})\boldsymbol{\beta} = f(\boldsymbol{\beta}'\mathbf{x})\boldsymbol{\beta}.$$

That is, the vector of marginal effects is a scalar multiple of the coefficient vector. The scale factor, $f(\boldsymbol{\beta}'\mathbf{x})$, is the density function, which is a function of $\mathbf{x}$. (The densities for the six binary choice models are listed in Section E27.2.1.) This function can be computed at any data vector desired. Average partial effects are computed by averaging the function over the sample observations. The elasticity of the probability is

$$\frac{\partial \log E[y\,|\,\mathbf{x}]}{\partial \log x_k} = \frac{x_k}{E[y\,|\,\mathbf{x}]}\frac{\partial E[y\,|\,\mathbf{x}]}{\partial x_k} = \frac{x_k}{E[y\,|\,\mathbf{x}]} \times \text{marginal effect}$$

When the variable in $\mathbf{x}$ that is changing in the computation is a dummy variable, the derivative approach to estimating the marginal effect is not appropriate. An alternative which is closer to the desired computation for a dummy variable, that we denote z, is

$$\begin{aligned}\Delta F_z &= \text{Prob}[y = 1\,|\,z = 1] - \text{Prob}[y = 1\,|\,z = 0]\\ &= F(\boldsymbol{\beta}'\mathbf{x} + \alpha z\,|\,z = 1) - F(\boldsymbol{\beta}'\mathbf{x} + \alpha z\,|\,z = 0)\\ &= F(\boldsymbol{\beta}'\mathbf{x} + \alpha) - F(\boldsymbol{\beta}'\mathbf{x}).\end{aligned}$$

LIMDEP examines the variables in the model and makes this adjustment automatically.

There are two programs in *LIMDEP* for obtaining partial effects for the binary choice (and most other) models, the built in computation provided by the model command and the **PARTIAL EFFECTS** command. Examples of both are shown below.

The **LOGIT**, **PROBIT**, etc. commands provide a built in, basic computation for partial effects. You can request the computation to be done automatically by adding

; Partial Effects (or ; Marginal Effects)

to your command. The results below are produced for logit model in the earlier example. The standard errors for the partial effects are computed using the delta method. See Section E27.12 for technical details on the computation. The results reported are the average partial effects.

-----------------------------------------------------------------------
```

The second method provides a variety of options for computing partial effects under various scenarios, plotting the effects, etc. See Chapter R11 for further details.

NOTE: If your model contains nonlinear terms in the variables, such as *age*^2 or interaction terms such as *age**female*, then you must use the **PARTIAL EFFECTS** command to obtain partial effects. The built in routine in the command, **; Partial Effects**, will not give the correct answers for variables that appear in nonlinear terms.

E27.6.1 The Krinsky and Robb Method

An alternative to the delta method described above that is sometimes advocated is the Krinsky and Robb method. By this device, we have our estimate of the model coefficients, **b**, and the estimated asymptotic covariance matrix, **V**. The marginal effects are computed as a function of **b** and the vector of means of the sample data, $\bar{\mathbf{x}}$, say $g_k(\mathbf{b}, \bar{\mathbf{x}})$ for the *k*th variable. The Krinsky and Robb technique involves sampling *R* draws from the asymptotic normal distribution of the estimator, computing the function with these *R* draws, then computing the empirical variance. This is not done automatically by the binary choice estimator, but you can easily do the computation using the **WALD** command. For an example, we will use this method to compute the marginal effects for two variables in the logit model estimated earlier. The program would be

```
NAMELIST    ; x = one,age,hhninc,hhkids,educ,married $
LOGIT       ; Lhs = doctor ; Rhs = x ; Partial Effects $
MATRIX      ; xbar = Mean(x) $
CALC        ; kx = Col(x) ; Ran(12345) $
WALD        ; Start = b ; Var = varb ; Labels = kx_b
            ; Fn1 = b2 * Lgd(b1'xbar)
            ; Fn2 = b3 * Lgd(b1'xbar)
            ; K&R ; Pts = 2000 $
```

```

      HHNINC       -.08666     .03911    2.22     -.16331      -.01001
---------------------------------------------------------------------
```

There is a second sources of difference between the Krinsky and Robb estimates and the delta method results that follow: The Krinsky and Robb procedure is based on the means of the data while the delta method averages the partial effects over the observations. It is possible to perform the K&R iteration at every observation to reproduce the APE calculations by adding **; Average** to the **WALD** command. The results below illustrate.

```
--------+--------------------------------------------------------------------
 Fncn(1)|     .00407***      .00085     4.80  .0000      .00241    .00573
 Fncn(2)|    -.08673**       .03929    -2.21  .0273     -.16373   -.00973
--------+--------------------------------------------------------------------
```

We do not recommend this as a general procedure, however. It is enormously time consuming and does not produce a more accurate result.

Estimating Marginal Effects by Strata

Marginal effects may be calculated for indicated subsets of the data by using

; Margin = variable

where '*variable*' is the name of a variable coded 0,1,... which designates up to 10 subgroups of the data set, in addition to the full data set. For example, a common application would be

; Margin = sex

in which the variable *sex* is coded 0 for men and 1 for women (or vice versa). The variable used in this computation need not appear in the model; it may be any variable in the data set.

For example, using our logit model above, we now compute marginal effects separately for men and women:

LOGIT ; Lhs = doctor
; Rhs = one,age,hhninc,hhkids,educ,married
; Margin = female $

Examining the Effect of a Variable Over a Range of Values

Another useful device is a plot of the probability (conditional mean) over the range of a variable of interest either holding other variables at their means, or averaging over the sample values. The figure below does this for the income variable in the logit model for doctor visits. The figure is plotted for *hhkids* = 1 and *hhkids* = 0 to show the two effects. We see that the probability falls with increased income, and also for individuals in households in which there are children.

SIMULATE ; Scenario: & hhninc = 0(.05).5 | hhkids=0,1 ; plot$

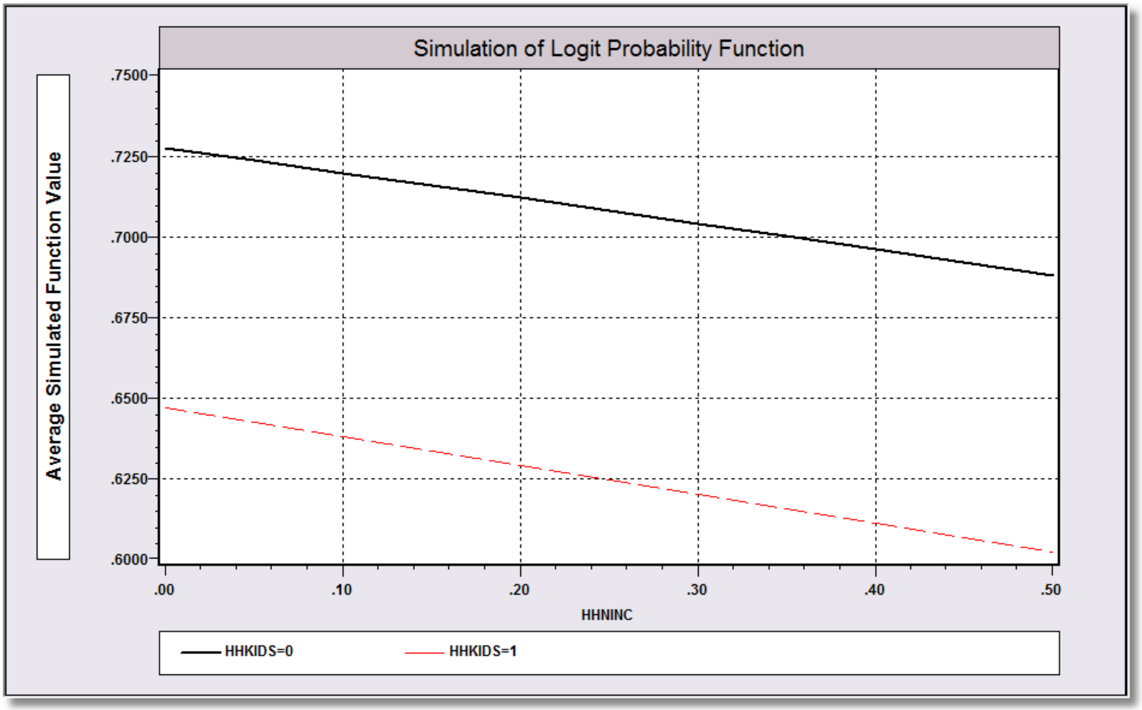

Figure E27.5 Probabilities Varying with Income

E27.7 Simulation and Analysis of a Binary Choice Model

This section describes a procedure that is used with all of the parametric models described above. It is used for two specific analyses. This procedure allows you to analyze the predictions made by a binary choice when the variables in the model are changed. It is similar to the **; Simulate** feature in *NLOGIT* 5. The analysis is provided in two parts:

- Change specific variables in the model by a prescribed amount, and examine the changes in the model predictions.
- Vary a particular variable over a range of values and examine the predicted probabilities when other variables are held fixed at their means.

This program is available for the six parametric binary choice models: *probit*, *logit*, *Gompertz*, *complementary log log*, *arctangent* and *Burr*. The *probit* and *logit* models may also be heteroscedastic. The routine is accessed as follows. First fit the model as usual. Then, use the identical model specification as shown below with the specifications indicated:

(MODEL) ; Lhs = ... ; Rhs = ... $

Then

```
BINARY CHOICE ; Lhs   = (the same) ; Rhs = (the same) ; ... (also the same)
              ; Model = Probit, Logit, Gompertz, Comploglog or Burr
              ; Start = B (from the preceding model)
```

(optional, the value to use for predicting Lhs = 1, default = .5)

; Threshold = P*

(optional) **; Scenario: variable operation = value /**
(variable operation = value) / ... (may be repeated)

(optional) **; Plot: variable (lower limit, upper limit) $**

In the **; Plot** specification, the limits part may be omitted, in which case the range of the variable is used. This will replicate for the one variable the computation of the program in the preceding section.

The **; Scenario** section computes all predicted probabilities for the model using the sample data and the estimated parameters. Then, it recomputes the probabilities after changing the variables in the way specified in the scenarios. (The actual data are not changed – the modification is done while the probabilities are computed.) The scenarios are of the form

variable operation = value

such as **hhkids + = 1** (effect of additional kids in the home)
or **hhninc * = 1.1** (effect of a 10% increase in income)

You may provide multiple scenarios. They are evaluated one at a time. This is an extension of the computation of marginal effects.

In the example below, we extend the analysis of marginal effect in the logit model used above. The scenario examined is the impact of every individual having one more child in the household then having a 50% increase in income. (Since *hhkids* is actually a dummy variable for the presence of kids in the home, increasing it by one is actually an ambiguous experiment. We retain it for the sake of a simple numerical example.) The plot shows the effect of income on the probability of visiting the doctor, according to the model.

```
NAMELIST    ; x = one,age,educ,married,hhninc,hhkids $
LOGIT       ; Lhs = doctor ; Rhs = x $
BINARY      ; Lhs = doctor ; Rhs = x
            ; Model = Logit ; Start = b
            ; Scenario:  hhkids + = 1 / hhninc * = 1.5  $
```

The model output is omitted for brevity.

```
+--------------------------------------------------------------+
|Scenario 1. Effect on aggregate proportions. Logit    Model  |
|Threshold T* for computing Fit = 1[Prob > T*] is  .50000     |
|Variable changing = HHKIDS  , Operation = +, value =   1.000 |

|Outcome           Base case       Under Scenario   Change    |
|      0        33 =    .98%       831 =   24.61%      798    |
|      1      3344 =  99.02%      2546 =   75.39%     -798    |
|  Total      3377 = 100.00%      3377 =  100.00%        0    |
+--------------------------------------------------------------+
+--------------------------------------------------------------+
|Scenario 2. Effect on aggregate proportions. Logit    Model  |
|Threshold T* for computing Fit = 1[Prob > T*] is  .50000     |
|Variable changing = HHNINC  , Operation = *, value =   1.500 |
+--------------------------------------------------------------+
|Outcome           Base case       Under Scenario   Change    |
|      0        33 =    .98%       106 =    3.14%       73    |
|      1      3344 =  99.02%      3271 =   96.86%      -73    |
|  Total      3377 = 100.00%      3377 =  100.00%        0    |
+--------------------------------------------------------------+
```

The **SIMULATE** command used in the example provides a greater range of scenarios that one can examine to see the effects of changes in a variable on the overall prediction of the binary choice model. The advantage of the **BINARY** command used here is that for straightforward scenarios, it can be used to provide useful tables such as the ones shown above.

E27.8 Measuring Fit in Binary Choice Models

A description of the ability of the binary choice model to predict the dependent variable is given by a 2×2 table which gives the success rate of the prediction rule

Predict $y_i = 1$ if fitted probability for $y_i = \hat{P}_i > P^*$, and 0 otherwise.

(This has been labeled a *confusion matrix* elsewhere in the literature.) This is the table produced by the logit model above.

```
+----------------------------------------------------------+
|Predictions for Binary Choice Model.  Predicted value is |
|1 when probability is greater than  .500000, 0 otherwise.|
|Note, column or row total percentages may not sum to     |
|100% because of rounding. Percentages are of full sample.|
+------+---------------------------------+----------------+
|Actual|         Predicted Value         |                |
|Value |       0                1        | Total Actual   |
+------+----------------+----------------+----------------+
|  0   |      21 (    .6%)|   1134 ( 33.6%)|   1155 ( 34.2%)|
|  1   |      12 (    .4%)|   2210 ( 65.4%)|   2222 ( 65.8%)|
+------+----------------+----------------+----------------+
|Total |      33 (  1.0%)|   3344 ( 99.0%)|   3377 (100.0%)|
+------+----------------+----------------+----------------+
```

The value of P^* is reported with the table. This will normally be 0.5. But, if your sample is very unbalanced you may wish to change this with

; Limit = the desired value

In general, the better the model is, the larger will be the number of observations on the diagonals of this table. For example, by adding

; Limit = .6

in the model command, we obtain the following results:

```
+----------------------------------------------------------+
|Predictions for Binary Choice Model.  Predicted value is |
|1 when probability is greater than  .600000, 0 otherwise.|
|Note, column or row total percentages may not sum to     |
|100% because of rounding. Percentages are of full sample.|
+------+---------------------------------+----------------+
|Actual|         Predicted Value         |                |
|Value |       0                1        | Total Actual   |
+------+----------------+----------------+----------------+
|  0   |     379 ( 11.2%)|    776 ( 23.0%)|   1155 ( 34.2%)|
|  1   |     555 ( 16.4%)|   1667 ( 49.4%)|   2222 ( 65.8%)|
+------+----------------+----------------+----------------+
|Total |     934 ( 27.7%)|   2443 ( 72.3%)|   3377 (100.0%)|
+------+----------------+----------------+----------------+
```

This actually worsens the fit of the model, based on the simple count of correct predictions. The change in the rule improves the ‘hit rate’ on the zeros, but at the cost of lowering the success at predicting the ones. This does say something about this criterion for model fit.

Hosmer and Lemeshow Diagnostic Statistic

Hosmer and Lemeshow have proposed a diagnostic measure for the probit and logit models (they focus on the latter) that assesses the match between actual and predicted values. To do the computation, we compute a fitted probability, F_i for each observation using the estimated model parameters. We then sort the fitted values in ascending order, carrying the actual y_i with them. The data are then divided into 10 percentiles based on the fitted values, and means of the predicted and actual data are computed within each group. The statistic is

$$H = \sum_{j=1}^{10} n_j \left[\frac{\left(\bar{y}_j - \bar{F}_j\right)^2}{\hat{\bar{P}}_j\left(1-\bar{F}_j\right)} \right]$$

(If the sample is not large, some groups at the high or low end may have insufficient variation to compute the denominator – the fitted values may all be very close to zero or one. The resulting statistic has a limiting chi squared distribution with eight (or fewer) degrees of freedom. Large values of the statistic suggest that the model is inappropriate. The example for the health care data below suggests this case.

```
-----------------------------------------------------------------------------
Binary Logit Model for Binary Choice
Dependent variable                 DOCTOR
Log likelihood function       -2121.43961

McFadden Pseudo R-squared        .0220490
Estimation based on N =    3377, K =    6
Inf.Cr.AIC  = 4254.879 AIC/N =     1.260
Hosmer-Lemeshow chi-squared =  17.65094
P-value=  .02400 with deg.fr. =       8
--------+--------------------------------------------------------------------
```

Scalar Fit Measures for Binary Choice Models

Numerous other scalar fit measures have been proposed for binary choice models. They share the flaw that none satisfactorily mimic the true measure of proportion of variation explained given by R^2 in the linear regression context. *LIMDEP* reports several of these in a table with each set of estimates: (We are unable to recommend any of these as optimal. There is some discussion in Estrella (1998) which may be useful. See, also, Greene and Hensher (2010, Chapter 4).)

```
+----------------------------------------+
| Fit Measures for Binomial Choice Model |
| Logit    model for variable DOCTOR     |
+----------------------------------------+
|                  Y=0       Y=1     Total|
| Proportions  .34202    .65798   1.00000|
| Sample Size    1155      2222      3377|
+----------------------------------------+
| Log Likelihood Functions for BC Model  |
|              P=0.50    P=N1/N   P=Model|
| LogL =     -2340.76  -2169.27  -2121.44|
+----------------------------------------+
```

```
+----------------------------------------+
| Fit Measures based on Log Likelihood   |
| McFadden = 1-(L/L0)          =  .02205|
| Estrella = 1-(L/L0)^(-2L0/n) =  .02824|
| R-squared (ML)               =  .02793|
| Akaike Information Crit.     = 1.25996|
| Schwartz Information Crit.   = 1.27084|
+----------------------------------------+
| Fit Measures Based on Model Predictions|
| Efron                        =  .02693|
| Ben Akiva and Lerman         =  .56223|
| Veall and Zimmerman          =  .04899|
| Cramer                       =  .02735|
+----------------------------------------+
```

The values in the table are computed as follows:

K	= number of coefficients in the model
N	= sample size
P_0	= proportion of zeros in the sample
P_1	$= 1 - P_0 = \overline{y}$
F_i	= Predicted probability that y_i equals 1 | $\mathbf{x}_i$
$\hat{P}_i$	= Predicted probability of observed $y_i = (1\text{-}y_i)(1\text{-}F_i) + y_iF_i$
L_0	= log likelihood with only a constant $= n\,(P_0 \log P_0 + P_1 \log P_1)$
L	= log likelihood $= \sum_{i=1}^{n} y_i \log F_i + (1-y_i)\log(1-F_i)$
McFadden	$= 1 - L/L_0$
Estrella	$= 1-(\log L/\log L_0)^{-2L_0/n}$
R^2 - ML	$= 1 - \exp[2(\log L_0 - \log L)/n]$
Akaike	$= (-2\log L + 2K)/n$
Schwarz	$= (-2\log L + K\log n)/n$
Efron	$= 1 - \sum_{i=1}^{n}\left(y_i - \hat{P}_i\right)^2 \Big/ \sum_{i=1}^{n}\left(y_i - \overline{y}\right)^2$
Ben-Akiva	$= \dfrac{1}{n}\sum_i \hat{P}_i$
Veall	$= \left[(\delta-1)/(\delta-\text{McFadden})\right]\text{McFadden}, \delta = \text{N}/(2\log\text{L}_0)$
Cramer	= Average value of $\hat{P}_i \| y_i = 1$ - Average value of $\hat{P}_i \| y_i = 0$

You can obtain this same table of values for a binary variable y and any set of predicted probabilities contained in a variable with

CALC ; Fit (name of y variable, name of probabilities variable) $

This command always produces the output even if **; List** is not specified, but it does not produce any other results. The result of the **CALC** command is zero. (When you use this, the information criteria are not computed, as the degrees of freedom is not known.)

A Goodness of Fit Measure for the Probit Model Based on the Normal Distribution

This program computes a pseudo R squared for a probit model based on the formula given by Zavoina and McKelvey (1975) in their paper on the ordered probit model:

$$E[y_i^*|y_i] = yf_i = \mathbf{x}_i'\boldsymbol{\beta} + \lambda_i$$
$$\lambda_i = (2y_i - 1)\phi(\mathbf{x}_i'\boldsymbol{\beta}) / \Phi[(2y_i - 1)\mathbf{x}_i'\boldsymbol{\beta}]$$
$$R^2 = \text{Var}(yf) / [1 + \text{Var}(yf)]$$

where λ_i is the inverse Mill's ratio usually kept for **SELECT**. After setting up the sample for the problem, the commands are

```
NAMELIST   ; x = the Rhs variables for the probit model $
PROBIT     ; Lhs = y ; Rhs = x ; Hold(IMR = lambda) $
CREATE     ; yf = x'b + lambda $
CALC       ; zm = Var(yf) / (1 + Var(yf)) $
```

ROC Plots for Binary Choice Models

ROC (receiver operating characteristic) plots provide a loose descriptive measure of fit in a binary choice model, and can be used to some extent to compare models. You may obtain these for all parametric binary choice models: *logit* (with or without heteroscedasticity), *probit* (with or without heteroscedasticity), *complementary log log*, *Gompertz* and *Burr*. The request is simply

; ROC

added to any binary choice model command. An example appears below. The curve is constructed by computing for the range of values of P^* from zero to one,

Sensitivity(P^*) = proportion of observations for which estimated and actual values of y_i are both equal to one when the estimated y_i equals one if the the predicted probability is greater than or equal to P^*.

and

Specificity(P^*) = the proportion of values for which predicted and actual zeros match.

The graph is constructed by plotting Sensitivity(P^*) against 1 - Specificity(P^*). The 'fit measure' is then computed as the area under the ROC curve. A greater area implies a greater model fit. (The field is a unit rectangle.) A model with no fit has an area of 0.5. The request for the ROC plot also produces a plot of the ability of the model to predict zeros and ones, again as a function of P^*. This figure is produced by plotting the Specificity(P^*) and Sensitivity(P^*) against P^*. An example based on the earlier logit model appears below.

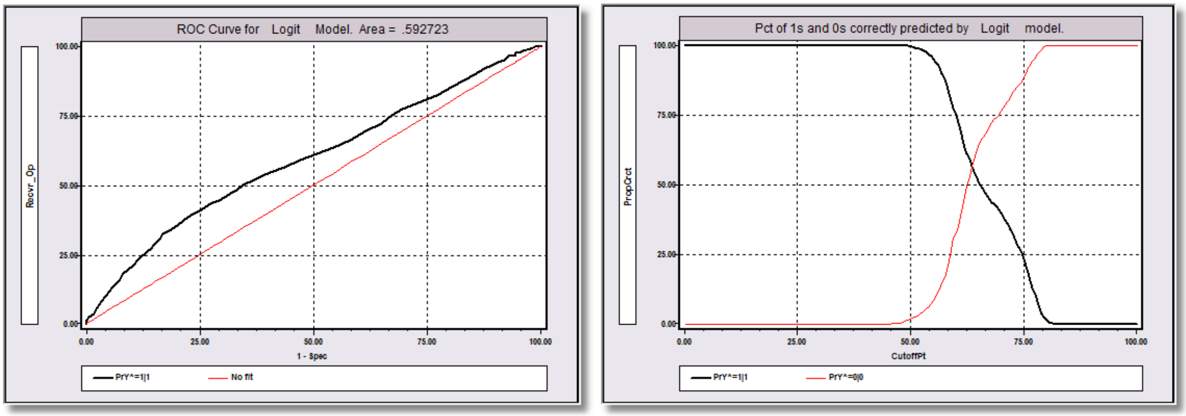

Figure E27.6 Analysis of Model Fit

E27.9 Saving Predictions and Residuals

Predictions for the binary choice models are created by adding

; Keep = the name of the variable.

Predictions are computed using the rule,

Predict y_i = 1 if fitted probability > P^*, and 0 otherwise.

Predictions retained with **; Keep = name** are the samples of ones and zeros produced by the prediction rule above. You may also keep the predicted probabilities, $F(\hat{\beta}'\mathbf{x}_i)$ with

; Prob = name

Residuals are requested with

; Res = name

They are the difference between actual and predicted values; residuals may be -1, 0, or 1. These results may be displayed with the model results by adding

; List

to the model command. The listing for probit model based on a small data set is shown below. (Our health care data set contains over 27,000 observations. We would not want to list a sample this large.) We do note, these ‘residuals’ are unlikely to be useable in this form. The generalized residuals for the model discussed below are likely to be more useable as a diagnostic tool.

Observation	Observed Y	Predicted Y	Residual	x(i)b	Prob[Y=1]
1	.00000	.00000	.0000	-2.0931	.0182
2	.00000	.00000	.0000	-1.6157	.0531
3	.00000	.00000	.0000	-.8782	.1899
4	.00000	.00000	.0000	-2.0842	.0186
5	1.0000	1.0000	.0000	.1372	.5546
(rows omitted)					
21	.00000	.00000	.0000	-1.5388	.0619
22	1.0000	1.0000	.0000	1.3079	.9045
23	.00000	.00000	.0000	-.6032	.2732
24	.00000	1.0000	-1.0000	1.0256	.8475
25	1.0000	1.0000	.0000	.9709	.8342

E27.10 Using Weights and Choice Based Sampling

The **; Wts** option can always be used in the usual fashion for the probit and logit models. However, in the grouped data case, a somewhat different treatment may be desired. The observations may consist of p_i, $\mathbf{x}_i$ and n_i, where n_i is the number of replications used to obtain p_i. The usual treatment assumes that p_i is a sample of one from a distribution with variance $p_i(1-p_i)$. But p_i is more precise than this. Its unconditional variance is $p_i(1-p_i)/n_i$. Thus, the efficiency of the estimator of $\boldsymbol{\beta}$ is underestimated. There is also an inherent heteroscedasticity which must be accounted for. The heteroscedasticity due to p_i is built into the likelihood function. But if your proportions are based on different numbers of observations, the variances will differ correspondingly. This can be accounted for by including n_i as a weighting variable. Since the weighting procedure automatically scales the weights so that they sum to the sample size, which would be inappropriate here, it is necessary to modify the specification. Use

; Wts = variable, Noscale

or just

; Wts = variable, N

to prevent the automatic scaling. This produces a replication of the observations, which is what is needed for grouped data.

This usage often has the surprising side effect of producing implausibly small standard errors. Consider, for example, using unscaled weights for statewide observations on election outcomes. The implication of the **Noscale** parameter is that each proportion represents millions of observations. Once again, this is an issue that must be considered on a case by case basis.

Choice Based Sampling

In some individual data cases, the data are deliberately sampled so that one or the other outcome is overrepresented in the sample. For example, suppose that in a binary response setting, the true proportion of ones in the population is .05 and the true proportion of zeros is .95. One might over sample the ones in order to learn more about the decision process. However, some account must be taken of this fact in the estimation since it obviously will impart some biases. The following assumes that these population proportions are known, which must be true to apply the technique. We use the assumed values to demonstrate the technique; other values would be substituted in the analogous manner.

The general principle involved is as follows: Suppose that the sample is deliberately drawn so that it contains 50% ones and 50% zeros while it is known that the true proportions in the population are .05 and .95. Then, the ones are overrepresented by a factor of .50/.05 = 10 while the zeros are underrepresented by a factor of .50/.95 = .5263. To obtain the right 'mix' in the sample, it is necessary to scale down the ones by a factor of .05/.50 = .1 and scale up the zeros by a factor of .95/.50 = 1.9. This can be handled simply by using a weighting variable during estimation to reweight the observations. The precise method of doing so is discussed below. (See, also, Manski and McFadden (1981).)

An additional change must be made in order to obtain the correct asymptotic covariance matrix for the estimates. Let **H** be the Hessian of the (weighted) log likelihood, i.e., the usual estimator for the variance matrix of the estimates, and let **G′G** be the summed outer products of the first derivatives of the (weighted) log likelihood. (This is the inverse of the BHHH estimator.) Manski and McFadden (1981) show that the appropriate covariance matrix for the estimates is

$$\mathbf{V} = (\mathbf{-H})^{-1}\ \mathbf{G'G}\ (\mathbf{-H})^{-1}.$$

The computation of the weighted estimator and the corrected asymptotic covariance is handled automatically in *LIMDEP* by the following estimation programs:

- univariate probit, logit, extreme value and Gompertz model,
- bivariate probit model with and without sample selection,
- binomial and multinomial logit models,
- discrete choice (conditional logit).

With the exception of the last of these, you request the estimator with

```
; Wts = name of weighting variable
; Choice Based
```

The weighting variable can usually be created with a single command. For example, the weighting variable suggested in the example used above would be specified as follows:

```
CREATE      ; wt = (.95/.50)*(y = 0)  +  (.05/.50)*(y = 1) $
```

For models that do not appear in the list above, there is a general way to do this kind of computation. How the weights are obtained will be specific to your application if you wish to do this. To compute the counterpart to **V** above, you can do the following:

```
CREATE      ; wt = the desired weighting variable $
Model name  ; ... specification of the model
            ; Wts = the weighting variable
            ; Cluster = 1 $
```

Since the 'cluster' estimator computes a sandwich estimator, we need only 'trick' the program by specifying that each cluster contains one observation. The observations in the parts will be weighted by the variable given, so this is exactly what is needed.

E27.11 Heteroscedasticity in Probit and Logit Models

The univariate choice model with multiplicative heteroscedasticity is

$$y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,$$

$$y_i = 1 \text{ if } y_i^* > 0 \text{ and } y_i = 0 \text{ if } y_i^* \leq 0,$$

$$\varepsilon_i \sim \text{Normal or Logistic with mean 0, and variance} \propto [\exp(\boldsymbol{\gamma}'\mathbf{w}_i)]^2$$

(In the logistic case, the true variance is scaled by $\pi^2/3$.)

NOTE: These heteroscedasticity models require individual data.

Request the model with heteroscedasticity with

```
PROBIT      ; Lhs  = dependent variable
or LOGIT    ; Rhs  = regressors in x
            ; Rh2 = list of variables in w
            ; Heteroscedasticity (or just ; Het) $
```

Other options and specifications for this model are the same as the basic model. (See Section E10.3 for discussion of variants of heteroscedasticity which can be accommodated with this model.) Two general options that are likely to be useful are

; Keep = name to retain predictions
; Prob = name to retain fitted probabilities

and the controls of the iterations and the amount of output.

NOTE: Do not include *one* in the Rh2 list. A constant in $\boldsymbol{\gamma}$ is not identified.

This model differs from the basic model only in the presence of the variance term. The output for this model is also the same, with the addition of the coefficients for the variance term. The initial OLS results are computed without any consideration of the heteroscedasticity, however.

Since the log likelihood for this model, unlike the basic model, is not globally concave, the default algorithm is BFGS, not Newton's method.

For purposes of hypothesis testing and imposing restrictions, the parameter vector is

$$\boldsymbol{\theta} = [\beta_1,...,\beta_K,\gamma_1,...,\gamma_L].$$

If you provide your own starting values, give the right number of values in exactly this order.

You can also use **WALD** and **; Test:** to test hypotheses about the coefficient vector. Finally, you can impose restrictions with

; Rst = ...

or **; CML: restrictions...**

NOTE: In principle, you can impose equality restrictions across the elements of $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ with **; Rst = ...**, (i.e., force an element in $\boldsymbol{\beta}$ to equal one in $\boldsymbol{\gamma}$), but the results are unlikely to be satisfactory. Implicitly, the variables involved are of different scales, and this will place a rather stringent restriction on the model.

Use

; Robust

or **; Cluster = id variable or group size**

to request the sandwich style robust covariance matrix estimator or the cluster correction.

NOTE: There is no 'robust' covariance matrix for the logit or probit model that is robust to heteroscedasticity, in the form of the White estimator for the linear model. In order to accommodate heteroscedasticity in a binary choice model, you must model it explicitly..

NOTE: **; Maxit = 0** provides an easy way to test for heteroscedasticity with an LM test.

To test the hypothesis of homoscedasticity against the specification of this more general model, the following template can be used: (The model may be **LOGIT** if desired.)

```
NAMELIST    ; x  = ... the Rhs of the probit model
            ; w  = ... the Rh2 of the heteroscedasticity model $
CALC        ; m = Col(w) $
PROBIT      ; Lhs  = ...
            ; Rhs  = x $
PROBIT      ; Lhs  = ...
            ; Rhs  = x
            ; Rh2 = w ; Het
            ; Start = b, m_0
            ; Maxit = 0 $
```

This produces an LM statistic and (superfluously) reproduces the restricted model.

The results that are saved automatically are the same as for the basic model, that is, *b*, *varb*, and the scalars. In this case, *b* will contain the full set of estimates, with the slopes followed by the variance parameters, i.e., [**b**,**c**]. The *Last Model* labels for the **WALD** command are [*b_variable*, *c_variable*].

We note, this model may be rather weakly identified by the observed data, unless they are plentiful and the model is sharply consistent with the data. In fact, identification is not a problem, and the model is straightforward to estimate. But, one could argue that the specification problem addressed by this model is one of functional form rather than heteroscedasticity. That is, the model specification is arguably indistinguishable from one with a peculiar kind of conditional mean function, which, in turn, could be standing in for some other, perhaps reasonable, albeit nonlinear model. In addition, it is common for the estimated standard errors that are computed for this model to be quite large, as a result of a kind of multicollinearity – the high correlation of the derivatives of the log likelihood.

Application

To illustrate the model, we have refit the specification of the previous section with a variance term of the form Var[ε] = $[\exp(\gamma_1 \textit{female} + \gamma_2 \textit{working})]^2$. Since both of these are binary variables, this is equivalent to a groupwise heteroscedasticity model. The variances are 1.0, $\exp(2\gamma_1)$, $\exp(2\gamma_2)$ and $\exp(2\gamma_1+2\gamma_2)$ for the four groups. We have fit the original model without heteroscedasticity first. The second **LOGIT** command carries out the LM test of heteroscedasticity. The third command fits the full heteroscedasticity model.

```
INCLUDE     ; New ; year = 1994 $
NAMELIST    ; x = one,age,educ,married,hhninc,hhkids,female $
LOGIT       ; Lhs = doctor ; Rhs = x
            ; Partial Effects $
NAMELIST    ; w = female,working $
CALC        ; m = Col(w) $
LOGIT       ; Lhs = doctor ; Rhs = x
            ; Heteroscedasticity ; Rh2 = w
            ; Start = b,m_0
            ; Maxit = 0 $
LOGIT       ; Lhs  = doctor ; Rhs = x
            ; Heteroscedasticity ; Rh2 = w
            ; Partial Effects $
PARTIALS    ; Effects: female $
```

The model results have been rearranged in the listing below to highlight the differences in the models. Also, for convenience, some of the results have been omitted.

```

The partial effects for the heteroscedasticity model are computed at the means of the variables. It is possible to obtain average partial effects by using the **PARTIAL EFFECTS** program rather than the built in marginal effects routine. The following shows the results for *female*, which appears in both parts of the model.

PARTIAL EFFECTS ; Effects: female $

```

APE. Function       .13430     .01653    8.12      .10190      .16669
```

These are the summaries of the predictions of the two estimated models. The performance of the two models in terms of the simple count of correct predictions is almost identical – the heteroscedasticity model correctly predicts three observations more than the homoscedasticity model. The mix of correct predictions is very different, however.

E27.12 Estimation Methods and Technical Details

This section will document the estimation methods used for fitting the binary choice models, and some options available for controlling these. We also lay out some of the technical background for the models.

E27.12.1 Maximum Likelihood Estimation

With only a few exceptions, the estimation technique used for fitting the binary choice models is maximum likelihood. For the parametric models, let y_i denote the observed individual outcome, and p_i denote an observed proportion in the grouped data case. The log likelihood functions for the two cases are

$$\log L = \Sigma_i\, w_i[(1 - y_i)\log(1 - F_i) + y_i \log F_i]$$

and

$$\log L = \Sigma_i\, w_i[n_i(1 - p_i)\log F_i + n_i\, p_i \log F_i]$$

where n_i is usually one, but may be the number of observations in the 'group,' w_i is a general weight, which may always be applied in estimation, and $F_i = F(\boldsymbol{\beta}'\mathbf{x}_i)$. Estimates of the model parameters are obtained by maximizing the log likelihood. In most cases, Newton's method is the most effective algorithm, though all others provided by *LIMDEP* may be used. The probit, logit, Gompertz and complementary log log models have globally concave log likelihoods, and estimation is generally routine. Unless the data are very badly conditioned, all of the estimators should converge uniformly and quite rapidly; none present particularly difficult problems of computation. The Burr model is typically more difficult to estimate because the log likelihood is not globally concave.

Asymptotic standard errors may be computed in a variety of ways. In most cases, the estimated asymptotic covariance matrix will be the negative inverse of the actual Hessian. For the models estimated by Newton's method, the covariance matrix for the coefficients is estimated with the second derivatives of the log likelihood. For the models computed with DFP, the summed outer products of the first derivatives of the log likelihood, the BHHH (Berndt, et al., (1974)), estimator is usually used instead. The Burr model is an example in which Newton's method is generally too crude without a line search.

The following results for binary choice models are widely known for the probit and logit models, but, it turns out, are completely general, and apply to the remainder as well. Some minor modification is required for models which contain ancillary parameters, such as the Burr model and the heteroscedasticity model discussed below, but nonetheless, the results are general. Also, the results below are extended to the grouped data case with only trivial modification. Denote by z_i the argument of F_i, $\boldsymbol{\beta}'\mathbf{x}_i$, and denote by f_i the derivative of F_i with respect to z_i – f_i will generally be the density function corresponding to CDF F_i. Then, for the individual data case,

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{n} w_i \left\{ -f_i \frac{1-y_i}{1-F_i} + f_i \frac{y_i}{F_i} \right\} \mathbf{x}_i \quad = \quad \sum_{i=1}^{n} w_i\, f_i \left\{ \frac{y_i}{F_i} - \frac{1-y_i}{1-F_i} \right\} \mathbf{x}_i \,.$$

Expressions for f_i for the various models estimated appear at the beginning of Section E26.2. Since $E[y_i] = F_i$, it follows obviously that the expected first derivative is zero, as would be required for a regular maximum likelihood problem.

The multiplier of $\mathbf{x}_i$ without the weight, w_i, is the generalized residual noted in Section E27.4.4. The specific forms of these terms are obtained as follows: Define

$$q_i = 2y_i - 1 = \text{-1 if } y_i \text{ equals 0, +1 if } y_i \text{ equals 1,}$$

$$a_i = \boldsymbol{\beta}'\mathbf{x}_i,$$

$$c_i = \exp(a_i),$$

$$d_i = \exp(-a_i)$$

Then, the generalized residuals are

Probit: $\dfrac{q_i\phi(q_i a_i)}{\Phi(q_i a_i)}$

Logit: $y_i - \Lambda(a_i)$

Comploglog: $c_i\left(\dfrac{y_i}{1+\exp(-c_i)} - 1\right)$

Gompertz: $\left(\dfrac{y_i - \exp(-d_i)}{1-\exp(-d_i)}\right)$

Arctangent: $\dfrac{q_i}{y_i F_i + (1-y_i)(1-F_i)}\left(\dfrac{2c_i}{\pi(1+c_i^2)}\right)$

Burr: $\left(y_i \;-\; \dfrac{(1-y_i)\Lambda_i^{\gamma}}{1-\Lambda_i^{\gamma}}\right)\gamma(1-\Lambda_i)$

The actual Hessian is

$$\frac{\partial^2 \log L}{\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}'} = \sum_{i=1}^{n} w_i\left[\, f_i'\left\{\frac{y_i}{F_i} - \frac{1-y_i}{1-F_i}\right\} - f_i\left\{\frac{y_i f_i}{F_i^2} + \frac{(1-y_i) f_i}{(1-F_i)^2}\right\}\right]\mathbf{x}_i\mathbf{x}_i'$$

Computation of the Hessian for Newton's method requires expressions for f_i'. For the five models, not including the Burr model – this is considered below – these are

Probit: $-z_i\phi_i$

Logit: $\Lambda_i(1 - \Lambda_i)(1 - 2\Lambda_i)$

Extreme Value: $\lambda_i \exp(-\lambda_i)(1 - \lambda_i)$, with $\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$

Gompertz: $\lambda_i \exp(-\lambda_i)(\lambda_i - 1)$, with $\lambda_i = \exp(-\boldsymbol{\beta}'\mathbf{x}_i)$.

Arctangent: $(2/\pi)[\lambda_i^2/(1+\lambda_i^2)^2](\lambda_i^2-2\lambda_i+1)$

The method of scoring can be used as well, by taking the expectation of the Hessian. Since y_i is the random variable of the expectation operator, and y_i enters the Hessian linearly, the surprisingly simple result which emerges is that for all the models,

$$E\left[\frac{\partial^2 \log L}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'}\right] = \sum_{i=1}^{n} -w_i \left[\frac{f_i^2}{F_i(1-F_i)}\right]\mathbf{x}_i\mathbf{x}_i'$$

which is the widely cited result. The third approach, for purposes of computing the BHHH estimator of the asymptotic covariance matrix is to use the outer product of gradients, or OPG estimator. This would be based on the inverse of

$$OPG = \sum_{i=1}^{n} w_i \left[f_i \left\{ \frac{y_i}{F_i} - \frac{1-y_i}{1-F_i} \right\} \right]^2 \mathbf{x}_i\mathbf{x}_i'.$$

Once again, this simplifies considerably. By expanding the square and using the results that y_i and $(1-y_i)$ both equal their squares, and $y_i\,(1-y_i) = 0$, the end result is simply

$$OPG = \sum_{i=1}^{n} w_i \left[\frac{f_i(y_i - F_i)}{F_i(1-F_i)} \right]^2 \mathbf{x}_i\mathbf{x}_i'.$$

As noted earlier, because of the extra parameter, γ, the Burr model does not fit into these neat simplifications. For this model, only the first derivatives are used in estimation by the BFGS algorithm and in computing the asymptotic covariance matrix by the OPG method. The first derivatives of the log likelihood for the Burr model are

$$\frac{\partial \log L}{\partial \begin{pmatrix} \boldsymbol{\beta} \\ \gamma \end{pmatrix}} = \sum_{i=1}^{n} w_i \left(y_i - \frac{(1-y_i)\Lambda_i^{\gamma}}{1-\Lambda_i^{\gamma}} \right) \begin{bmatrix} \gamma(1-\Lambda_i)\mathbf{x}_i \\ \log \Lambda_i \end{bmatrix}$$

The OPG estimator is formed directly by using the summed outer products. No simplification is possible. The Hessian for this model is

$$\frac{\partial^2 \log L}{\partial \begin{pmatrix} \boldsymbol{\beta} \\ \gamma \end{pmatrix} \partial \begin{pmatrix} \boldsymbol{\beta} \\ \gamma \end{pmatrix}} = \sum_{i=1}^{n} w_i \left(y_i - \frac{(1-y_i)\Lambda_i^{\gamma}}{1-\Lambda_i^{\gamma}} \right) \begin{bmatrix} -\gamma\Lambda_i(1-\Lambda_i)\mathbf{x}_i\mathbf{x}_i' & (1-\Lambda_i)\mathbf{x}_i \\ (1-\Lambda_i)\mathbf{x}_i' & 0 \end{bmatrix}$$

$$-\sum_{i=1}^{n} w_i \left(\frac{(1-y_i)\Lambda_i^{\gamma}}{(1-\Lambda_i^{\gamma})^2} \right) \begin{bmatrix} \gamma(1-\Lambda_i^{\gamma})\mathbf{x}_i \\ \log \Lambda_i \end{bmatrix} \begin{bmatrix} \gamma(1-\Lambda_i^{\gamma})\mathbf{x}_i \\ \log \Lambda_i \end{bmatrix}'$$

The expected Hessian is considerably simpler as the first term has expectation zero. Once again, y_i enters linearly in the second. Using its expectation, Λ_i^γ, the second term reduces the expression to

$$E\left[\frac{\partial^2 \log L}{\partial\begin{pmatrix}\boldsymbol{\beta}\\ \gamma\end{pmatrix}\partial\begin{pmatrix}\boldsymbol{\beta}\\ \gamma\end{pmatrix}}\right] = -\sum_{i=1}^{n} w_i\left(\frac{\Lambda_i^\gamma}{1-\Lambda_i^\gamma}\right)\begin{bmatrix}\gamma(1-\Lambda_i^\gamma)\mathbf{x}_i\\ \log\Lambda_i\end{bmatrix}\begin{bmatrix}\gamma(1-\Lambda_i^\gamma)\mathbf{x}_i\\ \log\Lambda_i\end{bmatrix}'$$

(Note that for the special case of $\gamma = 1$, this reduces to the familiar result for the logit model.)

Ancillary parameters such as the slopes in the heteroscedasticity models and γ in the Burr model are started at zero and one, respectively. In general, where there is no natural data/model based starting value, we use a value which as a restriction produces a simpler model. Thus, the choices noted for the heteroscedastic and the Burr models produce the homoscedastic models and the binary logit model.

E27.12.2 Minimum Chi Squared Estimation with Grouped Data

In the grouped data cases, weighted least squares is an alternative estimation strategy. The approach uses the inverse transformation of the probability function. Let π_i be the true value of F_i. Then, we write

$$F^{-1}(\pi_i) = \boldsymbol{\beta}'\mathbf{x}_i \text{ and } F^{-1}(p_i) = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i.$$

Expand the former in a linear Taylor series to obtain

$$F^{-1}(p_i) = F^{-1}(\pi_i) + (p_i - \pi_i)\frac{dF^{-1}(\pi_i)}{d\pi_i}.$$

The latter derivative is just the reciprocal of the density,$(1/f_i)$. The variance of the right hand side is, therefore, $\text{Var}[p_i - \pi_i]/(f_i)^2$, which suggests a generalized least squares approach. In each case, $\text{Var}[p_i - \pi_i]$ is $\pi_i(1 - \pi_i)/n_i$, which in the context of our model gives, finally,

$$\text{Var}[F^{-1}(p_i)] = \frac{F_i(1-F_i)}{n_i f_i^2}$$

With grouped data, then, one might use an iterative strategy. Given starting values for $\boldsymbol{\beta}$, compute the weights implied by the variance function above, then compute weighted least squares regression of $F^{-1}(p_i)$ on $\mathbf{x}_i$. The iteration can be reentered if desired. Once again, the Burr model does not lend itself to this approach, but for the other five, it is straightforward using the inverse transformations

Probit:	$F^{-1}(p_i)$	$= \Phi^{-1}(p_i)$ (must be approximated)
Logit:	$F^{-1}(p_i)$	$= \log[p_i/(1-p_i)]$
Extreme Value:	$F^{-1}(p_i)$	$= -\log(\log(1 - p_i))$
Gompertz:	$F^{-1}(p_i)$	$= -\log(-\log(p_i)$
Arctangent	$F^{-1}(p_i)$	$= \pi/2 \tan(p_i)$

Minimum chi squared estimators have the same properties as, but are numerically different from the maximum likelihood estimators.

Starting Values

The precise set of values to be provided for **; Start** varies from one model to another. Starting values may be provided for the model. Those used by the program if you do not provide your own are as follows:

- **Individual data:** Simple least squares regression of y on **X**
- **Grouped data:** The minimum chi squared, weighted least squares estimates.

The first round of these weighted least squares estimators, using p_i as F_i in the weights, is computed to obtain the starting values for the MLEs for each of the four models mentioned. The least squares results at the beginning of the output (when requested) will contain an indication that this has been the computation. Iteration of the minimum chi squared estimator is not continued, as the starting values are simply used to continue the maximum likelihood estimation. (Note, as well, that the MCS estimator has a problem not shared by the MLE. If any of the proportions are zero or one, the weights will not be computable. Authors have suggested various fixes; the most common is simply to use a small value such as $1/n$ or $1 - 1/n$ as appropriate.

Standard Errors for Marginal Effects Based on the Delta Method

Standard errors are computed using the delta method. Let $\boldsymbol{\delta}$ denote the marginal effects, and **d** denote the sample estimate. The asymptotic covariance matrix is estimated with

$$\text{Asy.Var}[\mathbf{d}] = \mathbf{G} \times \text{Asy.Var}\left[\left[\hat{\boldsymbol{\beta}}\right]\right] \times \mathbf{G}'$$

where **G** is the matrix of derivatives,

$$\mathbf{G} = \frac{\partial\boldsymbol{\delta}}{\partial\boldsymbol{\beta}'} = f(\boldsymbol{\beta}'\mathbf{x})\mathbf{I} + [\mathrm{d}f(\boldsymbol{\beta}'\mathbf{x})/\mathrm{d}(\boldsymbol{\beta}'\mathbf{x})]\boldsymbol{\beta}\mathbf{x}'$$

evaluated at $\hat{\boldsymbol{\beta}}$ and the particular vector (the vector of sample means). (In the Burr model, there is an extra column in **G** to account for the estimate of γ.) For a dummy variable, the asymptotic standard error must be changed slightly. This is accomplished simply by changing the appropriate row of **G** to

$$\mathbf{G}_z = [f(\boldsymbol{\beta}'\mathbf{x} + \alpha z)]\begin{pmatrix}\mathbf{x}\\1\end{pmatrix}' - [f(\boldsymbol{\beta}'\mathbf{x} + \alpha z)]\begin{pmatrix}\mathbf{x}\\0\end{pmatrix}'$$

NOTE: We are frequently asked about the hypothesis test that the marginal effects equal zero, and in particular, about the fairly common case in which a marginal effect is ‘insignificant’ when the corresponding coefficient is ‘significant.’ Our own assessment is that significance tests of the influence of a variable should be based on the coefficients, not the marginal effects. The latter is a function – and a highly nonlinear one at that – of all the coefficients in the model, and the hypothesis that this function equals zero is not equivalent to the hypothesis that the coefficient is zero or that the variable in question is not a significant determinant of the outcome.

Average Partial Effects vs. Partial Effects at the Means

Some authors (e.g., Wooldridge (1999)) argue that one *should* compute marginal effects by averaging the individual estimates, rather than computing the partial effects once at the means of the variables. Save for small sample variation, the difference in these two results is likely to be small, as suggested by the example below.

The built in **; Partial Effects** option for the binary choices uses the average partial effects in most cases, but partial effects at the means in a few cases such as the heteroscedastic models. The **PARTIAL EFECTS** command computes average partial effects by default in all cases but provides an option for you to choose to evaluate the effects at the means, instead.

E27.12.3 Binary Choice Models with Heteroscedasticity

The log likelihood function for the binary choice model with exponential heteroscedasticity is

$$\log L = \Sigma_i \log F(a_i),\ F = \Phi \text{ or } \Lambda,$$

where

$$a_i = (2y_i - 1)\boldsymbol{\beta}'\mathbf{x}_i \times \exp(-\boldsymbol{\gamma}'\boldsymbol{w}_i\ ).$$

We are taking advantage of the symmetry of the probit and logit functions to simplify the function. Let

$$\boldsymbol{\theta} = \text{the full parameter vector, } [\boldsymbol{\beta}',\boldsymbol{\gamma}']',\text{ in which } \boldsymbol{\gamma} \text{ may be } \mathbf{0}.$$

The derivatives are as follows, where we use the notation $\mathbf{a}_{i\theta}$ for $\partial a_i/\partial\boldsymbol{\theta}$:

$$\frac{\partial \log L}{\partial \boldsymbol{\theta}} = \Sigma_i [f(a_i)/F(a_i)]\partial a_i/\partial\boldsymbol{\theta} = \Sigma_i g_i \mathbf{a}_{i\theta}.$$

where $g_i = \phi(a_i)/\Phi(a_i)$ for the probit model ($f_i = \phi(a_i)$),

$g_i = (1 - \Lambda_i)$ for the logit model ($f_i = \Lambda_i(1-\Lambda_i)$),

and
$$\mathbf{a}_{i\theta} = (2y_i - 1)\exp(-\gamma'\mathbf{w}_i)\begin{bmatrix}\mathbf{x}_i \\ -(\boldsymbol{\beta}'\mathbf{x}_i)\mathbf{w}_i\end{bmatrix}$$

Using a similar subscripting notation for second derivatives, we have

$$\frac{\partial \log L}{\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}'} = \Sigma_i h_i \mathbf{a}_{i\theta}\mathbf{a}_{i\theta'} + g_i \mathbf{a}_{i\theta\theta'}$$

where
$$h_i = \frac{\partial g_i}{\partial a_i} = \begin{cases} -a_i g_i - g_i^2 & \text{for the probit model} \\ -\Lambda_i(1-\Lambda_i) & \text{for the logit model}\end{cases}$$

and
$$a_{i\beta\beta'} = \mathbf{0},$$
$$a_{i\beta\gamma'} = (2y_i - 1)\exp(-\boldsymbol{\gamma}'\mathbf{w}_i)\mathbf{x}_i(-\mathbf{w}_i'),$$
$$a_{i\gamma\gamma'} = (2y_i - 1)(\boldsymbol{\beta}'\mathbf{x}_i)\exp(-\boldsymbol{\gamma}'\mathbf{w}_i)\mathbf{w}_i\mathbf{w}_i'.$$

There are two sets of marginal effects in this model:

$$\frac{\partial E[y_i\,|\,\mathbf{x}_i]}{\partial \mathbf{x}_i} = f(a_i)\frac{\partial a_i}{\partial \mathbf{x}_i} = f(a_i)\exp(-\boldsymbol{\gamma}'\mathbf{w}_i)\boldsymbol{\beta}$$

$$\frac{\partial E[y_i\,|\,\mathbf{x}_i]}{\partial \mathbf{w}_i} = f(a_i)\frac{\partial a_i}{\partial \mathbf{w}_i} = -f(a_i)\exp(-\boldsymbol{\gamma}'\mathbf{w}_i)(\boldsymbol{\beta}'\mathbf{x}_i)\boldsymbol{\gamma}$$

If any variables appear in both **x** and **w**, then the marginal effect of that variable on the conditional mean is the sum of the two parts.

E28: Tests and Restrictions in Models for Binary Choice

E28.1 Introduction

We define models in which the response variable being described is inherently discrete as qualitative response (QR) models. Chapters E26 and E27 presented the model formulation and estimation and analysis tools. This chapter will detail some aspects of hypothesis testing. Most of these results are generic, and will apply in other models as well. The hypothesis tests are general restrictions on parameters. Section E28.3 considers two broader specification tests. Section E28.4 documents how to impose restrictions on the maximum likelihood estimator.

E28.2 Testing Hypotheses

The full set of options is available for testing hypotheses and imposing restrictions on the binary choice models. In using these, the set of parameters is

$$\beta_1, ..., \beta_K \text{ plus } \gamma \text{ for the Burr model}$$

In the parametric models, hypotheses can be done with the standard trinity of tests: Wald, likelihood ratio and Lagrange Multiplier. All three are particularly straightforward for the binary choice models.

E28.2.1 Wald Tests

Wald tests are carried out in two ways, with the **; Test:** specification in the model command and by using the **WALD** command after fitting the model. The former is used for linear restrictions. The **WALD** command is more general and allows for tests of nonlinear restrictions on parameters.

The Wald statistic is computed using the estimates of an unrestricted model. The hypothesis implies a set of restrictions

$$H_0: \mathbf{c}(\boldsymbol{\beta}) = \mathbf{0}.$$

(This may involve linear distance from a constant, such as $2\beta_3 - 1.2 = 0$. The preceding formulation is used to achieve the full generality that *LIMDEP* allows.) The Wald statistic is computed by the formula

$$W = \mathbf{c}(\hat{\boldsymbol{\beta}})'\left[\mathbf{G}(\hat{\boldsymbol{\beta}})\left\{Est.Asy.Var(\hat{\boldsymbol{\beta}})\right\}\mathbf{G}(\hat{\boldsymbol{\beta}})'\right]^{-1}\mathbf{c}(\hat{\boldsymbol{\beta}})$$

where $$\mathbf{G}(\hat{\boldsymbol{\beta}}) = \frac{\partial \mathbf{c}(\hat{\boldsymbol{\beta}})}{\partial \hat{\boldsymbol{\beta}}'}$$

and $\hat{\boldsymbol{\beta}}$ is the vector of estimated parameters.

You can request Wald tests of simple restrictions by including the request in the model command. For example:

```
PROBIT     ; Lhs = doctor
           ; Rhs = one,age,educ,married,hhninc,hhkids
           ; Test:  age + educ = 0,
                    married = 0 ,
                    hhninc + 2*hhkids = -.3  $
```

```

-----------------------------------------------------------------------------
```

When the restrictions are built into the estimator with CML, the information reported is only that the restrictions were imposed. The results of the Wald or LR test cannot be reported because the unrestricted model is not computed.

E28.2.2 Likelihood Ratio Tests

Use the log likelihood functions from both restricted and unrestricted models. Log likelihood functions are saved automatically by the estimators. Do keep in mind that these are overwritten each time – the scalar *logl* gets replaced by each model command. Your general strategy for carrying out a likelihood ratio test would be

Model name ; ... - specifies the unrestricted model
CALC ; lu = logl $ Capture log likelihood function
Model name ; ... - specifies the restricted model
CALC ; lr = logl
; List ; chisq = 2*(lu - lr)
; 1 - Chi(chisq, degrees of freedom) $

You must supply the degrees of freedom. If the result of the last line is less than your significance level – usually 0.05 – then, the null hypothesis of the restriction would be rejected. Here are two examples: We continue to examine the German health care data. For purposes of these tests, just for the illustrations, we will switch to a probit model.

Simple Linear Restriction

The following tests the pair of linear restrictions suggested above. Looking at the unrestricted results from earlier, the restrictions don't look like they are going to pass. The results bear this out.

```
SAMPLE      ; All $
NAMELIST    ; x = one,age,educ,married,hhninc,hhkids $
LOGIT       ; Lhs = doctor ; Rhs = x $
CALC        ; lu = logl $
LOGIT       ; Lhs = doctor ; Rhs = x
            ; Rst = b0, b1, b1, 0, b2, b3 $
CALC        ; lr = logl
            ; List ; chisq = 2*(lu - lr) ; 1 - Chi(chisq,2) $
```

```
[CALC] CHISQ   =    158.9035080
[CALC] *Result*=       .0000000
Calculator: Computed   3 scalar results
```

Homogeneity Test

We are frequently asked about this. The sample can be partitioned into a number of subgroups. The question is whether it is valid to pool the subgroups. Here is a general strategy that is the maximum likelihood counterpart to the Chow test for linear models: Define a variable, say, *group*, that takes values 1,2,...,*G*, that partitions the sample. This is a stratification variable. The test statistic for homogeneity is

$$\chi^2 = 2[(\Sigma_{groups} \text{ log likelihood for the group}) - \text{log likelihood for the pooled sample}]$$

The degrees of freedom is G-1 times the number of coefficients in the model.

Create the group variable.

```
SAMPLE      ; Pooled sample ... however defined ... $
Model name  ; ... ; Quiet $  Specify the appropriate model.  Suppress the output.
CALC        ; chisq = -2*logl ; df = -kreg $
```

Automate the model fitting estimation, and accumulate the statistic.

```
PROC
  INCLUDE    ; New ; Group = i $
  Model name ; ... ; Quiet $  Specify the same model.  Suppress the output.
  CALC       ; chisq = chisq + 2*logl ; df = df + kreg $
ENDPROC
```

Determine the number of groups.

```
CALC        ; g = Max(group) $
```

Estimate the model once for each group.

```
EXEC        ; i = 1,g $
CALC        ; List ; chisq ; df ; 1 - Chi(chisq,df)  $
```

This procedure produces only the output of the last **CALC** command, which will display the test statistic, the degrees of freedom and the p value for the test.

To illustrate, we'll test the hypothesis that the same probit model for doctor visits applies to both men and women. This command suppresses all output save for the actual test of the hypothesis.

```
NAMELIST   ; x = one,age,educ,married,hhninc,hhkids $
PROBIT     ; If [ female = 0] ; Lhs = doctor ; Rhs = x ; Quiet $
CALC       ; l0 = logl $
PROBIT     ; If [ female = 1] ; Lhs = doctor ; Rhs = x ; Quiet $
CALC       ; l1 = logl $
PROBIT     ; Lhs = doctor ; Rhs = x ; Quiet $
CALC       ; l01 = logl ; List
           ; chisq = -2*(l01 - l0 - l1)
           ; df = 2*kreg ; pvalue = 1 - Chi(chisq,df) $
```

The results of the chi squared test strongly reject the homogeneity restriction.

```
[CALC] CHISQ   =    549.3141072
[CALC] DF      =     12.0000000
[CALC] PVALUE  =       .0000000
Calculator: Computed   4 scalar results
```

E28.2.3 Lagrange Multiplier Tests

The third procedure available for testing hypotheses is the Lagrange Multiplier, or LM approach. The Lagrange Multiplier statistic is computed as a Wald statistic for testing the hypothesis that the derivatives of the log likelihood are zero when evaluated at the restricted maximum likelihood estimator;

$$LM = \mathbf{g}(\hat{\boldsymbol{\beta}}_R)'\left[Est.Asy.Var\left\{\mathbf{g}(\hat{\boldsymbol{\beta}}_R)\right\}\right]^{-1}\mathbf{g}(\hat{\boldsymbol{\beta}}_R)$$

where $\hat{\boldsymbol{\beta}}_R$ = MLE of the parameters of the model, with restrictions imposed

$\mathbf{g}(\hat{\boldsymbol{\beta}}_R)$ = derivatives of log likelihood of full model, evaluated at $\hat{\boldsymbol{\beta}}_R$

The estimated asymptotic covariance matrix of the gradient is any of the usual estimators of the asymptotic covariance matrix of the coefficient estimator, negative inverse of the actual or expected Hessian, or the BHHH estimator based on the first derivatives only.

Your strategy for carrying out LM tests with *LIMDEP* is as follows:

Step 1. Obtain the restricted parameter vector. This may involve an unrestricted parameter vector in some restricted model, padded with some zeros, or a similar arrangement.

Step 2. Set up the full, unrestricted model as if it were to be estimated, but include in the command

```
; Start  = restricted parameter vector
; Maxit  = 0
```

The rest of the procedure is automated for you. The **; Maxit = 0** specification takes on a particular meaning when you also provide a set of starting values. It implies that you wish to carry out an LM test using the starting values.

To demonstrate, we will carry out the test of the hypothesis

$$\beta\_age + \beta\_educ = 0$$
$$\beta\_married = 0$$
$$\beta\_hhninc + \beta\_hhkids = -.3$$

that we tested earlier with a Wald statistic, now with the LM test. The commands would be as follows:

```
PROBIT    ; Lhs = doctor
          ; Rhs = one,age,educ,married,hhninc,hhkids
          ; CML: age+educ = 0, married = 0 , hhninc + 2*hhkids = -.3 $
PROBIT    ; Lhs = doctor
          ; Rhs = one,age,educ,married,hhninc,hhkids
          ; Maxit = 0 ; Start = b $
```

The results of the second model command provide the Lagrange multiplier statistic. The value of 26.06032 is the same as the Wald statistic computed earlier, 26.06.

```
Maximum of     0 iterations. Exit iterations with status=1.
Maxit = 0. Computing LM statistic at starting values.
No iterations computed and no parameter update done.
-----------------------------------------------------------------------------

--------+--------------------------------------------------------------------
        |Index function for probability
Constant|    -.06593        .05655    -1.17  .2437     -.17678    .04491
     AGE|     .01484***     .00079    18.76  .0000      .01329    .01639
    EDUC|    -.01484***     .00351    -4.23  .0000     -.02171   -.00796
 MARRIED|       0.0         .02049      .00 1.0000 -.40156D-01  .40156D-01
  HHNINC|    -.09655**      .04636    -2.08  .0373     -.18741   -.00568
  HHKIDS|    -.10173***     .01821    -5.59  .0000     -.13742   -.06603
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

To complete the trinity of tests, we can carry out the likelihood ratio test, which we could do as follows:

```
PROBIT      ; Quiet ; Lhs = doctor
            ; Rhs = one,age,educ,married,hhninc,hhkids
            ; CML: b(2) + b(3) = 0, b(4) = 0, b(5) + b(6) = -.3 $
CALC        ; lr = logl $
PROBIT      ; Quiet ; Lhs = doctor
            ; Rhs = one,age,educ,married,hhninc,hhkids $
CALC        ; lu = logl ; List
            ; lrstat  = 2*(lu – lr) $
```

The result of the computation (which displays only the last statistic) is

```
[CALC] LRSTAT  =     26.0455042
Calculator: Computed   2 scalar results
```

The value of 26.0455 differs only trivially from the other values. This is actually not surprising, since they should all converge to the same statistic, and the sample in use here is very large.

E28.3 Two Specification Tests

The following are two specialized tests for the probit model, one for testing which of two competing models appears to be appropriate, and one test against the hypothesis of normality that underlies the probit model.

E28.3.1 A Test for Nonnested Probit Models

Davidson and MacKinnon (1993) present a test of the nonnested hypothesis that an alternative set of variables, $\mathbf{z}_i$, is the appropriate one for the structural equation of the probit model.

$$\text{Testing } y^* = \mathbf{x}'\boldsymbol{\beta} + \varepsilon \text{ vs. } y^* = \mathbf{z}'\boldsymbol{\gamma} + u$$

```
NAMELIST    ; x  = the independent variables
            ; z  = the competing list of independent variables $
CREATE      ; y  = the dependent variable $
PROBIT      ; Quiet ; Lhs = y ; Rhs = x $
CREATE      ; xbeta  = x’b; fx = N01(xbeta) ; px = Phi(xbeta)
            ; v  = Sqr(px*(1-px)) ; dev = (y - px) / v
            ; xv = fx*xbeta / v $
PROBIT      ; Quiet ; Lhs = y ; Rhs = z $
CREATE      ; pz = Phi(z’b) ; test = (px - pz) / v $
REGRESS     ; Lhs = dev ; Rhs  = xv,test $
```

The test is carried out by referring the t ratio on *test* to the t table. A value larger than the critical value argues in favor of *z* as the correct specification. For example, the following tests for which of two specifications of the right hand side of the probit model is preferred.

```
NAMELIST   ; x = one,age,educ,married,hhninc,hhkids,self
           ; z = one,age,educ,married,hhninc,female,working $
CREATE     ; y = doctor $
```

The remaining commands are identical.

The essential regression results are as follows. We also reversed the roles of *x* and *z*. Unfortunately, as often happens in specifications, the results are contradictory.

```
--------+------------------------------------------------------------------
        |                  Standard            Prob.       95% Confidence
     DEV|  Coefficient       Error         z   |z|>Z*          Interval
--------+------------------------------------------------------------------
      XV|     .04569**       .01985      2.30  .0214      .00678     .08459
    TEST|    -.79517***      .03995    -19.90  .0000    -.87348    -.71687
--------+------------------------------------------------------------------
      XV|     .04668**       .02033      2.30  .0217      .00684     .08652
    TEST|    -.26126***      .04273     -6.11  .0000    -.34500    -.17751
```

The t ratio of -19.9 in the first regression argues in favor of *z* as the appropriate specification. But, the also significant t ratio of -6.11 in the second argues in favor of *x*.

E28.3.2 A Test for Normality in the Probit Model

The second test is a Lagrange multiplier test against the null hypothesis of normality in the probit model. (The test was developed in Bera, Jarque and Lee (1984).) As usual in normality tests, the statistic is computed by comparing the third and fourth moments of an underlying variable to their expected value under normality. The computations are as follows, where *i* indicates the *i*th observation:

$$a_i = \mathbf{x}_i'\boldsymbol{\beta}$$

$$\phi_i = \phi(a_i)$$

$$\Phi_i = \Phi(a_i)$$

$$d_i = \phi_i\,(y_i - \Phi_i) \,/\, [\Phi_i(1 - \Phi_i)]$$

$$c_i = \phi_i^2 \,/\, [\Phi_i(1 - \Phi_i)]$$

$$m3_i = -1/2(a_i^2 - 1)$$

$$m4_i = 1/4\,(a_i\,(a_i^2 + 3))$$

$$\mathbf{z}_i = (\mathbf{x}_i', m3_i, m4_i)'$$

Then,

$$LM = \left(\sum\nolimits_{i=1}^{N} d_i\mathbf{z}_i\right)'\left(\sum\nolimits_{i=1}^{N} c_i\mathbf{z}_i\mathbf{z}_i'\right)^{-1}\left(\sum\nolimits_{i=1}^{N} d_i\mathbf{z}_i\right)$$

The commands below will carry out the test. The chi squared reported by the last line has two degrees of freedom.

```
NAMELIST    ; x = one,... $
CREATE      ; y = the dependent variable $
PROBIT      ; Lhs = y ; Rhs = x  $
CREATE      ; ai = b'x ; fi = Phi(ai) ; dfi = N01(ai)
            ; di = (y-fi) * dfi  /(fi*(1-fi)) ; ci = dfi^2 /(fi*(1-fi))
            ; m3i = -1/2*(ai^2-1) ; m4i =  1/4*(ai*(ai^2+3)) $
NAMELIST    ; z  = x,m3i,m4i $
MATRIX      ; List ; LM = di’z * <z'[ci]z> * z'di $
```

We executed the routine for our probit model estimated earlier, with

```
NAMELIST    ; x = one,age,educ,married,hhninc,hhkids,self $
CREATE      ; y = doctor $
```

The result of 93.12115 would lead to rejection of the hypothesis of normality; the 5% critical value for the chi squared variable with two degrees of freedom is 5.99.

```
      LM|             1
--------+--------------
       1|       93.1211
```

E28.4 The WALD Command

The **WALD** command may be used for linear and nonlinear restrictions. The model commands produce a set of names that can be used in **WALD** commands after estimation. For the binary choice commands, these are *b_variable*. The **WALD** command can be used with these names in specified restrictions, with no other information needed. For example:

```
PROBIT      ; Lhs = doctor
            ; Rhs = one,age,educ,married,hhninc,hhkids  $
WALD        ; Fn1 = b_age + b_educ - 0
            ; Fn2 = b_married - 0

```

You may follow a model command with as many **WALD** commands as you wish.

You can use **WALD** to obtain standard errors for linear or nonlinear functions of parameters. Just ignore the test statistics. Also, **WALD** produces some useful output in addition to the displayed results. The new matrix *varwald* will contain the estimated asymptotic covariance matrix for the set of functions. The new vector *waldfns* will contain the values of the specified functions. A third matrix, *jacobian*, will equal the derivative matrix, $\partial \mathbf{c}(\boldsymbol{\beta})/\partial \boldsymbol{\beta}'$. For the computations above, the three matrices are

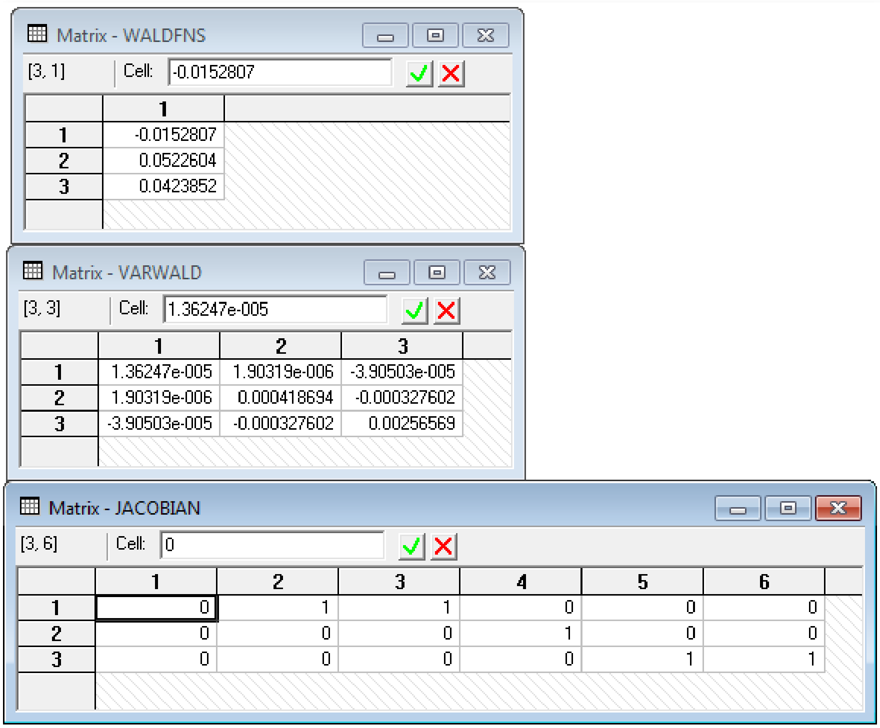

Figure E28.1 Matrix Results for the WALD Command

Thus, the command

MATRIX ; w = waldfns’ <varwald> waldfns $

would recompute the Wald statistic.

```
Matrix W         has  1 rows and  1 columns.
               1
        +--------------
       1|   24.95162
```

E28.5 Imposing Linear Restrictions

Fixed Value and Equality Restrictions

Fixed value and equality restrictions are imposed with

; Rst = the list of settings symbols for free parameters, values for specific values

For example,

```
NAMELIST    ; x = one,age,educ,married,hhninc,hhkids $
LOGIT       ; Lhs  =  doctor ; Rhs = x
            ; Rst  =  b0, b1, b1, 0, b2, b3 $
```

will force the second and third coefficients to be equal and the fourth to equal zero.

Linear Restrictions

These are imposed with

; CML: the set of linear restrictions

(See Section R13.6.2.) This is a bit more general than the Rst function, but similar. For example, to force the restriction that the coefficient on *age* plus that on *educ* equal twice that on *hhninc*, use

```
; CML:  age + educ - 2*hhninc = 0
```

E29: Extended Binary Choice Models

E29.1 Introduction

LIMDEP supports a large variety of models and extensions for the analysis of binary choice. This chapter documents sample selection models, models with endogenous right hand side variables and two step estimation of models that build on probit and logit models.

E29.2 Sample Selection in Probit and Logit Models

The model of sample selection can be extended to the probit and logit binary choice models. In both cases, we depart from

$$\text{Prob}[y_i = 1\,|\mathbf{x}_i] = \text{F}(\boldsymbol{\beta}'\mathbf{x}_i)$$

where $F(t) = \Phi(t)$ for the probit model and $\Lambda(t)$ for the logit model,

$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\; u_i \sim N[0,1],\; z_i = 1(z_i^* > 0)$$

y_i, $\mathbf{x}_i$ observed only when $z_i = 1$.

In both cases, as stated, there is no obvious way that the selection mechanism impacts the binary choice model of interest. We modify the models as follows:

For the probit model,

$$y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\; \varepsilon_i \sim N[0,1],\; y_i = 1(y_i^* > 0)$$

which is the structure underlying the probit model in any event, and

$$u_i, \varepsilon_i \sim \text{BVN}[(0,0),(1,\rho,1)].$$

This is precisely the structure underlying the bivariate probit model. Thus, the probit model with selection is treated as a bivariate probit model. Some modification of the model is required to accommodate the selection mechanism. The full set of results is presented in Section E33.4. The command is simply

```
BIVARIATE   ; Lhs  = y,z
            ; Rh1 = variables in x
            ; Rh2 = variables in w
            ; Selection $
```

For the logit model, a similar approach does not produce a convenient bivariate model. The probability is changed to

$$\text{Prob}(y_i = 1 \mid \mathbf{x}_i,\varepsilon_i) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)}.$$

With the selection model for z_i as stated above, the bivariate probability for y_i and z_i is a mixture of a logit and a probit model. The log likelihood can be obtained, but it is not in closed form, and must be computed by approximation. We do so with simulation. The model and the background results are presented in Section E54.5. The commands for the model are

PROBIT ; Lhs = z ; Rhs = variables in w ; Hold $
LOGIT ; Lhs = y ; Rhs = variables in x ; Selection $

The motivation for a probit selection mechanism into a logit model does seem ambiguous.

E29.3 Endogenous Variable in a Probit Model

This estimator is for what is essentially a simultaneous equations model. The model equations are

$$y_1{*} = \boldsymbol{\beta}'\mathbf{x} + \alpha y_2 + \varepsilon,\ y_1 = 1[y_1{*} > 0],$$
$$y_2 = \boldsymbol{\gamma}'\mathbf{z} + u,$$
$$(\varepsilon, u) \sim N\left[\begin{pmatrix}0\\0\end{pmatrix}, \begin{pmatrix}1 & \rho\sigma\\ \rho\sigma & \sigma^2\end{pmatrix}\right].$$

Probit estimation based on y_1 and $(\mathbf{x}_1,y_2)$ will not consistently estimate $(\boldsymbol{\beta},\alpha)$ because of the correlation between y_2 and ε induced by the correlation between u and ε. Several methods have been proposed for estimation. One possibility is to use the partial reduced form obtained by inserting the second equation in the first. This will produce consistent estimates of $\boldsymbol{\beta}/(1+\alpha^2\sigma^2+2\alpha\sigma\rho)^{1/2}$ and $\alpha\boldsymbol{\gamma}/(1+\alpha^2\sigma^2+2\alpha\sigma\rho)^{1/2}$. Linear regression of y_2 on $\mathbf{z}$ produces estimates of γ and σ^2, but there is no method of moments estimator of ρ produced by this procedure, so this estimator is incomplete. Newey (1987) suggested a 'minimum chi squared' estimator that does estimate all parameters. A more direct, and actually simpler approach is full information maximum likelihood. Details on the estimation procedure appear below after the application.

To estimate this model, use the command

PROBIT ; Lhs = y1, y2
; Rh1 = independent variables in probit equation
; Rh2 = independent variables in regression equation $

(Note, the probit must be the first equation.) Other optional features relating to fitted values, marginal effects, etc. are the same as for the univariate probit command. We note, marginal effects are computed using the univariate probit probabilities,

$$\text{Prob}[y_1 = 1] \sim \Phi[\beta'x + \alpha y_2]$$

These will approximate the marginal effects obtained from the conditional model (which contain u). When averaged over the sample values, the effect of u will become asymptotically negligible. Predictions, etc. are kept with **; Keep = name**, and so on. Likewise, options for the optimization, such as maximum iterations, etc. are also the same as for the univariate probit model.

Retained Results

The results saved by this binary choice estimator are:

Matrices: *b* = estimate of ($\boldsymbol{\beta}$,α,$\boldsymbol{\gamma}$). Using **; Par** adds σ and ρ to *b*.
varb = asymptotic covariance matrix.

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variable* (includes α) and, *c_variables.*

Last Function: $\Phi(\mathbf{b}'\mathbf{x} + ay_2) = \text{Prob}(y_1 = 1 \mid \mathbf{x},y_2)$.

The *Last Model* names are used with **WALD** to simplify hypothesis tests. The last function is the conditional mean function. The extra complication of the estimator has been used to obtain a consistent estimator of β,α. With that in hand, the interesting function is $E[y_1| \mathbf{x},y_2]$.

Technical Details

The log likelihood is built up from the joint density of y_1 and y_2, which we write as the product of the conditional and the marginal densities,

$$f(y_1,y_2) \;=\; f(y_1|y_2)\, f(y_2).$$

To derive the conditional distribution, we use results for the bivariate normal, and write

$$\varepsilon|u \;=\; [(\rho\sigma)/\sigma^2]\, u \;+\; w,$$

where w is normally distributed with $\text{Var}[w] = (1 - \rho^2)$. Inserting this in the first equation, we have

$$y_1^*|y_2 = \boldsymbol{\beta}'\mathbf{x} + \alpha y_2 \;+\; (\rho/\sigma)u \;+\; w.$$

Therefore,

$$\text{Prob}[y_1 = 1|y_2] \;=\; \Phi\left[\frac{\boldsymbol{\beta}'\mathbf{x} + \alpha y_2 + (\rho/\sigma)u}{\sqrt{1-\rho^2}}\right].$$

Inserting the expression for u, and using the normal density for the marginal distribution of y_2, we obtain the log likelihood function for the sample,

$$\log L = \sum\nolimits_{i=1}^{N} \;\log\Phi\left[(2y_{i1}-1)\left(\frac{\boldsymbol{\beta}'\mathbf{x}_i + \alpha y_{i2} + (\rho/\sigma)(y_{i2}-\boldsymbol{\gamma}'\mathbf{z}_i)}{\sqrt{1-\rho^2}}\right)\right] + \log\left[\frac{1}{\sigma}\phi\left(\frac{y_{i2}-\boldsymbol{\gamma}'\mathbf{z}_i}{\sigma}\right)\right]$$

We use several devices to make estimation easier. First, we use the Olsen transformation to reparameterize the log likelihood in

$$\theta \;=\; 1/\sigma$$

$$\boldsymbol{\delta} \;=\; (1/\sigma)\boldsymbol{\gamma}.$$

We ensure that θ is positive during estimation by estimating

$$\eta \;=\; \log\theta, \text{ so } \theta \;=\; \exp(\eta).$$

To force the correlation to remain in the (-1,+1) interval, we maximize the log likelihood with respect to

$$\tau \;=\; \log\left(\frac{1+\rho}{1-\rho}\right), \text{ so } \;\rho = \frac{\exp(\tau)-1}{\exp(\tau)+1}.$$

The log likelihood is, then,

$$\log L = \sum_{i=1}^{N} \log\Phi\left[(2y_{i1}-1)\left(\frac{\boldsymbol{\beta}'\mathbf{x}_i + \alpha y_{i2} + \rho(\theta y_{i2} - \boldsymbol{\delta}'\mathbf{z}_i)}{\sqrt{1-\rho^2}}\right)\right] + \log\left[\theta\phi\left(\theta y_{i2} - \boldsymbol{\delta}'\mathbf{z}_i\right)\right].$$

(The likelihood can actually be further simplified. Since $\boldsymbol{\beta}$ is a free parameter vector, we can let $\boldsymbol{\beta}_r$ equal $\boldsymbol{\beta}/(1 - \rho^2)^{1/2}$ and α_r equal $\alpha/(1 - \rho^2)^{1/2}$. Then, define $\omega = \rho/(1 - \rho^2)^{1/2}$. The resulting log likelihood is

$$\log L = \sum_{i=1}^{N} \log\Phi\left[(2y_{i1}-1)\left((\boldsymbol{\beta}_r'\mathbf{x}_i + \alpha_r y_{i2}) + \omega(\theta y_{i2} - \boldsymbol{\delta}'\mathbf{z}_i)\right)\right] + \log\left[\theta\phi\left(\theta y_{i2} - \boldsymbol{\delta}'\mathbf{z}_i\right)\right].$$

This simplifies the programming a bit, but does not actually improve the process of optimization.) The delta method is used after estimation to recover the estimates of the original parameters and estimators of their asymptotic variances.

E29.4 Using MAXIMIZE to Estimate Other Parametric Models

The general formulation used earlier suggests a means of extending the binary choice model to distributions other than the ones listed in Section E27.2. In particular, if the model is formulated as a single index regression:

y_i = a binary outcome taking values 0 or 1 with

Prob[$y_i = 1$] = $F(\boldsymbol{\beta}'\mathbf{x}_i)$, such that $F'(\boldsymbol{\beta}'\mathbf{x}_i) \geq 0$ and $0 < F(\boldsymbol{\beta}'\mathbf{x}_i) < 1$,

then any proper probability distribution function will suffice. This is simply a model, with no more or less justification than the logistic or normal distributions.

There are many possibilities that one might consider. The binary probability model is a particularly simple one to formulate, and *LIMDEP*'s **MAXIMIZE** routine is well suited to this type of problem. A template that one might use for this approach would be as follows:

```
NAMELIST    ; x  = the set of Rhs variables $
CREATE      ; y  = ... define the dependent variable $
CALC        ; k  = Col(x) $
MATRIX      ; b0 = Init(k,1,0.0) $
MAXIMIZE    ; Start = b0
            ; Labels = k_beta
            ; Fcn = bx = beta1'x |
                    p = ... the definition of F(bx) |
                    y * Log(p) + (1-y)*Log(1-p) $
```

E29.5 Two Step Estimation Using Binary Choice Models

The essential parts of a two procedure are

Step 1. A model is estimated by least squares or maximum likelihood. Denote the parameters estimated at this step as $\boldsymbol{\theta}_1$. For present purposes, this is the probit or logit model.

Step 2. A second model is estimated in which a predicted value from the model in Step 1 appears on the right hand side of the equation. Denote the full set of parameters estimated at this step as $\boldsymbol{\theta}_2$.

We assume that estimation at both steps is consistent – the modeler will have to verify this on a case by case basis. The remaining computation is the correction of the estimated asymptotic covariance matrix for the estimator at Step 2 for the randomness of the estimator carried forward from Step 1. We base our results for this computation on the Murphy and Topel (1985) paper which presents a general method of doing the calculations. (See Greene (2011) for additional discussion.) There are like results for GMM estimation – see Newey (1984) – however, we restrict our attention to maximum likelihood estimation in *LIMDEP*.

The underlying result is as follows (again, from Greene (2011)): Let $\mathbf{V}_2$ be the uncorrected covariance matrix computed at Step 2, using the parameter estimates obtained at Step 1 as if they were known, and $\mathbf{V}_1$ be the estimator of the asymptotic covariance matrix for the parameter estimates obtained at Step 1. Both of these estimators are based on the respective log likelihood functions. In addition, define

$$\mathbf{C} = \sum_{i=1}^{n}\left(\frac{\partial \log f_{i2}}{\partial \boldsymbol{\theta}_2}\right)\left(\frac{\partial \log f_{i2}}{\partial \boldsymbol{\theta}_1'}\right)$$

and

$$\mathbf{R} = \sum_{i=1}^{n}\left(\frac{\partial \log f_{i2}}{\partial \boldsymbol{\theta}_2}\right)\left(\frac{\partial \log f_{i1}}{\partial \boldsymbol{\theta}_1'}\right)$$

(Note the derivatives shown are the derivatives of individual terms in the two log likelihoods. These appear at various points above for the probit and logit models.) With these in hand, the corrected covariance matrix for the second step estimator is

$$\mathbf{V}_2^* = \mathbf{V}_2 + \mathbf{V}_2[\mathbf{C}\mathbf{V}_1\mathbf{C}' - \mathbf{R}\mathbf{V}_1\mathbf{C}' - \mathbf{C}\mathbf{V}_1\mathbf{R}']\mathbf{V}_2$$

A general case that has been automated in *LIMDEP* is a model of the form:

y_1 = a binary variable specified by a probit or logit formulation,

y_2 = a dependent variable whose conditional mean function is a function of $E[y_1]$.

Models of this sort could in principle be estimated by full information maximum likelihood. We consider two step estimation instead, which is often simpler. Models for which the second step shown above is automated are the following:

- Probit and probit with heteroscedasticity,
- Truncated regression,
- Tobit and tobit with heteroscedasticity,
- Poisson and negative binomial regression,
- Linear regression.

For these models, the estimation procedure is the following two steps:

```
PROBIT        ; Lhs = y1 ; Rhs = as usual
or LOGIT      ; Prob = py
              ; Hold $
Model name    ; Lhs = y2
              ; Rhs = as usual,py   Note, py, not y1.
              ; 2Step = py $
```

In the example shown below, a probit model is estimated and the results are held for the second step. At the second step, a Poisson regression model is estimated. (Results for the probit model are omitted.) The second set of estimates shown omit the Murphy and Topel correction.

The preceding includes a fairly large number of possible specifications, given all the different combinations. (Any of the first step models may be used with any of the second step models.) But, an essentially infinite number of possible different specifications remain. If you wish to use this procedure, you may have to program the second step correction yourself to do so. *LIMDEP*'s various programming features should make this fairly easy. To illustrate, we will present a moderately complicated case in detail. For the example, we consider a multinomial logit model for a y_2 which has three outcomes and a y_1 determined by a probit model. The model is

$$y_1^* = \boldsymbol{\theta}'\mathbf{z} + \varepsilon_1,$$

$$y_1 = \mathbf{1}(y_1^* > 0),$$

$$E[y_1] = \Phi(\boldsymbol{\theta}'\mathbf{z}),\ \varepsilon \sim N[0,\sigma^2],\ \Phi(.) = \text{standard normal CDF},$$

$$\text{Prob}[y_2 = j] = e_j / (e_0 + e_1 + e_2),\ j = 0, 1, 2,$$

$$e_0 = 1$$

$$e_1 = \exp[\ \boldsymbol{\beta}_1'\mathbf{x} + \gamma_1\Phi(\boldsymbol{\theta}'\mathbf{z})\ ]$$

$$e_2 = \exp[\ \boldsymbol{\beta}_2'\mathbf{x} + \gamma_2\Phi(\boldsymbol{\theta}'\mathbf{z})\ ]$$

At Step 1, $\boldsymbol{\theta}$ is estimated by maximizing the log likelihood

$$\log L_1 = \sum\nolimits_{i=1}^{n} \log f_{1i}(y_{1i}, \mathbf{z}_i \mid \boldsymbol{\theta}) = \sum\nolimits_{i=1}^{n} \log \Phi\left(q_i \boldsymbol{\theta}' \mathbf{z}_i\right), \text{ where } q_i = 2y_{1i} - 1.$$

After the first step is complete, the predictions, $\Phi(\boldsymbol{\theta}'\mathbf{z})$, are computed using the maximum likelihood estimates, then the log likelihood for the second model is maximized with respect to $\boldsymbol{\beta}_1,\gamma_1,\boldsymbol{\beta}_2,\gamma_2$ while treating the predictions as if they were observed data. The second step log likelihood function is

$$\log L_2 = \sum_{i=1}^{n} \log f_{2i}(y_{2i},\mathbf{x}_i,\Phi(\boldsymbol{\theta}'\mathbf{z}_i)\,|\,\boldsymbol{\beta}_1,\gamma_1,\boldsymbol{\beta}_2,\gamma_2)$$

$$= \sum_{i=1}^{n} \sum_{j=0}^{2} d_{ij} \log \text{Prob}[y_{2i} = j]-\text{, where } d_{ij} = 1 \text{ if } y_{2i} = j,\ j = 0,1,2$$

Each step produces its own estimated parameter vector and asymptotic covariance matrix. The matrices needed for the correction are:

$$\mathbf{C} = \sum_{i=1}^{n} \begin{bmatrix} (d_{i1}-P_{i1})\begin{pmatrix}\mathbf{x}_i \\ \Phi(\boldsymbol{\theta}'\mathbf{z}_i)\end{pmatrix} \\ (d_{i2}-P_{i2})\begin{pmatrix}\mathbf{x}_i \\ \Phi(\boldsymbol{\theta}'\mathbf{z}_i)\end{pmatrix}\end{bmatrix} \times \left[(d_{i1}-P_{i1})\gamma_1 + (d_{i2}-P_{i2})\gamma_2\right]\phi(\boldsymbol{\theta}'\mathbf{z}_i)\mathbf{z}_i'$$

$$\mathbf{R} = \sum_{i=1}^{n} \begin{bmatrix} (d_{i1}-P_{i1})\begin{pmatrix}\mathbf{x}_i \\ \Phi(\boldsymbol{\theta}'\mathbf{z}_i)\end{pmatrix} \\ (d_{i2}-P_{i2})\begin{pmatrix}\mathbf{x}_i \\ \Phi(\boldsymbol{\theta}'\mathbf{z}_i)\end{pmatrix}\end{bmatrix} \times \left[\frac{q_i\phi(\boldsymbol{\theta}'\mathbf{z}_i)}{\Phi(q_i\boldsymbol{\theta}'\mathbf{z}_i)}\mathbf{z}_i'\right]$$

(Derivatives for the multinomial logit log likelihood above appear later in this manual.)

This part of the routine is set up for the particular application. The remainder is general, and need not be changed.

```
NAMELIST    ; x   = … define the Rhs for the multinomial logit model
            ; z   = … define the Rhs for the probit model
CREATE      ; y1 = … dependent variable in the probit model
            ; y2 = … dependent variable in logit model
```

Estimate the probit model. The **IMR = lambda** is just for convenience. It computes the q*N01/Phi in the first log likelihood. Pick up other terms now.

```
PROBIT      ; Lhs = y1 ; Rhs = z ; Prob = prob ; Hold(IMR = lambda) $
CREATE      ; den1 = N01(b'z) $
MATRIX      ; v1 = varb $
```

Augment the Rhs of the logit model with the fitted probability from the probit model, then fit the logit model.

```
NAMELIST    ; xp = x,prob ; xbrep = xp,xp$
LOGIT       ; Lhs = y2 ; Rhs = xp $
```

Get the subvectors of the logit parameter vector and the coefficients on the fitted probability.

```
CALC        ; k = Col(xp) ; j21 = k+1 ; j22 = 2*k
            ; gamma1 = b(k) ; gamma2 = b(j22) $
MATRIX      ; b1 = b(1:k) ; b2 = b(j21:j22) $
```

Compute the scalars that appear in the summations in the construction of the **C** and **R** matrices.

```
CREATE      ; d0  = (y2 = 0) ; d1 = (y2 = 1) ; d2 = (y2 = 2)
            ; e0  = 1 ; e1 = Exp(b1'xp) ; e2 = Exp(b2'xp)
            ; p0  = e0 / (e0 + e1 + e2 ) ; p1 = e1 * p0 ; p2 = e2 * p0
            ; u1  = (d1 – p1 ) ; u2 = (d2 – p2 )
            ; dc1= u1 * (u1*gamma1 + u2*gamma2)*den1
            ; dc2= u2 * (u1*gamma1 + u2*gamma2)*den1
            ; dr1= u1 * lambda ; dr2 = u2 * lambda $
```

Note the matrix constructions. The namelist[variable]namelist format is specifically for computing matrices of the form of **C** and **R** in the expressions above. We compute both matrices in two parts, then stack the parts.

```
MATRIX      ; cm1 = xp' [dc1] z ; cm2 = xp' [dc2 ] z
            ; rm1 = xp' [dr1] z ; rm2 = xp' [dr2 ] z
            ; c = [cm1 / cm2] ; r = [rm1 / rm2] $
```

The last computation computes the corrected covariance matrix, then shows the results.

```
MATRIX      ; t = c * v1 * c' – c * v1 * r' – r * v1 * c'
            ; v2 = varb + varb * t * varb
            ; Stat(b,v2,xbrep) $
```

To illustrate, we used the procedure with the following variable definitions: The data set contains *newhsat*, which is a self assessment of health satisfaction ranked from zero to 10. (The raw data contain the variable *hsat*. *Newhsat* corrects some obvious coding errors.) We created the variable *lhsat* which is zero for *newhsat* less than six, one for *newhsat* from six to eight and two otherwise.

```
CREATE      ; lhsat = 0 + ((newhsat=6)+(newhsat=7)+(newhsat=8))+2*(newhsat > 8) - 1 $
NAMELIST    ; x = one,age,educ,married,working,bluec,whitec,self
            ; z = one,age,educ,married,hhninc,hhkids $
CREATE      ; y1 = doctor ; y2 = lhsat $
```

Estimates produced by the procedure are shown below. The intermediate output is omitted. The first set of results is the uncorrected results of the **LOGIT** command. The second use the Murphy and Topel correction to the asymptotic covariance matrix.

E29.6 Other Models that Build on the Binary Choice Models

A variety of the other models that are estimated with *LIMDEP* are built upon the binary choice framework, particularly the probit model. Some of the model extensions that may be of interest are:

- Bivariate and multivariate extensions of the probit model. These extend the latent regression model to a multivariate regression framework:

$$y_1^* = \boldsymbol{\beta}_1'\mathbf{x}_1 + \varepsilon_1,\ y_1 = 1 \text{ if } y_1^* > 0, 0 \text{ otherwise,}$$

$$y_2^* = \boldsymbol{\beta}_2'\mathbf{x}_2 + \varepsilon_2,\ y_2 = 1 \text{ if } y_2^* > 0, 0 \text{ otherwise,}$$

$$\ldots$$

$$y_M^* = \boldsymbol{\beta}_M'\mathbf{x}_M + \varepsilon_M,\ y_M = 1 \text{ if } y_M^* > 0, 0 \text{ otherwise,}$$

  The disturbances in the equations are allowed to be freely correlated. The bivariate probit model restricts this to two equations, but includes some useful extensions of the model.

  - Bivariate probit with exponential heteroscedasticity
  - Bivariate probit with sample selection: (y_1 ,$\mathbf{x}_1$) only observed when $y_2 = 1$.
  - Partial observability models: Only y_1y_2 is observed. (There are three variants.)

  The unrestricted multivariate probit (MVP) model stated above allows up to 20 equations.

- Multinomial probit (MNP). The MNP model is part of *NLOGIT* Version 5 and is not available in *LIMDEP* Version 10. The MNP model modifies the MVP model above by changing the observation mechanism. The observed outcome is an indicator, j, which denotes which of the M y_j*s is the maximum. The interpretation is that the right hand sides of the regressions are the random utilities associated with M choices, and the individual chooses the one which gives greatest utility.

- Sample selection models. This is a group of models that build on a regression type of model,

$$f(Y^*) = g(\boldsymbol{\gamma}'\mathbf{z} + u) \text{ where } f(.) \text{ is the probability distribution of some observed variable, which depends on a latent or observed regression model}$$

$$y^* = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\ y = 1 \text{ if } y^* > 0, 0 \text{ otherwise,}$$

  Y^* and $\mathbf{z}$ are observed only when $y = 1$, ε and u are correlated.

  Examples include the bivariate probit model mentioned earlier, a regression model (Heckman’s model of sample selection), an ordered probability model, and a Poisson regression model for counts. The models are presented in Chapter E54.

- Ordered probability models are forms of the probit and logit models in which there are more than two outcomes, coded 0,1,2,... The observed outcome occurs with probability drawn from the normal or logistic distribution, with the range of the latent variable divided into more than two parts. The base form of the ordered probability model is

$$y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, \ \ \varepsilon_i \sim \text{standard normal or standard logistic,}$$

$$y_i = 0 \text{ if } y_i^* \le \mu_0,$$

$$1 \text{ if } \mu_0 < y_i^* \le \mu_1,$$

$$2 \text{ if } \mu_1 < y_i^* \le \mu_2,$$

$$\ldots$$

$$J \text{ if } y_i^* > \mu_{J-1}.$$

The observed counterpart to y_i^* is y_i. Note that the probit model that has been discussed in this chapter is the special case when $J = 1$.

- Zero inflation models for count data. The models for count data specify that

$$\text{Prob}[y_i = j] = g(\boldsymbol{\gamma}'\mathbf{z}_i), j = 0,1,\ldots$$

The zero inflation models extend this framework to include the possibility that observations of zero may arise from two regimes. In regime 1, y always equals zero. In regime 2, y follows the distribution above. The determination of which regime applies is modeled as the outcome of a binary choice,

$$\text{Prob[regime 1]} = F(\boldsymbol{\beta}'\mathbf{x}), \ \ \text{Prob[regime 2]} = 1 - F(\boldsymbol{\beta}'\mathbf{x}).$$

The zero inflation models for count data are discussed in Section E43.6.

- Split population models. Parametric models of duration are based on data which are 'complete,' – a transition takes place and 'censored' – the transition has not taken place at the time of observation, and it is assumed that it will take place eventually. The split population models relax this assumption by extending the duration model with a binary choice equation that models the censoring process. The implication is that some observations which are observed as censored might be reasonably treated as if they would never actually experience the transition. See Section E61.5 for this development.

E30: Fixed and Random Effects Models for Binary Choice

E30.1 Introduction

The parametric models discussed in Chapters E27-E29 are extended to panel data formats. Four specific parametric model formulations are provided as internal procedures in *LIMDEP* for these binary choice models. These are the same ones described earlier, less the Burr distribution which is not included in this set. Four classes of models are supported:

- **Fixed effects:** $\text{Prob}[y_{it} = 1] = F(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i)$,
  α_i may be correlated with $\mathbf{x}_{it}$,

- **Random effects:** $\text{Prob}[y_{it} = 1] = \text{Prob}[\boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i > 0]$,
  u_i is uncorrelated with $\mathbf{x}_{it}$,

- **Random parameters:** $\text{Prob}[y_{it} = 1] = F(\boldsymbol{\beta}_i'\mathbf{x}_{it})$,
  $\boldsymbol{\beta}_i \mid i \sim h(\boldsymbol{\beta}|i)$ with mean vector $\boldsymbol{\beta}$ and covariance matrix $\boldsymbol{\Sigma}$

- **Latent class:** $\text{Prob}[y_{it} = 1|\text{class j}] = F(\boldsymbol{\beta}_j'\mathbf{x}_{it})$,
  $\text{Prob}[\text{class = j}] = F_j(\boldsymbol{\theta})$

The last two models provide various extensions of the basic form shown above.

NOTE: None of these panel data models require balanced panels. The group sizes may always vary.

NOTE: None of these panel data models are provided for the Burr (scobit) model.

All formulations are treated the same for the five models, probit, logit, extreme value, Gompertz and arctangent.

NOTE: The random effects estimator requires individual data. The fixed effects estimator allows grouped data.

The third and fourth arise naturally in a panel data setting, but in fact, can be used in cross section frameworks as well. The fixed and random effects estimators require panel data. The fixed and random effects models are described in this chapter. Random parameters and latent class models are documented in Chapter E31.

The probabilities and density functions supported here are as follows:

Probit

$$F = \int_{-\infty}^{\beta'\mathbf{x}_i} \frac{\exp(-t^2/2)}{\sqrt{2\pi}} dt = \Phi(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \phi(\boldsymbol{\beta}'\mathbf{x}_i)$$

Logit

$$F = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)} = \Lambda(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)[1 - \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)]$$

Complementary log log

$$F = 1 - \exp(-\exp(\boldsymbol{\beta}'\mathbf{x}_i)) = C(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \exp(\boldsymbol{\beta}'\mathbf{x}_i)[1 - C(\boldsymbol{\beta}'\mathbf{x}_i)]$$

Gompertz, or type 1 extreme value

$$F = \exp(-\exp(-\boldsymbol{\beta}'\mathbf{x}_i)) = G(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \exp(-\boldsymbol{\beta}'\mathbf{x}_i)G(\boldsymbol{\beta}'\mathbf{x}_i)$$

Arctangent

$$F = 2/\pi \arctan(\exp(\boldsymbol{\beta}'\mathbf{x}_i)), \qquad f = 2/\pi\, [1/(1 + \exp^2(\boldsymbol{\beta}'\mathbf{x}_i))\,]$$

The applications in this chapter are based on the German health care data used throughout the documentation (See Section E2.4). The data are an unbalanced panel of observations on health care utilization by 7,293 individuals. The group sizes in the panel number as follows: T_i: 1=1525, 2=2158, 3=825, 4=926, 5=1051, 6=1000, 7=987. There are altogether 27,326 observations. The variables in the file that are used here are

doctor = 1 if number of doctor visits > 0, 0 otherwise,
hhninc = household nominal monthly net income in German marks / 10000,
hhkids = 1 if children under age 16 in the household, 0 otherwise,
educ = years of schooling,
married = marital status,
female = 1 for female, 0 for male,
docvis = number of visits to the doctor,
hospvis = number of visits to the hospital,
newhsat = self assessed health satisfaction, coded 0,1,...,10.

(The data on health satisfaction in the raw data file, in variable *hsat*, contained some obvious coding errors. Our corrected data are in *newhsat*.)

E30.2 Commands

The essential model command for the models described in this chapter are

PROBIT **LOGIT** **COMPLOG** **GOMPERTZ** **ARCTANGENT**	**; Lhs = dependent variable** **; Rhs = independent variables - not including one** **; Panel** **; ... specification of the panel data model $**

As always, panels may be balanced or unbalanced. The panel is indicated with

SETPANEL ; Group = group identifier
; Pds = count variable to be created $

Thereafter,

; Panel

in the model command is sufficient to specify the panel setting. In circumstances where you have set up the count variable yourself, you may also use the explicit declaration in the command:

; Pds = the fixed number of periods if the panel is balanced
; Pds = a variable which, within a group, repeats the number of observations in the group

One or the other of these two specifications is required for the fixed and random effects estimators.

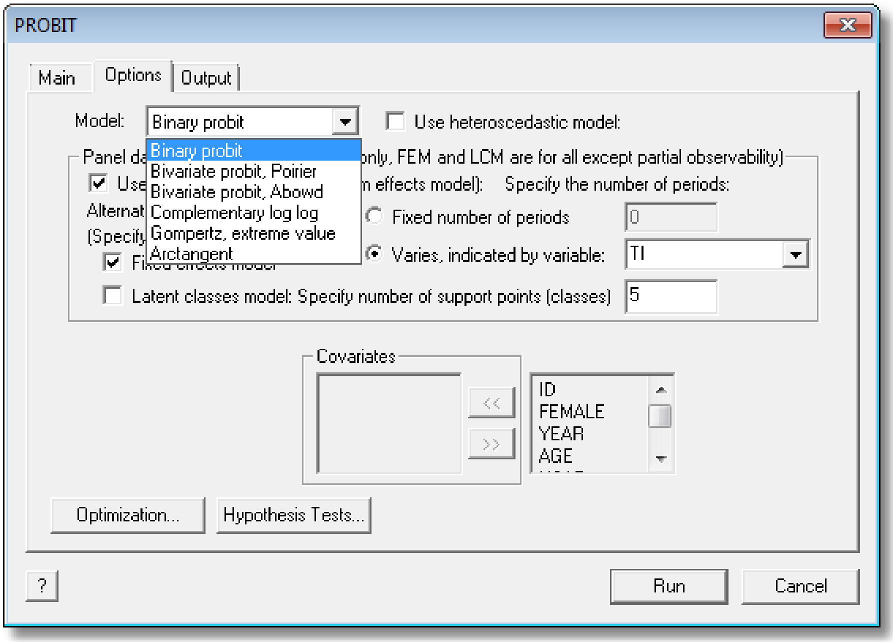
NOTE: For these estimators, you should not attempt to manage missing data. Just leave observations with missing values in the sample. *LIMDEP* will automatically bypass the missing values. Do not use **SKIP**, as it will undermine the setting of **; Pds = specification**.

The estimator produces and saves the coefficient estimator, *b* and covariance matrix, *varb*, as usual. Unless requested, the estimated fixed effects coefficients are not retained. (They are not reported regardless.) To save the vector of fixed effects estimates, α in a matrix named *alphafe*, add

; Parameters

to the command. The fixed effects estimators allow up to 100,000 groups. However, only up to 50,000 estimated constant terms may be saved in *alphafe*.

The Options pages of the Model:Binary Choice/Probit and Model:Binary Choice/ Logit provide command builders for the panel data models. The probit, complementary log log, arctangent and extreme value models are all in the **PROBIT** command builder.



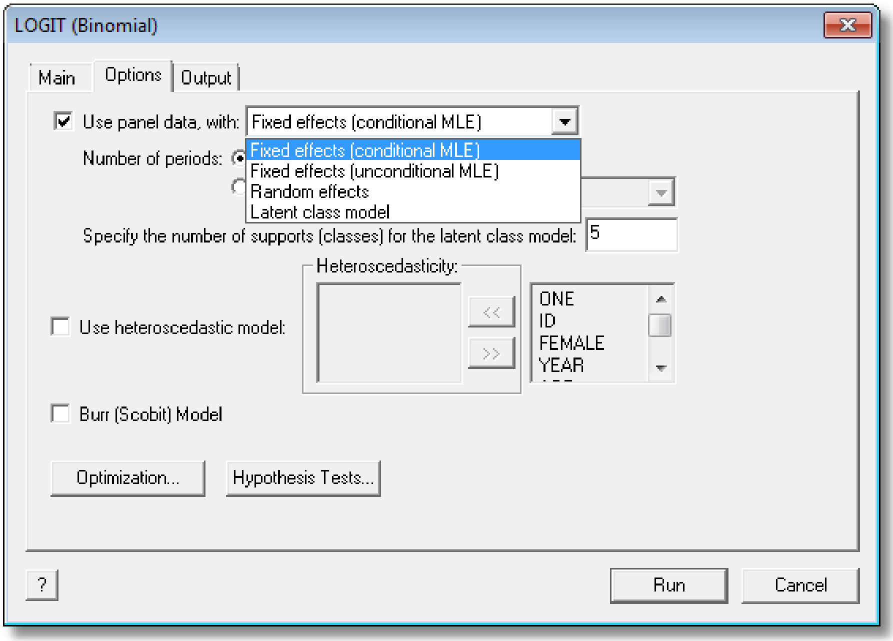


Figure E30.1 Command Builder for Panel Data Binary Logit Models

E30.3 Clustering, Stratification and Robust Covariance Matrices

The robust estimator based on sample clustering and stratification is available for the parametric binary choice models. Full details appear in Chapter R10 for the general case and Section E27.5.2 for the parametric binary choice models of interest here. The option for clustering is offered in the command builders for most of the nonlinear model and binary choice routines in the Model Estimates submenu. This will differ a bit from model to model. The one for the probit model is shown below in Figure E30.2. The Model Estimates dialog box is selected at the bottom of the Output page, then the clustering is specified in the next dialog box.

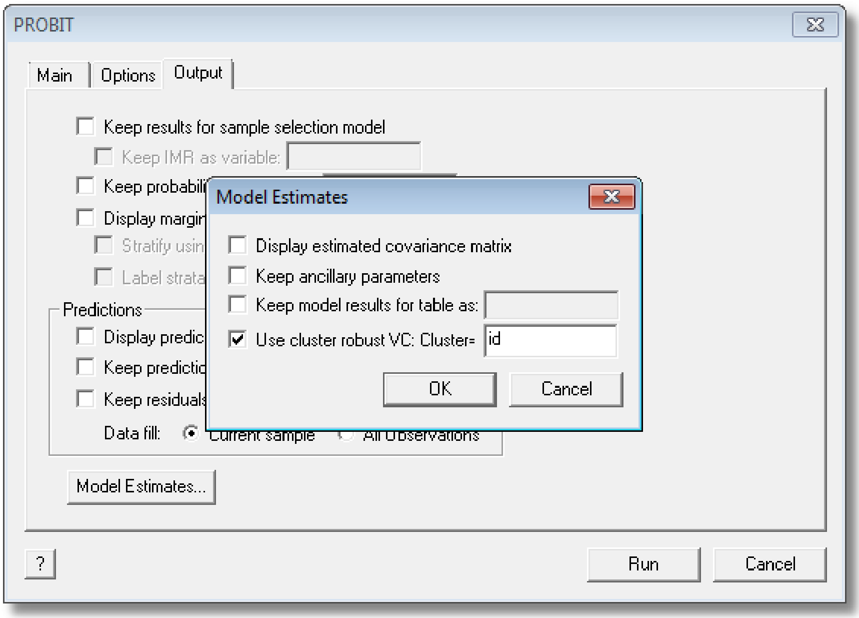

Figure E30.2 Command Builder for a Probit Model

This sampling setup may be used with any of the binary choice estimators. Do note, however, you should not use it with panel data models. The so called ‘clustering’ corrections are already built into the panel data estimators. (This is unlike the linear regression case, in which some authors argue that the correction should be used even when fixed or random effects models are estimated.)

To illustrate, the following shows the setup for the panel data set described in the preceding section. We have also artificially reduced the sample to 1,015 observations, 29 groups of 35 individuals, all of whom were observed seven times. The information below would appear with a model command that used this configuration of the data to construct a robust covariance matrix.

```
SAMPLE      ; 1-5000 $
REJECT      ; _groupti < 7 $
NAMELIST    ; x = age,educ,hhninc,hhkids,married $
PROBIT      ; Lhs = doctor ; Rhs = one,x
            ; Cluster = 7
            ; Stratum = 35
            ; Describe $
```

These results appear before any results of the probit command. They are produced by the **; Describe** specification in the command.

```

E30.4 One and Two Way Fixed Effects Models

The fixed effects models are estimated by unconditional maximum likelihood. The command for requesting the model is

PROBIT
LOGIT
COMPLOG
GOMPERTZ
ARCTANGENT

; Lhs = dependent variable
; Rhs = independent variables - not including one
; Panel
; Fixed Effects or ; FEM $

NOTE: Your Rhs list should not include a constant term, as the fixed effects model fits a complete set of constants for the set of groups. If you do include one in your Rhs list, it is automatically removed prior to beginning estimation.

The fixed effects model assumes a group specific effect:

$$\text{Prob}[y_{it} = 1] = F(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i)$$

where α_i is the parameter to be estimated. You may also fit a two way fixed effects model

$$\text{Prob}[y_{it} = 1] = F(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i + \gamma_t)$$

where γ_t is an additional, time (period) specific effect. The time specific effect is requested by adding

; Time

to the command if the panel is balanced, and

; Time = variable name

if the panel is unbalanced. For the unbalanced panel, we assume that overall, the sample observation period is

$$t = 1,2,..., T$$

and that the 'Time' variable gives for the specific group, the particular values of t that apply to the observations. Thus, suppose your overall sample is five periods. The first group is three observations, periods 1, 2, 4, while the second group is four observations, 2, 3, 4, 5. Then, your panel specification would be

; Pds = Ti, for example, where *Ti* = (3, 3, 3), (4, 4, 4, 4)
and **; Time = Pd,** for example, where *Pd* = (1, 2, 4), (2, 3, 4, 5).

NOTE: See the discussion in Section E30.4.2 that describes how this model is estimated. It places an important restriction on the two way fixed effects model.

Standard Model Specifications for the Fixed Effects Binary Choice Models

This is the full list of general specifications supported for this model.

Controlling Output from Model Commands

; Par keeps ancillary parameter matrix *alphafe* containing fixed effects.
; Margin displays marginal effects.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Prob = name saves probabilities as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

Starting values for the iterations are obtained by fitting the basic model without fixed effects. Thus, the initial results in the output for these models will be the binary choice models discussed in the preceding chapters. You will see a constant term in these results even though you have not included one in your commands. This is used to get starting value for the fixed effects. Iterations begin with the restricted model that forces all the fixed effects to equal the constant term in the restricted model. You may provide your own starting values for the slope parameters with

; Start = ... the list of values for β.

Do not include a set of constants. You may also provide a starting value which will be used identically for all the fixed effects by including one extra value at the end of your list of starting values.

Results that are kept for this model are

Matrices:	*b*	= estimate of $\boldsymbol{\beta}$
	varb	= asymptotic covariance matrix for estimate of $\boldsymbol{\beta}$.
	alphafe	= estimated fixed effects if the command contains **; Parameters**
Scalars:	*kreg*	= number of variables in Rhs
	nreg	= number of observations
	logl	= log likelihood function
Last Model:	*b_variables*	
Last Function:	None	

The upper limit on the number of groups is 100,000. Technical details on the method of estimation appear in Section E30.4.2. Partial effects are computed locally with **; Partial Effects** in the command. The post estimation **PARTIAL EFFECTS** command does not have the set of constant terms, some of which are infinite, so the probabilities cannot be computed.

E30.4.1 Application

The gender and kids present dummy variables are time invariant and are omitted from the model. Nonlinear models are like linear models in that time invariant variables will prevent estimation. This is not due to the ‘within’ transformation producing columns of zeros. The within transformation of the data is not used for nonlinear models. A similar effect does arise in the derivatives of the log likelihood, however, which will halt estimation because of a singular Hessian.

The results of fitting models with no fixed effects, with the person specific effects and with both person and time effects are listed below. The results are partially reordered to enable comparison of the results, and some of the results from the pooled estimator are omitted.

```
SAMPLE      ; All $
SETPANEL    ; Group = id ; Pds = ti $
NAMELIST    ; x = age,educ,hhninc,newhsat $
PROBIT      ; Lhs = doctor ; Rhs = x,one
            ; Partial Effects $
PROBIT      ; Lhs = doctor ; Rhs = x
            ; FEM
            ; Panel
            ; Parameters
            ; Partial Effects $
PROBIT      ; Lhs = doctor ; Rhs = x
            ; FEM
            ; Panel
            ; Time Effects
            ; Parameters
            ; Partial Effects $
```

These are the results for the pooled data without fixed effects.

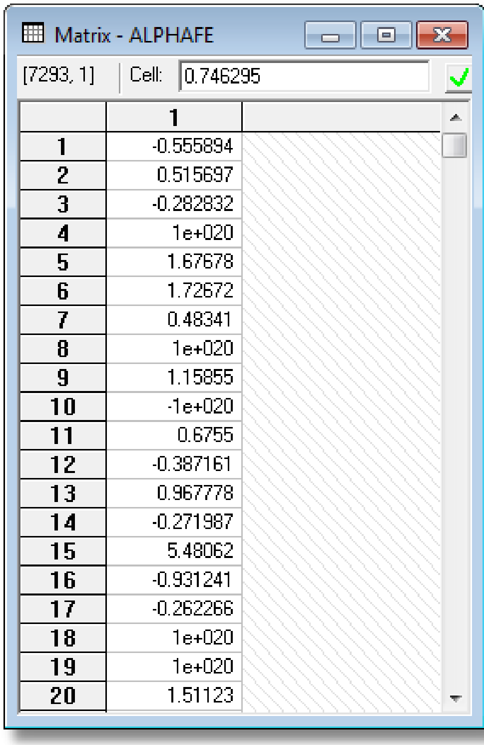

Figure E30.3 Estimated Fixed Effects

Note that the results report that 3046 groups had inestimable fixed effects. These are individuals for which the Lhs variable, *doctor*, was the same in every period, including 1525 groups with $T_i = 1$. If there is no within group variation in the dependent variable for a group, then the fixed effect for that group cannot be estimated, and the group must be dropped from the sample. The **; Parameters** specification requests that the estimates of α_i be kept in a matrix, *alphafe*. Groups for which α_i is not estimated are filled with the value -1.E20 if y_{it} is always zero and +1.E20 if y_{it} is always one, as shown above.

The log likelihood function has increased from -16,639.24 to -9187.45 in computing the fixed effects model. The chi squared statistic is twice the difference, or 14,903.57. This would far exceed the critical value for 95% significance, so at least at first take, it would seem that the hypothesis of no fixed effects should be rejected. There are two reasons why this test would be invalid. First, because of the incidental parameters issue, the fixed effects estimator is inconsistent. As such, the statistic just computed does not have precisely a chi squared distribution, even in large samples. Second, the fixed effects estimator is based on a reduced sample. If the test were valid otherwise, it would have to be based on the same data set. This can be accomplished by using the commands

```
CREATE   ; meandr = Group Mean(doctor, Str = id) $
REJECT   ; meandr < .1 | meandr > .9 $
PROBIT   ; Lhs = doctor ; Rhs = one,x $
```

(The mean value must be greater than zero and less than one. For groups of seven, it can be as high as 6/7 = .86.) Using the reduced sample, the log likelihood for the pooled sample would be -10,852.71. The chi squared is 11,573.31 which is still extremely large. But, again, the statistic does not have the large sample chi squared distribution that allows a formal test. It is a rough guide to the results, but not precise as a formal rule for building the model.

In order to compute marginal effects, it is necessary to compute the index function, which does require an α_i. The mean of the estimated values is used for the computation. The results for the pooled data are shown for comparison below the fixed effects results.

These are the partial effects for the fixed effects model.

E30.4.2 Technical Details

The fixed effects model is fit essentially by ‘brute force.’ *LIMDEP* actually estimates the full $K + N$ up to 100,150 coefficients by Newton’s method. It is possible to fit the huge number of coefficients because we take advantage of the properties of the sparse second derivatives matrix of the log likelihood. One of the implications, however, is that there is no covariance matrix computed for the fixed effects. As such, it is not possible to do any kind of inference for individual fixed effects.

The two way fixed effects estimator is computed by actually creating the time specific dummy variables and adding them to the model – see the results above. This means that the usual 150 parameter limit on model size applies to the number of variables in the model plus the number of periods (minus one).

Marginal effects in the fixed effects model are computed at the means of the data and with the sample average of the fixed effects estimates as the constant term.

The unconditional log likelihood is maximized by using Newton’s method. A full discussion of the method is given in Chapter R23. A short sketch of the result is given here, for the logit model. (The results for the other binary choice models are similar. For the models that have asymmetric probability functions, complementary log log, Gompertz and arctangent, the expressions below become more complicated as the zeros and ones are treated separately as required.) The log likelihood is

$$\log L = \sum_{i=1}^{n} \log\left[\prod_{t=1}^{T_i} \Lambda[(2y_{it}-1)(\alpha_i + \beta'\mathbf{x}_{it})]\right]$$

Let p_{it}, y_{it}, $\mathbf{x}_{it}$ and $q_{it} = 2y_{it} - 1$ denote the obvious components of this function. Then,

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{N}\sum_{t=1}^{T_i}(y_{it}-p_{it})\mathbf{x}_{it} = \mathbf{g}_{\beta}$$

$$\frac{\partial \log L}{\partial \alpha_i} = \sum_{t=1}^{T_i}(y_{it}-p_{it}) = g_i$$

$$\frac{\partial^2 \log L}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'} = -\sum_{i=1}^{N}\sum_{t=1}^{T_i} p_{it}(1-p_{it})\mathbf{x}_{it}\mathbf{x}_{it}' = \mathbf{H}_{\beta\beta'}$$

$$\frac{\partial^2 \log L}{\partial \alpha_i^2} = -\sum_{t=1}^{T_i} p_{it}(1\text{-}p_{it}) = h_{ii}$$

$$\frac{\partial^2 \log L}{\partial \boldsymbol{\beta}\partial \alpha_i} = -\sum_{t=1}^{T_i} p_{it}(1\text{-}p_{it})\mathbf{x}_{it} = \mathbf{h}_{\beta i}$$

Assemble the full set of first derivatives in a $(K+N)\times 1$ vector, $\mathbf{g}$ and the full set of second derivatives in a $(K+N)\times(K+N)$ matrix, $\mathbf{H}$. The iteration for Newton’s method is

$$\begin{aligned}\boldsymbol{\gamma}_{s+1} &= \boldsymbol{\gamma}_s - \mathbf{H}_s^{-1}\mathbf{g}_s \\ &= \boldsymbol{\gamma}_s + \mathbf{d}_s,\end{aligned}$$

where $\boldsymbol{\gamma}$ denotes the full $(K+N)\times 1$ parameter vector, $(\boldsymbol{\beta}',\alpha_1,\alpha_2,...,\alpha_N)'$ and s indexes iterations. This iteration then, computes a change vector, $\mathbf{d}_s$ as the product of the matrix and vector of derivatives. In principle, the matrix $\mathbf{H}$ is huge, which makes this computation unwieldy. However, the lower right $N\times N$ submatrix of $\mathbf{H}$ (the very large part) is a diagonal matrix – see above. Therefore, it is not necessary actually to compute the entire matrix. The change vector can be computed as a sum of $K\times 1$ vectors which are themselves functions only of the scalar diagonal parts of the submatrix and the $K\times K$ submatrix at the upper left, all of which is very easily done and requires no more computer memory than a conventional estimator, say least squares for a regression.

There is an important qualification to be made in the preceding. Consider the first order condition for the ith group specific constant term:

$$\frac{\partial \log L}{\partial \alpha_\iota} = \sum_{t=1}^{T_i} (y_{it} - p_{it}) = g_i$$

Now, suppose for group i, y_{it} is always one. Then, inserting the probability and expanding, this first order condition becomes

$$\frac{\partial \log L}{\partial \alpha_\iota} \left(\sum_{t=1}^{T_i} y_{it} = T_i\right) = T_i - \sum_{t=1}^{T_i} F(\beta'\mathbf{x}_{it} + \alpha_i) = 0$$

In order for this condition to be met, each probability in the last term must equal 1.0, which means, if the data and parameters are finite, α_i must go to $+\infty$. Thus, if every outcome in a group is one, the constant term is not estimable in any binary choice model. The same result occurs if every y_{it} in a group equals zero. Thus, such groups must be dropped from the sample. (See the example above.)

We use Newton's method for the computations, so the actual Hessian is available for estimation of the asymptotic covariance matrix of the estimators. Let $\mathbf{H}_{\beta\alpha'}$ denote the $K\times N$ submatrix of $\mathbf{H}$ obtained as $[\mathbf{h}_{\beta 1}, \mathbf{h}_{\beta 2}, ..., \mathbf{h}_{\beta N}]$ and let $\mathbf{H}_{\alpha\alpha'}$ denote the $N\times N$ diagonal lower right submatrix of $\mathbf{H}$ obtained as diag$[h_{ii}]$. Then, the estimator of the asymptotic covariance matrix for the MLE of $\boldsymbol{\beta}$ is the upper left submatrix of $-\mathbf{H}^{-1}$. Using the partitioned inverse formula, this is

$$\text{Asy.Var}[\mathbf{b}] = [-(\mathbf{H}_{\beta\beta'} - \mathbf{H}_{\beta\alpha'}(\mathbf{H}_{\alpha\alpha'})^{-1}\mathbf{H}_{\alpha\beta'})]^{-1}$$

The first matrix is given above. By inserting the formulas given above, and exploiting the fact that $\mathbf{H}_{\alpha\alpha'}$ is a diagonal matrix, we obtain the result

$$\mathbf{H}_{\beta\alpha'}(\mathbf{H}_{\alpha\alpha'})^{-1}\mathbf{H}_{\alpha\beta'} = \sum_{i=1}^{N} \frac{1}{h_{ii}}(\mathbf{h}_{\beta i})(\mathbf{h}_{\beta i})'.$$

This produces a sum of $K\times K$ matrices which is of the form of a moment matrix and which is easily computed. Thus, the asymptotic covariance matrix for the estimated coefficient vector is easily obtained in spite of the size of the problem. (In fact, for these binary choice models, the Hessian is actually in the form of a 'within groups' moment matrix for a panel. This result is derived in Greene (2011).

Two considerations remain. First, it is not possible to compute the asymptotic covariance matrix for the fixed effects estimator (unless there are relatively few of them). Using the partitioned inverse formula once again, we can show that the elements of Asy.Var[**a**] are contained in

$$\text{Asy.Var}[\mathbf{a}] = [-(\mathbf{H}_{\alpha\alpha'} - \mathbf{H}_{\alpha\beta'}(\mathbf{H}_{\beta\beta'})^{-1}\mathbf{H}_{\beta\alpha'})]^{-1}.$$

The *ij*th element of the matrix to be inverted is

$$(\mathbf{H}_{\alpha\alpha'} - \mathbf{H}_{\alpha\beta'}(\mathbf{H}_{\beta\beta'})^{-1}\mathbf{H}_{\beta\alpha'})_{ij} = \mathbf{1}(i=j)h_{ii} - \mathbf{h}_{\beta i}'(\mathbf{H}_{\beta\beta'})^{-1}\mathbf{h}_{\beta j}$$

This is a full $N \times N$ matrix, and so the model size problem will apply – it is not feasible to manipulate this matrix.

Finally, note that in Asy.Var[**b**], the terms are of order NT minus a sum of N order T outer products. Therefore, the end result is the inverse of an order NT matrix, which will converge to zero. What this establishes is that **b** does converge to a parameter in the sense that its asymptotic covariance matrix converges to zero. However, it converges to a function that deviates from $\boldsymbol{\beta}$ to the extent that plim a_i deviates from α_i. The asymptotic covariance matrix of the fixed effects estimators above is an $N \times N$ matrix that is the inverse of an order T matrix. Since T is fixed and may be very small, the fixed effects estimators are not consistent.

NOTE: Full estimation of the fixed effects model in this fashion encounters the *incidental parameters* problem. Some of the implications of this problem are discussed in Chapter R24. Also, a particular group specific effect, α_i cannot be estimated if y_{it} takes the same value (1 or 0) in every period. If the number of periods is small, this is likely to happen fairly often. You will see an indication in the results of how many such groups had to be dropped from the estimation. See the application above.

Little is known about the impact of the incidental parameters problem on ML estimators of binary choice models beyond the long established 100% bias of the logit estimator in the case of $T = 2$. The following table, extracted from Greene (2004a, pp. 98-119) is as extensive a study of the issue as is currently available. It is based on Monte Carlo analysis of probit and logit models with a continuous variable coefficient, β, and a dummy variable coefficient, δ. While Monte Carlo studies are never definitive, this should provide a moderately good guide to the extent of the problem for binary choice estimators. The table entry estimates the ratio of the expected value of the estimator to the parameter it is estimating for several sample sizes.

Means of empirical sampling distributions, N = 1,000 individuals based on 200 replications.

Table E30.1 Monte Carlo Simulations of Incidental Parameters Problem

E30.5 Conditional MLE of the Fixed Effects Logit Model

Two nonlinear models, the binomial logit and Poisson regression can be estimated by conditional maximum likelihood. (The MLE of the linear model is the within estimator. In principle, the exponential loglinear regression model also provides the needed sufficient statistics, but we have not seen this model employed in practice.) This is a specialized approach that was devised to deal with the problem of large numbers of incidental parameters discussed in the preceding section. We consider the logit case here and the count models in Section E44.4.1. (This model was studied, among others, by Chamberlain (1980).) The log likelihood for the binomial logit model with fixed effects is

$$\log L = \sum_{i=1}^{N} \sum_{t=1}^{T_i} \log\Lambda\left[\left(2y_{it}-1\right)(\boldsymbol{\beta}'\mathbf{x}_{it}+\alpha_i)\right]$$

The first term, $2y_{it}$ - 1, makes the sign negative for y_{it} = 0 and positive for y_{it} = 1, and $\Lambda(.)$ is the logistic probability, $\Lambda(z) = 1/[1 + \exp(-z)]$. Direct maximization of this log likelihood involves estimation of N+K parameters, where N is the number of groups. As N may be extremely large, this is a potentially difficult estimation problem. As we saw in the preceding section, direct estimation with up to 100,000 coefficients is feasible. But, the method discussed here is not restricted – the number of groups is unlimited because the fixed effects coefficients are not estimated. Rather, the fixed effects are conditioned out of the log likelihood. The main appeal of this approach, however, is that whereas the brute force estimator of the preceding section is subject to the incidental parameters bias, the conditional estimator is not; it is consistent even for small T (even for T = 2).

The contribution to the likelihood function of the T_i observations for group i can be conditioned on the sum of the observed outcomes to produce the conditional log likelihood,

$$L_c = \frac{\prod_{t=1}^{T_i} \exp[y_{it}\boldsymbol{\beta}'\mathbf{x}_{it}]}{\sum_{\textit{all arrangements of } T_i \textit{ outcomes with the same sum}} \prod_{s=1}^{T_i} \exp[y_{is}\boldsymbol{\beta}'\mathbf{x}_{is}]}$$

$$= \frac{\exp\left[\sum_{t=1}^{T_i} y_{it}\boldsymbol{\beta}'\mathbf{x}_{it}\right]}{\sum_{\textit{all arrangements of } T_i \textit{ outcomes with the same sum}} \exp\left[\sum_{s=1}^{T_i} d_{is}\boldsymbol{\beta}'\mathbf{x}_{is}\right]}.$$

This function can be maximized with respect to the slope parameters, $\boldsymbol{\beta}$, with no need to estimate the fixed effects parameters. The number of terms in the denominator of the probability may be exceedingly large, as it is the sum of T* terms where T* is equal to the binomial coefficient $\binom{T_i}{S_i}$ and S_i is the sum of the binary outcomes for the ith group. This can be extremely large. The computation of the denominator is accomplished by means of a recursion presented in Krailo and Pike (1984). Let the denominator be denoted $A(T_i,S_i)$. The authors show that for any T and S the function obeys the recursion

$$A(T,S) = A(T\text{-}1,S) + \exp(\mathbf{x}_{iT}'\boldsymbol{\beta})A(T\text{-}1,S\text{-}1)$$

with initial conditions $A(T,s) = 0$ if $T < s$ and $A(T,0) = 1$.

This enables rapid computation of the denominator for T_i up to 200 which is the internal limit. (If your model is this large, expect this computation to be quite time consuming. Although 200 periods (or more) is technically feasible, the number of terms rises geometrically in T_i, and more than 20 or 30 or so is likely to test the limits of the program (as well as your patience). Note, as well that when the sum the observations is zero or T_i, the conditional probability is one, since there is only a single way that each of these can occur. Thus, groups with sums of zero or T_i fall out of the computation. There is one exception. If you are fitting a discrete choice model (see the discussion of **CLOGIT** in Chapter E38) with more than 100 choices, you can use this estimator for models with up to 200 choices. Note in this case, although T_i may be very large, S_i will equal one, so the problem is simple.

Estimation of this model is done with Newton's method. When the data set is rich enough both in terms of variation in $\mathbf{x}_{it}$ and in S_i, convergence will be quick and simple.

E30.5.1 Command

The command for estimation of the model by this method is

LOGIT ; Lhs = dependent variable
; Rhs = dependent variables (do not include one)
; Pds = fixed number of periods or variable for group sizes $

NOTE: You must omit the **; FEM** from the logit command. This is the default panel data estimator for the binary logit model. Use **; Fixed Effects** or **; FEM** to request the unconditional estimator discussed in the previous section.

You may use weights with this estimator. Presumably, these would reflect replications of the observations. Be sure that the weighting variable takes the same value for all observations within a group. The specification would be

; Wts = variable, Noscale

The **Noscaling** option should be used here if the weights are replication factors. If not, then do be aware that the scaling will make the weights sum to the sample size, not the number of groups.

Results that are retained with this estimator are the usual ones from estimation:

Matrices: *b* = estimate of β
varb = asymptotic covariance matrix for estimate of β

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variables*

Last Function: None

E30.5.2 Application

The following will fit the binary logit model using the two methods noted. Bear in mind that with $T_i < \underline{7}$, the unconditional estimator is inconsistent and in fact likely to be substantially biased. The conditional estimator is consistent. Based on the simulation results cited earlier, the second results should exceed the first by roughly 40%. Marginal effects are shown as well. Computation is discussed below.

```
NAMELIST    ; x = age,educ,hhninc,newhsat $
LOGIT       ; Lhs = doctor ; Rhs = x,one $
LOGIT       ; Lhs = doctor ; Rhs = x
            ; Panel $          (Chamberlain conditional estimator)
LOGIT       ; Lhs = doctor ; Rhs = x
            ; Panel ; FEM $  (unconditional estimator)
```

These are the pooled estimates.

These are the conditional maximum likelihood estimates followed by the unconditional fixed effects estimates. For these data, the unconditional estimates are closer to the conditional ones than might have been expected, but still noticeably higher as the received results would predict. The suggested proportionality result also seems to be operating, but with an unbalanced panel, this would not necessarily occur, and should not be used as any kind of firm rule (save, perhaps for the case of $T_i = 2$).

```

This count would be meaningless in an unbalanced panel, so it is omitted.

How should you choose which estimator to use? We should note that the two approaches will generally give different numerical answers. The conditional and unconditional log likelihoods are different. In general, you should use the conditional estimator if T is not relatively large. The conditional estimator is less efficient by construction, but consistency trumps efficiency at this level. In addition, if you have more than 50,000 groups, you must use the conditional estimator. If, on the other hand, T is larger than, say, 10, and N is less than 50,000, then the unconditional estimator might be preferred. The additional consideration discussed in the next section might also weigh in favor of the unconditional estimator.

E30.5.3 Estimating the Individual Constant Terms

The conditional fixed effects estimator for the logit model specifically eliminates the fixed effects, so they are not directly estimated. Without them, however, the parameter estimates are of relatively little use. Fitted probabilities and marginal effects will both require some estimate of a constant term. You can request post estimation computation of the fixed effects by using the specification

; Parameters

This saves a matrix named *alphafe* in your matrix work area. This will be a vector with number of elements equal to the number of groups, containing an ad hoc estimate of α_i for the groups for which there is within group variation in $y_{it.}$ We note how this is done. The logit model is

$$\text{Prob}[y_{it} = 1|\mathbf{x}_{it}] = \Lambda(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i) \text{ where } \Lambda(z) = \exp(z)/[1+\exp(z)]$$

After estimation of $\boldsymbol{\beta}$, we treat the $\boldsymbol{\beta}'\mathbf{x}_{it}$ part of this as known, and let $z_{it} = \boldsymbol{\beta}'\mathbf{x}_{it}$. These are now just data. As such, the log likelihood for group i would be

$$\log L_i = \Sigma_t \log \Lambda[(2y_{it} - 1)(z_{it} + \alpha_i)]$$

The likelihood equation for α_i would be

$$\Sigma_t (y_{it} - P_{it}) = 0 \text{ where } P_{it} = \Lambda(z_{it} + \alpha_i)$$

The implicit solution for α_i is given by

$$\Sigma_t y_{it} = \Sigma_t w_{it} / (a_i + w_{it}) \text{ where } w_{it} = \exp(z_{it}) \text{ and } a_i = \exp(-\alpha_i).$$

If y_{it} is always zero or always one in every period, t, then there is no solution to maximizing this function. The corresponding element of *alphafe* will be set equal to -1.d20 or +1.d20 But, if the y_{it}s differ, then the α_i that equates the left and right hand sides can be found by a straightforward search. The remaining rows of *alphafe* will contain the individual specific solutions to these equations. (This is the method that Heckman and MaCurdy (1980) suggested for estimation of the fixed effects probit model.)

We emphasize, this is not the maximum likelihood estimator of α_i because the conditional estimator of $\boldsymbol{\beta}$ is not the unconditional MLE. Nor, in fact, is it consistent in N. It is consistent in T_i, but that is not helpful here since T_i is fixed, and presumably small. This estimator is a means to an end. The estimated marginal effects can be based on this estimator – it will give a reasonable estimator of an overall average of the constant terms, which is all that is needed for the marginal effects. Individual predicted probabilities remain ambiguous.

E30.5.4 A Hausman Test for Fixed Effects in the Logit Model

The fixed effects estimator is illustrated with the data used in the preceding examples: Note that the first estimator is the pooled estimator. Under the alternative hypothesis of fixed effects, it is inconsistent. Under the null, it is consistent and efficient. The second estimator is the conditional MLE and the third one is the unconditional fixed effects estimator. The unconditional fixed estimator cannot be used for formal testing because of the incidental parameters problem – it is inconsistent. The pooled estimator and the conditional fixed effects estimator use different samples, so the likelihoods are not comparable. Therefore, testing for the joint significance of the effects is problematic for the conditional estimator. What one can do is use a Hausman test. The test is constructed as follows:

H_0: There are no fixed effects; unconditional ML estimators are $\mathbf{b}_0$ and $\mathbf{V}_0$

H_1: There are fixed effects: conditional ML estimators are $\mathbf{b}_1$ and $\mathbf{V}_1$

Under H_0, $\mathbf{b}_0$ is consistent and efficient, while $\mathbf{b}_1$ is consistent but inefficient. Under H_1, $\mathbf{b}_0$ is inconsistent while $\mathbf{b}_1$ is consistent and efficient. The Hausman statistic would therefore be

$$H = (\mathbf{b}_1 - \mathbf{b}_0)' [\mathbf{V}_1 - \mathbf{V}_0]^{-1}(\mathbf{b}_1 - \mathbf{b}_0)$$

The statistic can be constructed as follows:

```
NAMELIST    ; x = the independent variables, not including one $
LOGIT       ; Lhs =  ... ; Rhs = x, one $
CALC        ; k = Col(x) $
MATRIX      ; b0 = b(1:k) ; v0 = varb(1:k,1:k) $
LOGIT       ; Lhs = ... ; Rhs = x ; Pds = ... ; FEM $
MATRIX      ; b1 = b ; v1 = varb $
MATRIX      ; d = b1 - b0 ; List ; h = d’ * Nvsm(v1, -v0) * d $
```

We apply this to our innovation data by defining *x = imprtshr,fdishare,logsales,relsize,prod* and the dependent variable is *innov*. The remaining commands are generic.

The three sets of parameter estimates were given earlier. The Hausman statistic using the procedure suggested above is

```
SAMPLE      ; All $
SETPANEL    ; Group = id ; Pds = ti $
NAMELIST    ; x = age,educ,hhninc,newhsat $
LOGIT       ; Lhs = doctor ; Rhs = x, one $
CALC        ; k = Col(x) $
MATRIX      ; b0 = b(1:k) ; v0 = Varb(1:k,1:k) $
LOGIT       ; Lhs = doctor ; Rhs = x ; Panel $
MATRIX      ; b1 = b ; v1 = varb $
MATRIX      ; d = b1 - b0 ; List ; h = d' * Nvsm(v1, -v0) * d $
```

The final result of the **MATRIX** command is

```
       H|             1
--------+--------------
       1|       98.1550
```

This statistic has four degrees of freedom. The critical value from the chi squared table is 9.49, so based on this test, we would reject the null hypothesis of no fixed effects.

E30.6 Random Effects Models for Binary Choice

The five models we have developed here can also be fit with random effects instead of fixed effects. The structure of the random effects model is

$$z_{it} \mid u_i = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i$$

where u_i is the unobserved heterogeneity for the ith individual,

$$u_i \sim N[0,\sigma_u^2],$$

and ε_{it} is the stochastic term in the model that provides the *conditional* distribution.

$$\text{Prob}[y_{it} = 1 \mid \mathbf{x}_{it}, u_i] = F(\boldsymbol{\beta}'\mathbf{x}_{it} + u_i),\ i = 1,...,N,\ t = 1,...,T_i.$$

where $F(.)$ is the distribution discussed earlier (normal, logistic, extreme value, Gompertz). Note that the unobserved heterogeneity, u_i is the same in every period. The parameters of the model are fit by maximum likelihood. As usual in binary choice models, the underlying variance,

$$\sigma^2 = \sigma_u^2 + \sigma_\varepsilon^2$$

is not identified. The reduced form parameter,

$$\rho = \frac{\sigma_u^2}{\sigma_\varepsilon^2 + \sigma_u^2},$$

is estimated directly. With the normalization that we used earlier, $\sigma_\varepsilon^2 = 1$, we can determine

$$\sigma_u = \sqrt{\frac{\rho}{1-\rho}}.$$

Further discussion of the estimation of the structural parameters appears at the end of this section.

The model command for this form of the model is

PROBIT
LOGIT
COMPLOG
GOMPERTZ
ARCTANGENT

; Lhs = dependent variable
; Rhs = independent variables
; Panel
; Random Effects $

NOTE: For this model, your Rhs list should include a constant term, *one*.

Standard Model Specifications for the Random Effects Binary Choice Models

This is the full list of general specifications applicable to this model estimator. See Chapter E1 and references noted there for further details on these specifications.

Controlling Output from Model Commands

; Par keeps ancillary parameter ρ with main parameter β vector in *b*.
; Margin displays marginal effects.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Hpt = n sets the number of points to use for Hermite quadrature
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Prob = name saves probabilities as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

Marginal effects are computed by setting the heterogeneity term, u_i to its expected value of zero. Restrictions may be tested and imposed exactly as in the model with no heterogeneity. Since restrictions can be imposed on all parameters, including ρ, you can fix the value of ρ at any desired value. Do note that forcing the ancillary parameter, in this case, ρ, to equal a slope parameter will almost surely produce unsatisfactory results, and may impede or even prevent convergence of the iterations.

Starting values for the iterations are obtained by fitting the basic model without random effects. Thus, the initial results in the output for these models will be the binary choice models discussed in the preceding sections. You may provide your own starting values for the parameters with

; Start = ... the list of values for β, value for ρ

There is no natural moment based estimator for ρ, so a relatively low guess is used as the starting value instead. The starting value for ρ is approximately .2 ($\theta = [2\rho/(1-\rho)]^{1/2} \approx .29$ – see the technical details below. Maximum likelihood estimates are then computed and reported, along with the usual diagnostic statistics. (An example appears below.) This model is fit by approximating the necessary integrals in the log likelihood function by Hermite quadrature. An alternative approach to estimating the same model is by Monte Carlo simulation. You can do exactly this by fitting the model as a random parameters model with only a random constant term.

Your data might not be consistent with the random effects model. That is, there might be no discernible evidence of random effects in your data. In this case, the estimate of ρ will turn out to be negligible. If so, the estimation program issues a diagnostic and reverts back to the original, uncorrelated formulation and reports (again) the results for the basic model.

Results that are kept for this model are

Matrices:	*b*	= estimate of **β**
	varb	= asymptotic covariance matrix for estimate of **β**
Scalars:	*kreg*	= number of variables in Rhs
	nreg	= number of observations
	logl	= log likelihood function
	rho	= estimated value of ρ
	varrho	= estimated asymptotic variance of estimator of ρ
Last Model:	*b_variables, ru*	

Last Function: Prob($y = 1|\mathbf{x},u=0$) (Note: None if you use **; RPM** to fit the RE model.)

The additional specification **; Par** in the command requests that ρ be included in *b* and the additional row and column corresponding to ρ be included in *varb*. If you have included **; Par**, *rho* and *varrho* will also appear at the appropriate places in *b* and *varb*.

NOTE: The hypothesis of no group effects can be tested with a Wald test (simple t test) or with a likelihood ratio test. The LM approach, using **; Maxit = 0** with a zero starting value for ρ does not work in this setting because with ρ = 0, the last row of the covariance matrix turns out to contain zeros.

E30.6.1 Application

The following study fits the probit model under four sets of assumptions. The first uses the pooled estimator, then corrects the standard errors for the clustering in the data. The second is the unconditional fixed effects estimator. The third and fourth compute the random effects estimator, first by quadrature, using the Butler and Moffitt method and the second using maximum simulated likelihood with Halton draws. The output is trimmed in each model to compare only the estimates and the marginal effects.

```
NAMELIST    ; x = age,educ,hhninc,newhsat $
SAMPLE      ; All $
SETPANEL    ; Group = id ; Pds = ti $
PROBIT      ; Lhs  = doctor ; Rhs = x,one ; Partial Effects
            ; Cluster = id $
PROBIT      ; Lhs  = doctor ; Rhs = x ; Partial Effects
            ; Panel ; FEM $
PROBIT      ; Lhs  = doctor ; Rhs = x,one ; Partial Effects
            ; Panel ; Random Effects $
```

The random parameters model described in Chapter E31 provides an alternative estimator for the random effects model based on maximum simulated likelihood rather than with Hermite quadrature. The general syntax is used below for a probit model to illustrate the method.

```
PROBIT      ; Lhs  = doctor ; Rhs = x,one  ; Partial Effects
            ; Panel ; RPM  ; Fcn = one(n) ; Pts = 25 ; Halton $
CALC        ; List ; b(6)^2/(1+b(6)^2) $
```

These are the pooled estimates with corrected standard errors.

```

These are the random effects estimates. The variance of u and correlation parameter ρ are given explicitly in the results. In the MSL random effects estimates that appear next, only the standard deviation of u is given. Squaring the 1.37554428 gives 1.892122, which is nearly the same as the 1.888060 given in the first results. In order to compare the first estimates to the MSL estimates, it is necessary to divide the first by the estimate of $1+\rho$. Thus, the scaled coefficient on *age* in the first set of estimates would be 0.019322; that on *educ* would be -.027611, and so on. Thus, the two sets of estimates are quite similar.

The random parameters approach provides an alternative way to estimate a random effects model. A comparison of the two sets of results illustrates the general result that both are consistent estimators of the same parameters. We note, however, the Hermite quadrature approach produces an estimator of $\rho = \sigma_u^2/(1 + \sigma_u^2)$ while the RP approach produces an estimator of σ_u. To check the consistency of the two approaches, we compute an estimate of ρ based on the RP results. The result below demonstrates the near equivalence of the two approaches.

```
CALC ; List ; b(6)^2/(1+b(6)^2)$

E30.6.2 Technical Details for the Random Effects Models

The structure of the random effects model is

$$z_{it} \mid u_i = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + \sigma_u u_i$$

where u_i ~ N[0,1], and ε_{it} is the stochastic term in the model that provides the *conditional* distribution.

$$\text{Prob}[y_{it} = 1 \mid \mathbf{x}_{it}, u_i] = F(\boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_u u_i),\ i = 1,...,N,\ t = 1,...,T_i.$$

where $F(.)$ is the distribution discussed earlier (normal, logistic, extreme value, Gompertz, arctangent). The parameter vector for the random effects model is

$$\boldsymbol{\theta} = [\beta_1,...,\beta_K, \rho]'.$$

With the usual normalization, $\sigma_\varepsilon = 1$ and $\sigma_u = \sqrt{\rho/(1-\rho)}$. The log likelihood function is

$$\log L = \Sigma_i \log L_i$$

where $\log L_i$ is the contribution of the ith individual (group) to the total. Conditioned on u_i, the joint probability for the ith group is

$$\text{Prob}[Y_{i1} = y_{i1},...,Y_{iTi} = y_{iTi} \mid \mathbf{x}_{i1,...,}u_i] = \prod_{t=1}^{T_i} F\left[\boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_u u_i\right]^{y_{it}} \left(1 - F\left[\boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_u u_i\right]\right)^{1-y_{it}}$$

where now, u_i is normalized to unit variance. Since u_i is unobserved, it is necessary to obtain the unconditional log likelihood by taking the expectation of this over the distribution of u_i. For convenience, write the tth term in the probability above as $G(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)$, where $\gamma = \sigma_u$, so that

$$L_i \mid u_i = \prod_{t=1}^{T_i} G(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i).$$

Then,

$$L_i = E_{ui}[L_i \mid u_i] = \int_{-\infty}^{\infty} \frac{\exp(-u_i^2/2)}{\sqrt{2\pi}} \prod_{t=1}^{T_i} P(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)\, du_i$$

NOTE: It can be seen in the likelihood function that it is necessary actually to compute the product of the probabilities for the group, not the sum of the logs. For this reason, the number of observations in a group cannot be extremely large. Since the probability is likely to be on the order of .25 or so, the product of 100 probabilities is on the order of 10^{-100}. This means that the end result is more rounding error than result. In worse cases, the computation will 'overflow' – that is, exceed the computer's capacity to compute the value. For example, the correct result for the product of 100 probabilities on the order of .01 cannot be computed in the accuracy of the computer, which is about $10^{+/-380}$. The diagnostic that this estimator produces mentions a 'Bad counter...' When the counter for group size exceeds 100, the estimator assumes that you have made some kind of error.

Then, finally,

$$\log L \quad = \quad \sum_{i=1}^{N} \log L_i$$

The function is maximized by solving the likelihood equations:

$$\frac{\partial \log L}{\partial \begin{pmatrix} \boldsymbol{\beta} \\ \gamma \end{pmatrix}} \;=\; \sum_{i=1}^{N} \frac{\partial \log L_i}{\partial \begin{pmatrix} \boldsymbol{\beta} \\ \gamma \end{pmatrix}} \;=\; \mathbf{0}.$$

For convenience below, let $\boldsymbol{\theta}$ denote the full parameter vector, $[\boldsymbol{\beta},\gamma]'$.

The integration is done with Hermite quadrature. Make the change of variable to $v_i = u_i/\sqrt{2}$. Then,

$$\log L_i \;=\; \log \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} \exp(-v_i^2) \prod_{t=1}^{T_i} P(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta v_i)\; dv_i$$

where $\delta = \gamma\times\sqrt{2}$ [so $\rho = \delta^2/(2 + \delta^2)$] and $\sigma_u = [\rho/(1-\rho)]^{1/2}$]. The integral of the form $\int_{-\infty}^{\infty} \exp(-v^2) g(v) dv$ is approximated by the Hermite quadrature,

$$\int_{-\infty}^{\infty} \exp(-v^2) g(v) dv \;\approx\; \sum_{h=1}^{H} w_h\, g(z_h)$$

where w_h are the weights and z_h are the abscissas for the approximation. (See Section R23.3.1 Butler and Moffitt (1982) and Abramovitz and Stegun (1972) for further details.) Collecting terms, then, the log likelihood is computed with

$$\text{logL} \;\approx\; \sum_{i=1}^{N} \;\log \left\{ \frac{1}{\sqrt{\pi}} \sum_{h=1}^{H} w_h \left[\prod_{t=1}^{T_i} P(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta z_h) \right] \right\}$$

The derivatives of the log likelihood function are approximated as well,

$$\frac{\partial \log L}{\partial \boldsymbol{\theta}} \approx \sum_{i=1}^{N} \frac{\left\{\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H} w_h \left[\prod_{t=1}^{T_i} P(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta z_h)\right]\left[\sum_{t=1}^{T_i}\frac{\partial \log P(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta z_h)}{\partial \boldsymbol{\theta}}\right]\right\}}{\left\{\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H} w_h \left[\prod_{t=1}^{T_i} P(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta z_h)\right]\right\}}$$

Note that L_i and its derivatives are approximated separately. The summation involves two separate integrals. We use a 20 point quadrature by default, but you can change the number of quadrature points by including **; Hpt = p** in the command, where 'p' is the desired number of points, from 4 to 96 (even). In some cases, the accuracy of the computations will improve with the number of quadrature points. However, the amount of computation will as well (linearly).

The variance, δ, appears linearly in the function along with **β**, so no complication is added by this additional parameter as the summation is done over the abscissas. In each case, the term

$$P(y_{it}, \boldsymbol{\beta}'\mathrm{x}_{it} + \gamma z_h) \quad = \quad F\left[\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma z_h\right]^{y_{it}}\left(1 - F\left[\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma z_h\right]\right)^{1-y_{it}}$$

so

$$\log P(y_{it}, \boldsymbol{\beta}'\mathrm{x}_{it} + \gamma z_h) \quad = \quad y_{it} \log F_{it} + (1 - y_{it})\log(1 - F_{it}).$$

Thus,

$$\frac{\partial \log P(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta z_h)}{\partial \boldsymbol{\theta}} = \left(\frac{y_{it}}{F_{it}} - \frac{1 - y_{it}}{1 - F_{it}}\right) g_{it}(.)\begin{bmatrix}\mathbf{x}_{it} \\ z_h\end{bmatrix}$$

The forms of the particular density functions, $g_{it}(\bullet)$, differs among the five models. The functional forms appear in Section E27.2.1. Using the functions defined there, the log derivatives, $g(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)$ are as follows:

Probit: $$\frac{(2y_{it} - 1)\phi(\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)}{\Phi[(2y_{it} - 1)(\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)]}$$

Logit: $(2y_{it} - 1)\{1 - \Lambda[(2y_{it} - 1)(\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)]\}$

Comp. log log: $\exp(\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)\times\{ y_{it}[1-C(.)]/C(.) - (1 - y_{it})\}$

Gompertz: $\exp[-(\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)]\times\{y_{it} - (1 - y_{it})G(.)/[1-G(.)]\}$

Arctangent: $$\frac{(2y_i - 1)2}{\pi}\frac{1}{F_i}\frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1 + [\exp(\boldsymbol{\beta}'\mathbf{x}_i)]^2}$$

The asymptotic covariance matrix is estimated by the BHHH estimator,

$$\mathbf{H} = \left[\sum_{i=1}^{N}\left(\frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}\right)\left(\frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}\right)'\right]^{-1}$$

E31: Random Parameter Models for Binary Choice

E31.1 Introduction

The parametric binary choice models discussed in Chapter E27 are extended to panel data formats as internal procedures. Four classes of models are supported:

- **Fixed effects:** $\text{Prob}[y_{it} = 1] = F(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i)$,
  α_i correlated with $\mathbf{x}_{it}$,
- **Random effects:** $\text{Prob}[y_{it} = 1] = \text{Prob}[\boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i > 0]$,
  u_i uncorrelated with $\mathbf{x}_{it}$,
- **Random parameters:** $\text{Prob}[y_{it} = 1] = F(\boldsymbol{\beta}_i'\mathbf{x}_{it})$,
  $\boldsymbol{\beta}_i \mid i \sim h(\boldsymbol{\beta}|i)$ with mean vector $\boldsymbol{\beta}$ and covariance matrix $\boldsymbol{\Sigma}$
- **Latent class:** $\text{Prob}[y_{it} = 1|\text{class j}] = F(\boldsymbol{\beta}_j'\mathbf{x}_{it})$,
  $\text{Prob}[\text{class} = \text{j}] = F_j(\boldsymbol{\theta})$

The first two were developed in Chapter E30. This chapter documents the use of random parameters (mixed) and latent class models for binary choice. Technical details on estimation of random parameters are given in Chapter R24. Technical details for estimation of latent class models are given in Chapter R25.

NOTE: None of these panel data models require balanced panels. The group sizes may always vary.

The random parameters and latent class models do not require panel data. You may fit them with a cross section. If you omit **; Pds** and **; Panel** in these cases, the cross section case, $T_i = 1$, is assumed. (You can also specify **; Pds = 1**.) Note that this group of models (and all of the panel data models described in the rest of this manual) does not use the **; Str** = variable specification for indicating the panel – that is only for **REGRESS**.

The probabilities and density functions supported here are as follows:

Probit

$$F = \int_{-\infty}^{\beta'\mathbf{x}_i} \frac{\exp(-t^2/2)}{\sqrt{2\pi}}dt = \Phi(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \phi(\boldsymbol{\beta}'\mathbf{x}_i)$$

Logit

$$F = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)} = \Lambda(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)[1 - \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)]$$

Complementary log log

$$F = 1 - \exp(-\exp(\boldsymbol{\beta}'\mathbf{x}_i)) = \mathrm{C}(\boldsymbol{\beta}'\mathbf{x}_i), \qquad f = \exp(\boldsymbol{\beta}'\mathbf{x}_i)[1 - \mathrm{C}(\boldsymbol{\beta}'\mathbf{x}_i)]$$

Gompertz, or type 1 extreme value

$$F = \exp(-\exp(-\boldsymbol{\beta}'\mathbf{x}_i)) = \mathrm{G}(\boldsymbol{\beta}'\mathbf{x}_i) \qquad f = \exp(-\boldsymbol{\beta}'\mathbf{x}_i)\mathrm{G}(\boldsymbol{\beta}'\mathbf{x}_i)$$

Arctangent

$$F = 2/\pi \arctan(\exp(\boldsymbol{\beta}'\mathbf{x}_i)), \qquad f = 2/\pi\ [1/(1 + \exp^2(\boldsymbol{\beta}'\mathbf{x}_i))$$

E31.2 Binary Choice Models with Random Parameters

There is a growing literature on the random parameters modeling approach in transportation studies associated primarily with the discrete choice models described in the *NLOGIT 5 Reference Guide*. We have extended the random parameters model to the binary choice models as well as many other models including the tobit and exponential regression models. Some of the relevant background literature includes Revelt and Train (1998), Train (1998), Brownstone and Train (1999), and Greene (2001a). (In that literature, the models are described under the heading ‘mixed logit’ models. We will require a broader rubric for our purposes.) The structure of the random parameters model is based on the conditional probability

$$\mathrm{Prob}[y_{it} = 1|\, \mathbf{x}_{it}, \boldsymbol{\beta}_i] = F(\boldsymbol{\beta}_i'\mathbf{x}_{it}),\ i = 1,...,N,\ t = 1,...,T_i.$$

where $F(.)$ is the distribution discussed earlier (normal, logistic, extreme value, Gompertz). The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals)

$$\mathrm{E}[\boldsymbol{\beta}_i|\, \mathbf{z}_i] = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i,$$

(the second term is optional – the mean may be constant),

$$\mathrm{Var}[\boldsymbol{\beta}_i|\, \mathbf{z}_i] = \boldsymbol{\Sigma}.$$

The model is operationalized by writing

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i \text{ where } \mathbf{v}_i \sim \mathrm{N}[\mathbf{0},\mathbf{I}].$$

As noted earlier, the heterogeneity term is optional. In addition, it may be assumed that some of the parameters are nonrandom. It is convenient to analyze the model in this fully general form here. One can easily accommodate nonrandom parameters just by placing rows of zeros in the appropriate places in $\boldsymbol{\Delta}$ and $\boldsymbol{\Gamma}$. The command structure for these models makes this simple to do.

NOTE: If there is no heterogeneity in the mean, and only the constant term is considered random – the model may specify that some parameters are nonrandom – then this model is equivalent to the random effects model of the preceding section.

E31.2.1 Command for the Random Parameters Models

The basic model command for this form of the model is

PROBIT
LOGIT
COMPLOG
GOMPERTZ
ARCTANGENT

; Lhs = dependent variable
; Rhs = independent variables
; Panel or Pds = fixed periods or count variable
; RPM
; Fcn = random parameters specification $

NOTE: For this model, your Rhs list should include a constant term.

NOTE: The **; Pds** specification is optional. You may fit these models with cross section data.

Specifying Random Parameters

The **; Fcn = specification** is used to define the random parameters. It is constructed from the list of Rhs names as follows: Suppose your model is specified by

; Rhs = one, x1, x2, x3, x4

This involves five coefficients. Any or all of them may be random; any not specified as random are assumed to be constant. For those that you wish to specify as random, use

; Fcn = variable name (distribution),
variable name (distribution), ...

Three distributions may be specified. All random variables have mean 0.

n = standard normal distribution, variance = 1,
t = triangular (tent shaped) distribution in [-1,+1], variance = 1/6,
u = standard uniform distribution [-1,1], variance = 1/3,
l = lognormal distribution, variance = exp(.5),
o = tent shaped distribution with one anchor at zero
g = log gamma
or *c* = variance = 0. (The parameter is not random.)

Each of these is scaled as it enters the distribution, so the variance is only that of the random draw before multiplication. The normal distribution is used most often, but there are several other possibilities. Numerous other formats for random parameters are described in Section R24.3. Those results all apply to the binary choice models. To specify that the constant term and the coefficient on *x*1 are each normally distributed with given mean and variance, use

; Fcn = one(n), x1(n).

This specifies that the first and second coefficients are random while the remainder are not. The parameters estimated will be the mean and standard deviations of the distributions of these two parameters and the fixed values of the other three.

The results include estimates of the means and standard deviations of the distributions of the random parameters and the estimates of the nonrandom parameters. The log likelihood shown in the results is conditioned on the random draws, so one might be cautious about using it to test hypotheses, for example, that the parameters are random at all by comparing it to the log likelihood from the basic model with all nonrandom coefficients. The test becomes valid as R increases, but the 50 used in our application is probably too few. With several hundred draws, one could reliably use the simulated log likelihood for testing purposes.

Correlated Random Parameters

The preceding defines an estimator for a model in which the covariance matrix of the random parameters is diagonal. To extend it to a model in which the parameters are freely correlated, add

; Correlation (or just ; Cor)

to the command. An example appears below.

Heterogeneity in the Means

The preceding examples have specified that the mean of the random variable is fixed over individuals. If there is measured heterogeneity in the means, in the form of

$$E[\beta_{ki}] = \beta_k + \Sigma_m \delta_{km} z_{mi}$$

where z_m is a variable that is measured for each individual, then the command may be modified to

; RPM = list of variables in z

In the data set, these variables must be repeated for each observation in the group. In the application below, we have specified that the random parameters have different means for individuals depending on gender and marital status.

Autocorrelation

You may change the character of the heterogeneity from a time invariant effect to an AR(1) process,

$$v_{kit} = \rho_k v_{ki,t-1} + w_{kit}.$$

(See Section R24.3 for details.)

E31.2.2 Results from the Estimator and Applications

The results produced by this estimator begin with the familiar diagnostic statistics, likelihood function, information criteria, etc. The coefficient estimates are possibly rearranged so that the nonrandom parameters appear first. In the base case of a diagonal covariance matrix, the means of the random parameters appear next, followed in the same order by the estimated scale parameters. The example below illustrates. For normally distributed parameters, these are the standard deviations. For other distributions, these scale factors are multiplied by the relevant standard deviation to obtain the standard deviation of the parameter. For example, if we had specified

; Fcn = educ(u)

in the model command, then the parameter on *educ* would be defined to have mean 1.697 and standard deviation .08084 times 1/sqr(6). (The uniform draw is transformed to be *U*[-1,+1].)

```

When the random parameters are specified to be correlated, the output is changed. The parameter vector in this case is written

$$\boldsymbol{\beta}_i = \boldsymbol{\beta}^0 + \boldsymbol{\Gamma}\,\mathbf{v}_i$$

where $\boldsymbol{\Gamma}$ is a lower triangular Cholesky matrix. In this case, the nonrandom parameters and the means of the random parameters are reported as before. The table then reports $\boldsymbol{\Gamma}$ in two parts. The diagonal elements are reported first. These would correspond to the case above. The nonzero elements of $\boldsymbol{\Gamma}$ below the diagonal are reported next, rowwise. In the example below, there are three random parameters, so there are 1 + 2 elements below the main diagonal of $\boldsymbol{\Gamma}$ in the reported results. The covariance matrix for the random parameters in this specification is

$$\text{Var}[\boldsymbol{\beta}_i] = \boldsymbol{\Omega} = \boldsymbol{\Gamma}\mathbf{A}\boldsymbol{\Gamma}'$$

where $\mathbf{A}$ is the known diagonal covariance matrix of $\mathbf{v}_i$. For normally distributed parameters, $\mathbf{A} = \mathbf{I}$. This matrix is reported separately after the tabled coefficient estimates. Finally, the square roots of the diagonal elements of the estimate of $\boldsymbol{\Omega}$ are reported, followed by the correlation matrix derived from $\boldsymbol{\Omega}$. The example below illustrates.

Finally, if you specify that there is observable heterogeneity in the means of the parameters with

; RPM = list of variables

then the model changes to

$$\boldsymbol{\beta}_i = \boldsymbol{\beta}^0 + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\,\mathbf{v}_i.$$

The elements of $\boldsymbol{\Delta}$, rowwise, are reported after the decomposition of $\boldsymbol{\Gamma}$. The example below, which contains gender and marital status, illustrates. Note that a compound name is created for the elements of $\boldsymbol{\Delta}$.

Results saved by this estimator are:

Matrices: *b* = estimate of θ
varb = asymptotic covariance matrix for estimate of θ.
gammaprm = the estimate of Γ
beta_i = individual specific parameters, if **; Par** is requested
sdbeta_i = individual specific parameter standard deviations if **; Par** is requested

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variables*

Last Function: None

Simulation based estimation is time consuming. The sample size here is fairly large (27,326 observations). We limited the simulation to 25 Halton draws. The amount of computation rises linearly with the number of draws. A typical application of the sort pursued here would use perhaps 300 draws, or 12 times what we used. Estimation of the last model required two minutes and 30 seconds, so in full production, estimation of this model might take 30 minutes. In general, you can get an idea about estimation times by starting with a small model and a small number of draws. The amount of computation rises linearly with the number of draws – that is the main consumer. It also rises linearly with the number of random parameters. The time spent fitting the model will rise only slightly with the number of nonrandom numbers. Finally, it will rise linearly with the number of observations. Thus, a model with a doubled sample and twice as many draws will take four times as long to estimate as one with the original sample and number of draws.

When you include **; Par** in the model command, two additional matrices are created, *beta_i* and *sdbeta_i*. Extensive detail on the computation of these matrices is provided in Section R24.5. For the final specification described above, the results would be as shown in Figure E31.1.

Figure E31.1 Estimated Conditional Parameter Means

E31.2.3 Controlling the Simulation

R is the number of points in the simulation. Authors differ in the appropriate value. Train recommends several hundred. Bhat suggests 1,000 is an appropriate value. The program default is 100. You can choose the value with

; Pts = number of draws, R

The value of 50 that we set in our experiments above was chosen purely to produce an example that you could replicate without spending an inordinate amount of waiting for the results.

The standard approach to simulation estimation is to use random draws from the specified distribution. As suggested immediately above, good performance in this connection requires very large numbers of draws. The drawback to this approach is that with large samples and large models, this entails a huge amount of computation and can be very time consuming. Some authors have documented dramatic speed gains with no degradation in simulation performance through the use of a small number of Halton draws instead of a large number of random draws. Halton sequences are discussed in Section R24.7. Authors (e.g., Bhat (2001)) have found that a Halton sequence of draws with only one tenth the number of draws as a random sequence is equally effective. To use this approach, add

; Halton

to your model command.

In order to replicate an estimation, you must use the same random draws. One implication of this is that if you give the identical model command twice in sequence, you will not get the identical set of results because the random draws in the sequences will be different. To obtain the same results, you must reset the seed of the random number generator with a command such as

CALC ; Ran(seed value) $

(Note that we have used **Ran(12345)** before some of our earlier examples, precisely for this reason. The specific value you use for the seed is not of consequence; any odd number will do.

The random sequence used for the model estimation must be the same in order to obtain replicability. In addition, during estimation of a particular model, the same set of random draws must be used for each person every time. That is, the sequence $\mathbf{v}_{i1}$, $\mathbf{v}_{i2}$, ..., $\mathbf{v}_{iR}$ used for each individual must be same every time it is used to calculate a probability, derivative, or likelihood function. (If this is not the case, the likelihood function will be discontinuous in the parameters, and successful estimation becomes unlikely.) One way to achieve this which has been suggested in the literature is to store the random numbers in advance, and simply draw from this reservoir of values as needed. Because *LIMDEP* is able to use very large samples, this is not a practical solution, especially if the number of draws is large as well. We achieve the same result by assigning to each individual, *i*, in the sample, their own random generator seed which is a unique function of the global random number seed, *S*, and their group number, *i*;

$$\text{Seed}(S,i) = S + 123.0 \times i, \text{ then minus 1.0 if the result is even.}$$

Since the global seed, *S*, is a positive odd number, this seed value is unique, at least within the several million observation range of *LIMDEP*.

E31.2.4 Other Options

Standard Model Specifications for the Random Parameters Binary Choice Models

This is the full list of general specifications applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps individual specific parameter estimates.
; Margin	displays marginal effects.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Prob = name	saves probabilities as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test
; Rst = list imposes equality and fixed value restrictions
; CML: spec imposes linear restrictions on parameters during estimation.

Marginal effects are computed by setting the heterogeneity terms to their expected value of zero.

E31.2.5 The Parameter Vector and Starting Values

Starting values for the iterations are obtained by fitting the basic model without random parameters. Other parameters are set to zero. Thus, the initial results in the output for these models will be the binary choice models discussed in the preceding sections. You may provide your own starting values for the parameters with

; Start = ... the list of values for θ.

The parameter vector is laid out as follows, in this order:

$\alpha_1, ..., \alpha_K$ are the K nonrandom parameters,

$\beta_1,...,\beta_M$ are the M means of the distributions of the random parameters,

$\sigma_1,\sigma_2,...,\sigma_M$ are the M scale parameters for the distributions of the random parameters.

These are the essential parameters. If you have specified that parameters are to be correlated, then the σs are followed by the below diagonal elements of $\mathbf{\Gamma}$. (The σs are the diagonal elements.) If you have specified heterogeneity variables, **z**, then the preceding are followed by the rows of $\mathbf{\Delta}$. Consider an example: The model specifies:

; RPM = z1,z2
; Rhs = one,x1,x2,x3,x4 ? base parameters β_1, β_2, β_3, β_4, β_5
; Fcn = one(n),x2(n),x4(n)
; Cor

Then, after rearranging, the model becomes

Variable	Parameter
$x1$	α_1
$x3$	α_2
one	$\beta_1 + \sigma_1 v_{i1} \qquad\qquad\qquad\qquad + \delta_{11}z_{i1} + \delta_{12}z_{i2}$
$x2$	$\beta_2 + \sigma_2 v_{i2} + \gamma_{21}v_{i1} \qquad\qquad + \delta_{11}z_{i1} + \delta_{12}z_{i2}$
$x4$	$\beta_3 + \sigma_3 v_{i3} + \gamma_{31}v_{i1} + \gamma_{32}v_{i2} + \delta_{11}z_{i1} + \delta_{12}z_{i2}$

and the parameter vector would be

$$\boldsymbol{\theta} = \alpha_1, \alpha_2, \beta_1, \beta_2, \beta_3, \sigma_1, \sigma_2, \sigma_3, \gamma_{21}, \gamma_{31}, \gamma_{32}, \delta_{11}, \delta_{12}, \delta_{21}, \delta_{22}, \delta_{31}, \delta_{32}.$$

You may use **; Rst** and **; CML** to impose restrictions on the parameters. Use the preceding as a guide to the arrangement of the parameter vector. We do note, using **; Rst** to impose fixed value, such as zero restrictions, will generally work well. Other kinds of restrictions, particularly across the parts of the parameter vector, will generally produce unfavorable results.

The variances of the underlying random variables are given earlier, 1 for the normal distribution, 1/3 for the uniform, and 1/6 for the tent distribution. The σ parameters are only the standard deviations for the normal distribution. For the other two distributions, σ_k is a scale parameter. The standard deviation is obtained as $\sigma_k/\sqrt{3}$ for the uniform distribution and $\sigma_k/\sqrt{6}$ for the triangular distribution. When the parameters are correlated, the implied covariance matrix is adjusted accordingly. The correlation matrix is unchanged by this.

E31.2.6 A Dynamic Probit Model

We consider estimation of the dynamic (habit persistence) probit model

$$y_{it}^* = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \gamma y_{i,t-1} + \varepsilon_{it} + \sigma u_i, \ \mathrm{t} = 0,...,T_i, \ i = 1,...,N$$
$$y_{it} = 1(y_{it}^* > 0).$$

Simple estimation of the model by maximum likelihood is clearly inappropriate owing to the random effect. ML random effects is likewise inconsistent because $y_{i,t-1}$ will be correlated with the random effect. Following Heckman (1981), a suggested formulation and procedure for estimation are as follows: Treat the initial condition as an equilibrium, in which

$$y_{i0}^* = \phi + \boldsymbol{\delta}'\mathbf{x}_{i0} + \varepsilon_{i0} + \tau u_i$$
$$y_{i0} = 1(y_{i0*} > 0)$$

and retain the preceding model for periods $1,...,T_i$. Note that the same random effect, u_i appears throughout, but the scaling parameter and the slope vector are different in the initial period. The lagged value of y_{it} does not appear in period 0. This model can be estimated in this form with the random parameters estimator in *LIMDEP*. Use the following procedure. Set up the variables:

d_{it} = 1 in period 1, 0 in all other periods,

f_{it} = $1 - d_{it}$ = 1 in all periods except period 1,

$\mathbf{x}_{it}$ = the set of regressors in the model, 0 in the first period,

$\mathbf{x}_{i0}$ = the set of regressors in the model in period 0, 0 in all other periods,

$y_{i,-1}$ = $y_{i,t-1}$ in periods $1,...,T_i$, 0 in the first period.

Then, the encompassing model is

$$y_{it}^* = \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}'\mathbf{x}_{i0} + \phi d_{it} + \alpha f_{it} + \gamma y_{i,-1} + \varepsilon_{it} + \sigma f_{it} u_i + \tau d_{it} u_i,$$
$$y_{it} = 1(y_{it}^* > 0), \ t = 0,1,...,T_i.$$

The commands you might use to set up the data would follow these steps. First, use **CREATE** to set up your group size count variable, *_groupti*.

```
CREATE    ; yit = the dependent variable
          ; yit1 = yit[-1] ? Make sure that yit1 = 0 in the first period.
          ; t = Trn(-ti,1)  or whatever means to set up 1,2,...Ti + 1
          ; dit = (t=1) ; fit = (t > 1) $
CREATE    ; set up the xit and xi0 sets of variables $
```

The estimation command is a random parameters probit model. We make use of a special feature of the RPM that allows the random component of the random parameters to be shared by more than one parameter. This is precisely what is needed to have both τu_i and σu_i appear in the equation without forcing $\tau = \sigma$.

```
PROBIT   ; Lhs = yit
         ; Rhs = xit, xi0, yit1, dit, fit
         ; Panel
         ; RPM
         ; Fcn = dit(n), fit(n)
         ; Common
         ; ... any other desired specifications for the estimation $
```

A refinement of this model assumes that $u_i = \boldsymbol{\lambda}'\mathbf{z}_i + w_i$ for a set of time invariant variables. (See Hyslop (1999) and Greene (2011). One possibility is the vector of group means of the variables $\mathbf{x}_{it}$. (Only the time varying variables would be included in these means.) These can be created and included as additional Rhs variables.

E31.3 Latent Class Models for Binary Choice

The binary choice model for a panel of data, $i = 1,...,N$, $t = 1,...,T_i$ is

$$\text{Prob}[Y_{it} = y_{it} \mid \mathbf{x}_{it}] = F(y_{it},\boldsymbol{\beta}'\mathbf{x}_{it}) = P(i,t),\ y_{it} = 0 \text{ or } 1.$$

Henceforth, we use the term 'group' to indicate the T_i observations on respondent i in periods $t = 1,...,T_i$. Unobserved heterogeneity in the distribution of y_{it} is assumed to impact the density in the form of a random effect. The continuous distribution of the heterogeneity is approximated by using a finite number of 'points of support.' The distribution is approximated by estimating the location of the support points and the mass (probability) in each interval. In implementation, it is convenient and useful to interpret this discrete approximation as producing a sorting of individuals (by heterogeneity) into J classes, $j = 1,...,J$. (Since this is an approximation, J is chosen by the analyst.)

Thus, we modify the model for a latent sorting of y_{it} into J 'classes' with a model which allows for heterogeneity as follows: The probability of observing y_{it} given that regime j applies is

$$P(i,t|j) = \text{Prob}[Y_{it} = y_{it}| \mathbf{x}_{it}, j]$$

where the density is now specific to the group. The analyst does not observe directly which class, $j = 1,...,J$ generated observation $y_{it}|j$, and class membership must be estimated. Heckman and Singer (1984) suggest a simple form of the class variation in which only the constant term varies across the classes. This would produce the model

$$P(i,t|j) = F[y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta_j], \text{Prob}[\text{class} = j] = F_j$$

We formulate this approximation more generally as,

$$P(i,t|j) = F[y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}_j'\mathbf{x}_{it}], F_j = \exp(\theta_j) / \Sigma_j \exp(\theta_j), \text{ with } \theta_J = 0.$$

In this formulation, each group has its own parameter vector, $\boldsymbol{\beta}_j' = \boldsymbol{\beta} + \boldsymbol{\delta}_j$, though the variables that enter the mean are assumed to be the same. (This can be changed by imposing restrictions on the full parameter vector, as described below.) This allows the Heckman and Singer formulation as a special case by imposing restrictions on the parameters. You may also specify that the latent class probabilities depend on person specific characteristics, so that

$$\theta_{ij} = \boldsymbol{\theta}_j'\mathbf{z}_i, \boldsymbol{\theta}_J = \mathbf{0}.$$

The estimation command for this model is

PROBIT
LOGIT
COMPLOG
GOMPERTZ
ARCTANGENT

; Lhs = ...
; Rhs = independent variables
; LCM (for latent class model)
; Panel $

The default number of support points is five. You may set J from two to nine classes with

; Pts = the value

Use

; LCM = list of variables in $\mathbf{z}_i$

to specify the multinomial logit form of the latent class probabilities.

Standard Model Specifications for the Latent Class Binary Choice Models

This is the full list of general specifications from Chapter E1. Those marked by '*' are not available or not applicable to this model estimator. See Chapter E1 and references noted there for further details on these specifications.

Controlling Output from Model Commands

; Par keeps individual specific parameter estimates.
; Margin displays marginal effects.
; OLS displays least squares starting values when (and if) they are computed.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Prob = name saves probabilities as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

Some particular values computed for the latent class model are

; Group = the index of the most likely latent class
; Cprob = estimated posterior probability for the most likely latent class

You can obtain a listing of these two results by using

; List

The posterior probabilities for each individual are saved by the following steps:

1. Create a set of variables, pr1=0, pr2=0,… (using any names you wish) so that there is one variable for each class

2. Create a namelist for these variables:

   NAMELIST ; prgroup = pr1,pr2,… $

   Again, use any name you wish.

3. In the model command, include

   ; Classp = the namelist name.

You can use the **; Rst = list** option to structure the latent class model so that different variables appear in different classes. Alternatively, you can use this to force the Heckman and Singer form of the model as follows, where we use a three class model as an example:

```
NAMELIST    ; x = ... one, list of variables $
CALC        ; k1 =  Col(x) - 1 $
LOGIT       ; Lhs = ... ; Rhs = x ; LCM ; Pts = 3
            ; Rst = d1, k1_b, d2, k1_0, d3, k1_0, t1, t2, t3 $
```

Estimates retained by this model include

Matrices: *b* = full parameter vector, $[\beta_1', \beta_2', \ldots F_1, \ldots, F_J]$
varb = full covariance matrix
Note that *b* and *varb* involve $J\times(K+1)$ estimates.

Two additional matrices are created:

b_class = a $J\times K$ matrix with each row equal to the corresponding β_j
class_pr = a $J\times 1$ vector containing the estimated class probabilities

If the command specifies **; Parameters**, then the additional matrix created is:

beta_i = individual specific parameters

Scalars: *kreg* = number of variables in Rhs list
nreg = total number of observations used for estimation
logl = maximized value of the log likelihood function
exitcode = exit status of the estimation procedure

E31.3.1 Application

To illustrate the model, we will fit probit models with three latent classes as alternatives to the continuously varying random parameters models in the preceding section. This model requires a fairly rich data set – it will routinely fail to find a maximum if the number of observations in a group is small. In addition, it will break down if you attempt to fit too many classes. (This point is addressed in Heckman and Singer.)

The model estimates include the estimates of the prior probabilities of group membership. As shown in Section R25.7.1, it is also possible to compute the posterior probabilities for the groups, conditioned on the data. The **; List** specification will request a listing of these. The final illustration below shows this feature for a small subset of the data used above. The models use the following commands: The first is the pooled probit estimator. The second is a basic, three class LCM. The third models the latent class probabilities as functions of the gender and marital status dummy variables. The final model command fits a comparable random parameters model. We will compare the two estimated models.

Fit the pooled probit model first, basic latent class, then latent class with the gender and marital status dummy variables in the class probabilities.

```
PROBIT      ; Lhs = doctor ; Rhs = x,one
            ; Partial Effects
            ; Cluster = id $
MATRIX      ; betapool = b' $
PROBIT      ; Lhs = doctor ; Rhs = x,one
            ; Partial Effects
            ; Pds = _groupti
            ; LCM
            ; Pts = 3 $
PROBIT      ; Lhs = doctor ; Rhs = x,one
            ; Partial Effects
            ; Pds = _groupti
            ; LCM = female,married
            ; Pts = 3
            ; Parameters $
```

Fit the random parameters probit model with heterogeneity in means.

```
PROBIT      ; Lhs = doctor ; Rhs = x,one
            ; Partial Effects
            ; Pds = _groupti
            ; RPM = female,married
            ; Fcn = one(n),hhninc(n),newhsat(n)
            ; Correlated
            ; Pts = 25
            ; Halton
            ; Parameters $
```

These are the estimated parameters of the pooled probit model. The cluster correction is shown with the pooled results.

```

Since the class probabilities now differ by observation, the program reports an average using the data means. The earlier fixed prior class probabilities are shown below the averages for this model. The extension brings only marginal changes in the averages, but this does not show the variances across the different demographic segments (female/male, married/single) which may be substantial.

These are the estimated 'individual' parameter vectors.

E32: Semiparametric and Nonparametric Models for Binary Choice

E32.1 Introduction

This chapter will present three non- and semiparametric estimators for binary choice models. Familiar parametric estimators of binary response models, such as the probit and logit are based on the log likelihood criterion,

$$\log L \;=\; \frac{1}{n}\sum_{i=1}^{n} \log F(y_i \,|\, \boldsymbol{\beta}'\mathbf{x}_i)\;.$$

The Cramer-Rao theory justifies this procedure on the basis of efficiency of the parameter estimates. But, it is to be noted that the criterion is not a function of the ability of the model to predict the response. Moreover, in spite of the widely observed similarity of the predictions from the different models, the issue of which parametric family (normal, logistic, etc.) is most appropriate has never been settled, and there exist no formal tests to resolve the question in any given setting. Various estimators have been suggested for the purpose of broadening the parametric family, so as to relax the restrictive nature of the model specification. Two semiparametric estimators are presented in *LIMDEP*, Manski's (1975, 1985) and Manski and Thompson's (1985, 1987) maximum score (MSCORE) estimator and Klein and Spady's (1993) kernel density estimator.

The MSCORE estimator is constructed specifically around the prediction criterion

Choose $\boldsymbol{\beta}$ to maximize $S \;=\; \Sigma_i\, [y_i^* \;\times z_i^*]$,

where y_i^* = sign (-1/1) of the dependent variable

z_i^* = the sign (-1/1) of $\boldsymbol{\beta}'\mathbf{x}_i$.

Thus, the MSCORE estimator seeks to maximize the number of correct predictions by our familiar prediction rule – predict $y_i = 1$ when the estimated Prob[$y_i = 1$] is greater than .5, *assuming that the true, underlying probability function is symmetric*. In those settings, such as probit and logit, in which the density is symmetric, the sign of the argument is sufficient to define whether the probability is greater or less than .5. For the asymmetric distributions, this is not the case, which suggests a limitation of the MSCORE approach. The estimator does allow another degree of freedom in the choice of a quantile other than .5 for the prediction rule – see the definition below – but this is only a partial solution unless one has prior knowledge about the underlying density.

Klein and Spady's semiparametric density estimator is based on the specification

$$\text{Prob}[y_i = 1] \;=\; P(\boldsymbol{\beta}'\mathbf{x}_i)$$

where P is an unknown, continuous function of its argument with range [0,1]. The function P is not specified a priori; it is estimated with the parameters. The probability function provides the location for the index that would otherwise be provided by a constant term. The estimation criterion is

$$\log L \;=\; \frac{1}{n}\sum_{i=1}^{n} [y_i \log P_n(\boldsymbol{\beta}'\mathbf{x}_i) + (1-y_i)\log(1-P_n(\boldsymbol{\beta}'\mathbf{x}_i))]$$

where P_n is the estimator of P and is computed using a kernel density estimator.

The third estimator is a nonparametric treatment of binary choice based on the index function estimated from a parametric model such as a logit model.

E32.2 Maximum Score Estimation - MSCORE

Maximum score is a semiparametric approach to estimation which is based on a prediction rule. The base case (quantile = ½) is

$$S = \Sigma_i [y_i^* \times z_i^*],$$

where y_i^* is the sign (-1/1) of the dependent variable and z_i^* is the counterpart for the fitted model; z_i^* = the sign (-1/1) of $\boldsymbol{\beta}'\mathbf{x}_i$. Thus, this base case is formulated precisely upon the ability of the sign of the estimated index function to predict the sign of the dependent variable (which, in the binary response models, is all that we observe). Formally, MSCORE maximizes the sample score function

$$\text{Max}_{\boldsymbol{\beta}\varepsilon\mathbf{B}}\, S_{n\alpha}(\boldsymbol{\beta}) = (1/n)\Sigma_i[y_i^* - (1\text{-}2\alpha)]\text{Sgn}(\boldsymbol{\beta}'\mathbf{x}_i),$$

where $\mathbf{B} = \{\boldsymbol{\beta}\ \varepsilon\ R^K : \|\boldsymbol{\beta}\| = 1\}.$

The sample data consist of n observations $[y_i^* ,\mathbf{x}_i]$ where y_i^* is the binary response. Input of y_i is the usual binary variable taking values zero and one; y_i^* is obtained internally by converting zeros to minus ones. The quantile, α, is between zero and one and is provided by the user. The vector $\mathbf{x}_i$ is the usual set of K regressors, usually including a constant. An equivalent problem is to maximize the normalized sample score function

$$S_{N\alpha}^*(\boldsymbol{\beta}) = (1/n)[S_{n\alpha}(\boldsymbol{\beta}) / W_n + 1],$$

where $W_n = (1/n)\Sigma_i w_i$

and $w_i = \text{abs}(y_i^* - (1\text{-}2\alpha)).$

This may then be rewritten as

$$S_{n\alpha}^*(\boldsymbol{\beta}) = \Sigma_i\, w_i^* \times \mathbf{1}[y_i^* = \text{Sgn}(\boldsymbol{\beta}'\mathbf{x}_i)],$$

where $w_i^* = w_i / W_n.$

and $\mathbf{1}[\bullet]$ is the indicator function which equals 1 if the condition in the brackets is true and 0 otherwise. Thus, in the preceding, $\mathbf{1}[\bullet]$ equals 1 if the sign of the index function, $\boldsymbol{\beta}'\mathbf{x}_i$, correctly predicts y_i^*. The normalized sample score function is, thus, a weighted average of the prediction indicators. If α = ½, then w_i^* equals $1/n$, and the normalized score is the fraction of the observations for which the response variable is correctly predicted. Maximum score estimation can therefore be interpreted as the problem of finding the parameters that maximize a weighted average number of correct predictions for the binary response.

The following shows how to use the **MSCORE** command and gives technical details about the procedure. An application is given with the development of **NPREG**, which is a companion program, in Section E32.4.

E32.2.1 Command for MSCORE

The mandatory part of the command for invoking the maximum score estimator

MSCORE ; Lhs = y ; Rhs = x list of independent variables $

The first element of *x* should be *one*. The variable *y* is a binary dependent variable, coded 0/1. The following are the optional specifications for this command. The default values given are used by *LIMDEP* if the option is not specified on the command. **MSCORE** is designed for relatively small problems. The internal limits are 15 parameters and 10,000 observations.

E32.2.2 Options Specific to the Maximum Score Estimator

Quantile

The quantile defines the way the score function is computed. The default of .5 dictates that the score is to be calculated as $(1/n)$ times the number of correctly predicted signs of the response variable. You may choose any value between 0 and 1 with

; Qnt = quantile (default = .5; this is α).

Number of Bootstrap Replications

Bootstrap estimates are computed as follows: After computing the point estimate, **MSCORE** generates R bootstrap samples from the data by sampling n observations with replacement. The entire point estimation procedure, including computation of starting values is repeated for each one. Let $\mathbf{b}$ be the maximum score estimate, R be the number of bootstrap replications, and $\mathbf{d}_i$ be the ith bootstrap estimate. The mean squared deviation matrix,

$$\mathbf{MSD} = (1/R)\Sigma_i\,[(\mathbf{d}_i - \mathbf{b})(\mathbf{d}_i - \mathbf{b})'],$$

is computed from the bootstrap estimates. This is reported in the output as if it were the estimated covariance matrix of the estimates. But, it must be noted that there is no theory to suggest that this is correct. In purely practical terms, the deviations are from the point estimate, not the mean of the bootstrap estimates. The results are merely suggestive. The use of **; Test:** should also be done with this in mind. Use

; Nbt = number of bootstraps (default = 20)

to set the number of bootstrap iterations.

Analysis of Ties

The specification for analysis of ties is

; Ties to analyze ties (default = no)

If the **; Ties** option is chosen, **MSCORE** reports information about regions of the parameter space discovered during the endgame searches for which the sample score is tied with the score at the final estimates. If a tie is found in a region, **MSCORE** records the endpoints of the interval, the current search direction, and some information which records each observation's contribution to the sample score in the region. It is possible to determine whether ties found on separate great circle searches represent disjoint regions or intersections of different great circles. Since the region containing the final estimates is partially searched in each iteration, the tie checking procedure records extensive information about this region. For each region, **MSCORE** reports the minimum and maximum angular direction from the final estimates. These are labeled PSI-low and PSI-high. The parameter values associated with these endpoints are also reported.

If tie regions are found that are far from the point estimate, it may be that the global maximum remains to be found. If so, it may be useful to rerun the estimator using a starting value in the tied region. The existence of many tie regions does not necessarily indicate an unreliable estimate. Particularly in large samples, there may be a large number of disjoint regions in a small neighborhood of the global maximum.

Number of Endgame Iterations

The number of endgame iterations is specified with

; End = number endgame iterations (default = 5)

A given set of great circle searches may miss a direction of increase in the score function. Moreover, even if the trial maximum is a true local maximum, it may not be a global maximum. For these reasons, upon finding a trial maximum, **MSCORE** conducts a user specified number of 'endgame iterations.' These are simply additional iterations of the maximization algorithm. The random search method is such that with enough of these, the entire parameter space would ultimately be searched with probability one. If the endgame iterations provide no improvement in the score, the trial maximum is deemed the final estimate. If an improvement is made during an endgame search, the current estimate is updated as usual and the search resumes. The logic of the algorithm depends on the endgame searches to ensure that all regions of the parameter space are investigated with some probability. The density of the coverage is an increasing function of the number of endgame searches.

There are no formal rules for the number of endgame searches. It should probably increase with K and (perhaps a little less certainly) with n. But, because the step function more closely approximates a continuous population score function, it may be that fewer endgame searches will be needed as N increases.

Starting Values

Starting values are specified with

; Start = starting values (default = none).

If starting values are not provided by the user, they are computed as follows: For each of the K parameters, we form a vector equal to the kth column of an identity matrix. The sample score function is evaluated at this vector, and the kth parameter is set equal to this value. At the conclusion, the starting vector is normalized to unit length. If you do provide your own starting values, they will be normalized to unit length before the iterations are begun.

Technical Output

Technical output is specified with

; Output = 4 or 5 for output of trace of bootstraps to output file
(default = neither).

This is used to control the amount of information about the bootstrap iterations that is produced. This can generate hundreds or thousands of lines of output, depending on the number of bootstrap estimates computed and the number of endgame searches requested. This information is displayed on the screen, in order to trace the progress of execution. In general, the output is not especially informative except in the aggregate. That is, individual lines of this trace are likely to be quite similar. The default is not to retain information about individual bootstraps or endgame searches in the file. Use **; Output = 4** to request only the bootstrap iterations (one line of output per). Use **; Output = 5** to include, in addition, the corresponding information about the endgame searches.

E32.2.3 General Options for MSCORE

The following general options used with the nonlinear estimators in *LIMDEP* are available for MSCORE:

; Covariance Matrix:	to display MSE matrix (default = no), same as **; Printvc**
; List	to display predicted values (default = no list)
; Keep = name	to retain predictions in name (default = no)
; Res = name	to retain fitted values in name (default = no)
; Test: spec	to specify restriction (default = none)
; Maxit = n	to set maximum iterations (default = 50)

Note the earlier caution about the MSD matrix when using the **; Test:** option. The **; Rst = ...** and **; CML:** options for imposing restrictions are not available with this estimator.

E32.2.4 Output from MSCORE

Output from **MSCORE** consists of the following, in the order in which it will appear on your screen or your output file:

1. The iteration summary for the primary estimation procedure (this is labeled bootstrap sample 0') and, if you have requested them, the bootstrap sample estimations. With each one, we report the number of iterations, the number of completed 'endgame iterations' (see the discussion above), the maximum normalized score, and the change in the normalized score.

2. Echo of input parameters in your command.

3. The score function and normalized score function evaluated at three different points:

    a. naive, the first element of β is 1 or -1 and all other values are 0,
    b. the starting values,
    c. the final estimates.

4. The deviations of the bootstrap estimates from the point estimates are summarized in the root mean square error and mean absolute angular deviation between them.

5. The point estimates of the parameters.

NOTE: The estimates are presented in *LIMDEP*'s standard format for parameter estimates. If you have computed bootstrap estimates, the mean square deviation matrix (from the point estimate) is reported as if it were an estimate of the covariance matrix of the estimates. This includes 'standard errors,' 't ratios,' and 'prob. values.' These may, in fact, not be appropriate estimates of the asymptotic standard errors of these parameter estimates. Discussion appears in the references below.

If you change the number of bootstrap estimates, you may observe large changes in these standard errors. This is not to be interpreted as reflecting any changes in the precision of the estimates. If anything, it reflects the unreliability of the bootstrap MSD matrix as an estimate of the asymptotic covariance matrix of the estimates. It has been shown that the asymptotic distribution of the maximum score estimator is not normal. (See Kim and Pollard (1990).) Moreover, even under the best of circumstances, there is no guarantee that the bootstrap estimates or functions of them (such as t ratios), converge to anything useful.

6. A cross tabulation of the predictions of the model vs. the actual values of the Lhs variable.

7. If the model has more than two parameters, and you have requested analysis of the ties, the results of the endgame searches are reported last. Records of ties are recorded in your output file if one is opened, but not displayed on your screen.

The predicted values computed by **MSCORE** are the sign of $\mathbf{b}'\mathbf{x}_i$, coded 0 or 1. Residuals are $y_i - \hat{y}_i$, which will be 1, 0, or -1. The **; List** specification also produces a listing of $\mathbf{b}'\mathbf{x}_i$. The last column of the listing, labeled Prob[y = 1] is the probabilities computed using the standard normal distribution. Since the probit model has not been used to fit the model, these may be ignored.

Results which are saved by **MSCORE** are:

b = final estimates of parameters
varb = mean squared deviation matrix for bootstrap estimates
score = scalar, equal to the maximized value of the score function

The *Last Model* labels are *b_variable*. But, note once again, that the underlying theory needed to justify use of the Wald statistic does not apply here.

E32.2.5 Technical Details

The score function maximized by MSCORE is a step function in contrast to the smooth criterion maximized by, e.g., *LIMDEP*'s probit estimator. As such, the method used here is quite unlike the familiar gradient/search algorithms used for differentiable criteria.

Let $\boldsymbol{\beta}^\circ$ be the current best estimate of $\boldsymbol{\beta}$, and let there be K parameters. MSCORE selects a set of K-1 orthogonal vectors, $\mathbf{c}_1...\mathbf{c}_{K-1}$ all orthogonal to $\boldsymbol{\beta}^\circ$. The score function is then maximized on the great circle connecting $\boldsymbol{\beta}^\circ$ and $\mathbf{c}_1$. The maximum occurs on one or more intervals of positive length on the great circle. If the score is increased relative to that for $\boldsymbol{\beta}^\circ$, the new best estimate becomes the midpoint of the interval. In case of a tie (recall, the score function is a step function), the interval with midpoint closest to the current estimate is chosen. If there is no function improvement, the old estimate is retained. MSCORE then repeats the process with the great circle connecting the new best estimate and $\mathbf{c}_2$. The process is repeated until all K-1 directions have been searched. This process constitutes an iteration. Iterations are continued until no improvement of the function is achieved.

The basis vectors, $\mathbf{c}_1...\mathbf{c}_{K-1}$ are chosen as follows: For each vector $\mathbf{c}_k$, K independent draws from a random number generator are used to produce a vector uniformly distributed on a K-dimensional hypercube $[-1,1]^K$. The K-1 vectors so produced with $\boldsymbol{\beta}^\circ$ are then orthogonalized using the Gram-Schmidt procedure. (Excessively short vectors are discarded and replaced to insure numerical stability.) The vectors are then normalized to unit length. This method insures that all search directions from $\boldsymbol{\beta}^\circ$ are generated with strictly positive probability, but the distribution of directions is not uniform because of the nonlinearity of the transformation. There is an exception to this procedure if an iteration occurs following an iteration in which there was an improvement in the score on two or more of the great circle searches. Let $\boldsymbol{\beta}^\circ$ be the initial estimate and let $\boldsymbol{\beta}^1$ be the final estimate on the most recent iteration. Then the great circle connecting these points is the first direction searched in the current iteration. The remaining directions are searched at random.

We note an important aspect of this procedure. Because the search direction is random and because the criterion is a step function, small changes in the random sample can lead to sizable changes in the parameter estimates. In particular, we have found experimentally that consecutive runs of MSCORE with the same data produced noticeably different parameter estimates, though only occasionally any change in the score. (In almost all cases, the score, itself, was unchanged.) *LIMDEP* imposes one degree of control on this. The seed for the random number generator is always set to the same value upon entry to MSCORE. As such, you will always get the same results with a given data set and model specifications. However, be aware that small changes, (e.g., in the number of observations or in the set of regressors) can bring noticeable changes in the parameter estimates. Once again, 'what counts' is the score function, not the parameters.

When there are only two parameters, the parameter space is the unit circle, and there is only one great circle to search. As such, the algorithm is guaranteed to find the global maximum in one iteration. In problems of higher dimension, convergence cannot be assured in a finite number of iterations.

If bootstrap estimates are computed, we compute the angular deviation between them and the point estimates. (I.e., the angle between them, ArcCos[$(\mathbf{d}_i\mathbf{b}_i/(\mathbf{d}_i'\mathbf{d}_i \times \mathbf{b}_i'\mathbf{b}_i)^{1/2}$].) Since all parameter vectors have unit length, the angular deviation is also the great circle distance between the estimates along the unit hypersphere. The root mean square angular deviation is the square root of the average squared deviation. We also report the mean absolute value of the angular deviations. The units for both are radians. Discussion of this and other computational aspects of this estimator may be found in Manski and Thompson (1985).

E32.2.6 Extensions

The MSCORE procedure may be used to compute Han's (1987) Maximum Rank Correlation (MRC) estimator for binary response models. The MRC estimator is defined to be the value of $\boldsymbol{\beta}$ that maximizes

$$R(\boldsymbol{\beta}) \;=\; \Sigma_{i,j}\,(y_i - y_j) \times \text{Sgn}(\boldsymbol{\beta}'\mathbf{x}_i - \boldsymbol{\beta}'\mathbf{x}_j).$$

This can be computed by using MSCORE with quantile = .5 on a sample constructed from the original $[y_i,\mathbf{x}_i]$ as follows: For each distinct (i,j) pair for which y_i is not equal to y_j, compute an observation m consisting of

$$d_m = 1 \text{ if } y_i=1 \text{ and } y_j = 0, \text{ and 0 otherwise,}$$

$$\mathbf{x}_m = \mathbf{x}_i - \mathbf{x}_j.$$

This may require some processing outside of *LIMDEP* since this may generate a sample far larger than the original. However, once constructed, the estimation is simple.

Han claims that the estimator is consistent and asymptotically normally distributed. It requires somewhat more stringent assumptions than maximum score. If they are met, the estimator may be more efficient than maximum score.

Manski (1987) analyzes the model

$$y_{i,t} \;=\; \boldsymbol{\beta}'\mathbf{x}_{i,t} + c_i + u_{i,t},\;\; t = 0,1,$$

where c_i is a random effect. The observable indicator $z_{i,t}$ is defined in the usual way for binomial response models; $z_{i,t} = 1$ if $y_{i,t} > 0$, and 0 otherwise. Under the assumptions stated in Manski's paper, the model may be estimated by maximum score by using the reduced sample

$$z_i \;=\; z_{i,1} - z_{i,0}$$

and

$$\mathbf{w}_i \;=\; \mathbf{x}_{i,1} - \mathbf{x}_{i,0}.$$

E32.3 Klein and Spady's Semiparametric Binary Choice Model

Klein and Spady's semiparametric density estimator is based on the specification

$$\text{Prob}[y_i = 1] \;=\; P(\boldsymbol{\beta}'\mathbf{x}_i)$$

where P is an unknown, continuous function of its argument with range [0,1]. The function P is not specified a priori; it is estimated with the parameters. The probability function provides the location for the index that would otherwise be provided by a constant term. The estimation criterion is

$$\log L \;=\; \frac{1}{n}\sum\nolimits_{i=1}^{n}\;[y_i \log P_n(\boldsymbol{\beta}'\mathbf{x}_i) + (1-y_i)\log(1-P_n(\boldsymbol{\beta}'\mathbf{x}_i))]$$

where P_n is the estimator of P and is computed using a kernel density estimator. The probability function is estimated with a kernel estimator,

$$P_n(\boldsymbol{\beta}'\mathbf{x}_i) \;=\; \frac{\sum\nolimits_{j=1}^{n}\;\dfrac{y_j}{h}K\left(\dfrac{\boldsymbol{\beta}'(\mathbf{x}_i-\mathbf{x}_j)}{h}\right)}{\sum\nolimits_{j=1}^{n}\;\dfrac{1}{h}K\left(\dfrac{\boldsymbol{\beta}'(\mathbf{x}_i-\mathbf{x}_j)}{h}\right)}.$$

Two kernel functions are provided, the logistic function, $\Lambda(z)$ and the standard normal CDF, $\Phi(z)$.

As in the other semiparametric estimators, the bandwidth parameter is a crucial input. The program default is $n^{-(1/6)}$, which ranges from .3 to about .6 for n ranging from 30 to 1000. You may provide an alternative value.

E32.3.1 Command

The command for this estimator is

SEMIPARAMETRIC
; Lhs = dependent, binary variable
; Rhs = independent variables $

Do not include one on the Rhs list. The function itself is playing the role of the constant. Optional features include those specific to this model,

; Smooth = desired value for h
; Kernel = Normal – the logistic is standard

and the general ones available with other estimators,

; Partial Effects	
; Prob = name	to retain fitted probabilities
; Keep = name	to retain predictions
; Res = name	to retain residuals
; Covariance Matrix	to display the estimated asymptotic covariance matrix, same as **; Printvc**.

The semiparametric log likelihood function is a continuous function of the parameters which is maximized using *LIMDEP*'s standard tools for optimization. Thus, the options for controlling optimization are available,

; Maxit = n	to set maximum iterations
; Output = 1, 2, 3	to control intermediate output
; Alg = name	to select algorithm

Restrictions may be imposed and tested with

; Test: spec	to specify restriction (default = none)
; Rst = list	to specify fixed value and equality restrictions
; CML: spec	to specify other linear constraints

E32.3.2 Output

Output from this estimator includes the usual table of statistical results for a nonlinear estimator. Note that the estimator constrains the constant term to zero and also normalizes one of the slope coefficients to one for identification. This will be obvious in the results. Since probabilities which are a continuous function of the parameters are computed, you may also request marginal effects with

; Partial Effects (or ; Marginal Effects)

Marginal effects are computed using $P_n(\boldsymbol{\beta}'\mathbf{x}_i)$ and its derivatives (which are simple sums) computed at the sample means.

Results Kept by the Semiparametric Estimator

The model results kept by this estimator are

Matrices:	*b*	= final estimates of parameters
	varb	= mean squared deviation matrix for bootstrap estimates
Scalars:	*logl*	= log likelihood
	kreg	= number of Rhs variables
	nreg	= number of observations used to fit the function
	exitcode	= exit status for estimator

Last Model: The labels are *b_variable*

Last Function: None

E32.3.3 Application

The Klein and Spady estimator is computed with the binary logit model. We use only a small subset of the data, the observations that are observed only once. The complete lack of agreement of the two models is striking, though not unexpected.

E32.3.4 Technical Details

The log likelihood function,

$$\log L = \frac{1}{n}\sum_{i=1}^{n} [y_i \log P_n(\boldsymbol{\beta}'\mathbf{x}_i) + (1-y_i)\log(1-P_n(\boldsymbol{\beta}'\mathbf{x}_i))]$$

$$P_n(\boldsymbol{\beta}'\mathbf{x}_i) = \frac{\sum_{j=1}^{n} \frac{y_j}{h} K\left(\frac{\boldsymbol{\beta}'(\mathbf{x}_i - \mathbf{x}_j)}{h}\right)}{\sum_{j=1}^{n} \frac{1}{h} K\left(\frac{\boldsymbol{\beta}'(\mathbf{x}_i - \mathbf{x}_j)}{h}\right)}$$

is easily computed by simple summation for the value of h, $\boldsymbol{\beta}$, and the specified kernel functions,

$$K(.) = \Lambda(.) \quad \text{for the logistic model, with } K'(.) = \Lambda(.)[1 - \Lambda(.)], \text{ or}$$

$$= \Phi(.) \quad \text{for the normal distribution, with } K'(.) = \phi(.).$$

Let the numerator and denominator of $P_n(\boldsymbol{\beta}'\mathbf{x}_i)$ be denoted F_{i0} and F_{i1}, respectively, and let G_{i0} and G_{i1} denote the numerator and denominator computed at $K'(.)$ instead of $K(.)$. Then, let

$$\mathbf{d}_i = \mathbf{x}_i - \mathbf{x}_j.$$

Let

$$g_i = \frac{y_i}{P_n(\boldsymbol{\beta}'\mathbf{x}_i)} - \frac{1-y_i}{1-P_n(\boldsymbol{\beta}'\mathbf{x}_i)}$$

Then, collecting all terms, the vector of derivatives of the log likelihood is

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{n} g_i \left[\frac{G_{i0}}{F_{i1}} - \frac{F_{i0}G_{i1}}{F_{i1}^2}\right]\mathbf{d}_i = \sum_{i=1}^{n} \mathbf{w}_i$$

The estimator of the asymptotic covariance matrix is the BHHH estimator,

$$\text{Est.Asy.Var} = \left[\sum_{i=1}^{n} \mathbf{w}_i \mathbf{w}_i'\right]^{-1}$$

E32.4 Nonparametric Binary Choice Model

The kernel density estimator is a device used to describe the distribution of a variable nonparametrically, that is, without any assumption of the underlying distribution. This section describes an extension to a simple regression function. The kernel density function estimates any sufficiently smooth regression function, $F_\beta(z) = E[\delta|\boldsymbol{\beta}'\mathbf{x}=z]$, using the method of kernels, for any parameter vector $\boldsymbol{\beta}$. δ must be a response variable with bounded range [0,1]. In the special case in which δ is a binary response taking values 0/1, **NPREG** estimates the probability of a positive response conditional on the linear index $\boldsymbol{\beta}'\mathbf{x}$. With an appropriate choice of $\mathbf{x}$ and $\boldsymbol{\beta}$, and by rescaling the response, this estimator can estimate any sufficiently smooth univariate regression function with known bounded range. One simple approach is to assume that $\mathbf{x}$ is a single variable and $\boldsymbol{\beta}$ equals 1.0, in which case, the estimator describes $E[y_i|x_i]$. Alternatively, **NPREG** may be used with the estimated index function, $\boldsymbol{\beta}'\mathbf{x}_i$, from any binary choice estimator. The natural choice in this instance would be MSCORE, since MSCORE does not compute the probabilities (that is, the conditional mean). In principle, the estimated index function could come from any estimator, but from a probit or other parametric model, this would be superfluous.

The regression function computed is

$$F(z_j) = \frac{\sum_{i=1}^{N} y_i \frac{1}{h} K\left(\frac{z_j - z_i}{h}\right)}{\sum_{i=1}^{N} \frac{1}{h} K\left(\frac{z_j - z_i}{h}\right)} ., \; j = 1,...,M, \; i = 1,..., \text{number of observations.}$$

The function is computed for a specified set of values z_j, j = 1,...,M. Note that each value requires a sum over the full sample of n values. The primary component of the computation is the kernel function, K[.]. Eight alternatives are provided:

1. Epanechnikov:	$K[z]$	$= .75(1 - .2z^2)$ / Sqr(5) if $\lvert z\rvert <= 5$, 0 else,
2. Normal:	$K[z]$	$= \phi(z)$ (normal density),
3. Logit:	$K[z]$	$= \Lambda(z)[1-\Lambda(z)]$ (default),
4. Uniform:	$K[z]$	$= .5$ if $\lvert z\rvert < 1$, 0 1 else,
5. Beta:	$Z[z]$	$= (1-z)(1+z)/24$ if $\lvert z\rvert < 1$, 0 1 else,
6. Cosine:	$K[z]$	$= 1 + \cos(2\pi z)$ if $\lvert z\rvert < .5$, 0 else,
7. Triangle:	$K[z]$	$= 1 - \lvert z\rvert$, if $\lvert z\rvert <= 1$, 0 else.
8. Parzen:	$K[z]$	$= 4/3 - 8z^2 + 8\lvert z\rvert^3$ if $\lvert z\rvert <= .5$, $8(1-\lvert z\rvert)^3$ else.

The other essential part of the computation is the smoothing (bandwidth) parameter, h. Large values of h stabilize the function, but tend to flatten it and reduce the resolution. Small values of h produce greater detail, but also cause the estimator to become less stable.

The basic command is

```
NPREG     ; Lhs = the dependent variable
          ; Rhs = the variable $
```

With no other options specified, the routine uses the logit kernel function, and uses a bandwidth equal to

$$h = .9Q/n^{0.2} \text{ where } Q = \min(\text{std.dev., range}/1.5)$$

You may specify the kernel function to be used with

; Kernel = one of the names of the eight types of kernels listed above

The bandwidth may be specified with

; Smooth = the bandwidth parameter

There is no theory for choosing the right smoothing parameter, λ. Large values will cause the estimated function to flatten at the average value of y_i. Values close to zero will cause the function to pass through the points z_i, y_i and to become computationally unstable elsewhere. A choice might be made on the basis of the *CVMSPE*. (See Wong (1983) for discussion.) A value that minimizes *CVMSPE*(λ) may work well in practice. Since *CVMSPE* is a saved result, you could compute this for a number of values of λ then retrieve the set of values to find the optimal one.

The default number of points specified is 100, with z_j = a partition of the range of the variable. You may specify the number of points, up to 200 with

; Pts = number of points to compute and plot

The range of values plotted is the equally spaced grid from min(x)-h to max(x)+h, with the number of points specified.

E32.4.1 Output from NPREG

Output from **KERNEL** is a set of points for an estimated function, several descriptive statistics, and a plot of the estimated regression function. The added specification

; List

displays the specific results, z_i for the sample observations and the associated estimated regression functions. These values are also placed in a two column matrix named *kernel* after estimation of the function.

The cross validation mean squared prediction error (*CVMSPE*) is a goodness of fit measure. Each observation, '*i*' is excluded in turn from the sample. Using the reduced sample, the regression function is reestimated at the point z_i in order to provide a point prediction for y_i. The average squared prediction error defines the *CVMSPE*. The calculation is defined by

$$F_i^*(z) = \frac{\sum_{j \neq i} \frac{1}{h} y_j K\left(\frac{x_j - x_i}{h}\right)}{\sum_{j \neq i} \frac{1}{h} K\left(\frac{x_j - x_i}{h}\right)}$$

Then, $$CVMSPE(h) = (1/n) \Sigma_i [y_i - F_i^*(x_i)]^2.$$

E32.4.2 Application

The following estimates the parameters of a regression function using **MSCORE**, then uses **NPREG** to plot the regression function.

```
REJECT      ; _groupti > 1 $
NAMELIST    ; x = one,age,hhninc,hhkids,educ,married $
MSCORE      ; Lhs = doctor ; Rhs =x $
CREATE      ; xb = x'b$
NPREG       ; Lhs = doctor ; Rhs = xb $
```

```

E33: Bivariate and Multivariate Probit and Partial Observability Models

E33.1 Introduction

The basic formulation of the models in this chapter is the bivariate probit model:

$$z_{i1} = \boldsymbol{\beta}_1'\mathbf{x}_{i1} + \varepsilon_{i1},\ \ y_{i1} = 1 \text{ if } z_{i1} > 0,\ y_{i1} = 0 \text{ otherwise,}$$

$$z_{i2} = \boldsymbol{\beta}_2'\mathbf{x}_{i2} + \varepsilon_{i2},\ \ y_{i2} = 1 \text{ if } z_{i2} > 0,\ y_{i2} = 0 \text{ otherwise,}$$

$[\varepsilon_{i1},\varepsilon_{i2}]$ ~ bivariate normal (BVN) $[0,0,1,1,\rho]$, $-1 < \rho < 1$,

individual observations on y_1 and y_2 are available for all i.

(This model is also available for grouped (proportions) data. See Section E33.2.3.) The model given above would be estimated using a complete sample on $[y_1, y_2, \mathbf{x}_1, \mathbf{x}_2]$ where y_1 and y_2 are binary variables and $\mathbf{x}_{ij}$ are sets of regressors. This chapter will describe estimation of this model and several variants:

- The disturbances in one or both equations may be heteroscedastic.
- The observation mechanism may be such that y_{i1} is not observed when y_{i2} equals zero.
- The observation mechanism may be such that only the product of y_{i1} and y_{i2} is observed. That is, we only observe the compound outcomes 'both variables equal one' or 'one or both equal zero.'
- The basic model is extended to as many as 20 equations as a *multivariate probit model*.

NOTE: It is not necessary for there to be different variables in the two (or more) equations. The Rh1 and Rh2 lists may be identical if your model specifies that. There is no issue of identifiability or of estimability of the model – the variable lists are unrestricted. This is not a question of identification by functional form. The analogous case is the SUR model which is also identified even if the variables in the two equations are the same.

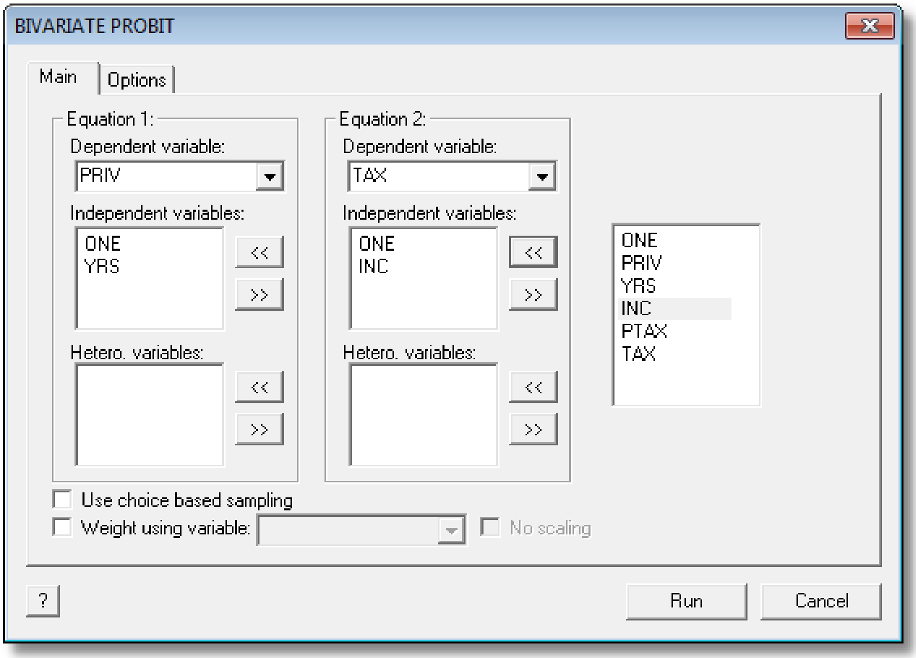
- Some extensions to a simultaneous equations model are easily programmed.
- The bivariate probit and partial observability models are extended to the random parameters modeling framework for panel data.

E33.2 Estimating the Bivariate Probit Model

The two equations can each be estimated consistently by individual single equation probit methods (see Chapter E27). However, this is inefficient and incomplete in that it ignores the correlation between the disturbances. Moreover, the correlation coefficient itself might be of interest. The comparison is analogous to that between OLS and GLS in the multivariate regression model. The model is estimated in *LIMDEP* using full information maximum likelihood. The essential command is

```
BIVARIATE PROBIT      ; Lhs = y1,y2
(or just BIVARIATE)   ; Rh1 = right hand side for equation 1
                      ; Rh2 = right hand side for equation 2 $
```

The command builder for this model is in Model:Binary Choice/Bivariate Probit. The two dependent variables and the right hand sides of the two equations are specified on the Main page. You can also specify a model with heteroscedasticity in either or both equations on this page. The Options page allows you to specify the model above (normal) or the sample selection or partial observability model.



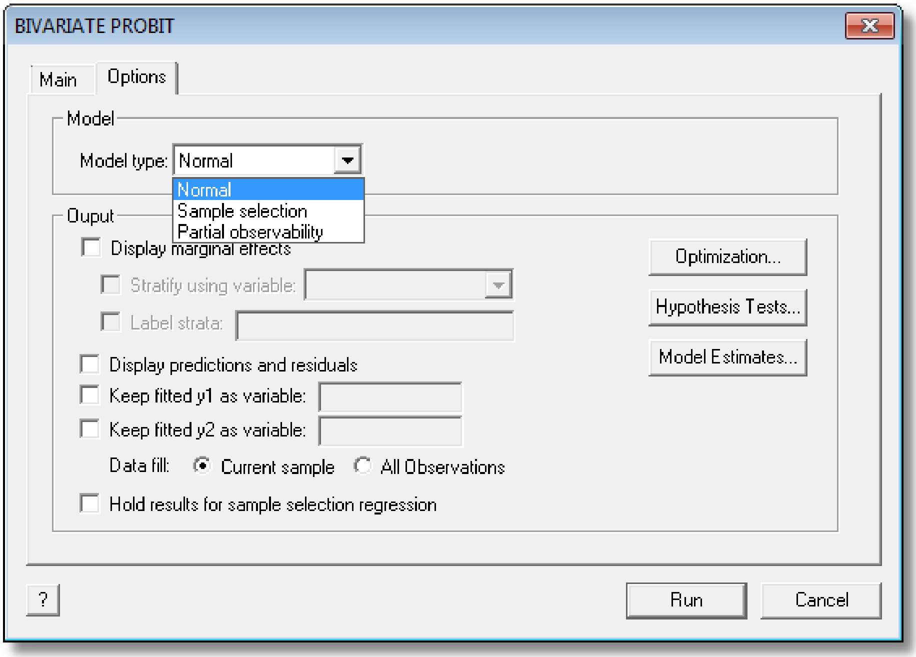


Figure E33.1 Command Builder for Bivariate Probit Models

E33.2.1 Options for the Bivariate Probit Model

Restrictions may be imposed both between and within equations by using

; Rst = list of specifications...

and **; CML: linear restrictions**

You might, for example, force the coefficients in the two equations to be equal as follows:

```
NAMELIST    ; x = ... $
CALC        ; k = Col(x) $
BIVARIATE   ; Lhs = y1,y2 ; Rh1 = x ; Rh2 = x ; Rst = k_b, k_b, r $
```

(The model *is* identified with the same variables in the two equations.)

NOTE: You should not use the name *rho* for ρ in your **; Rst** specification; *rho* is the reserved name for the scalar containing the most recently estimated value of ρ in whatever model estimated it. If it has not been estimated recently, it is zero. Either way, when **; Rst** contains the name *rho*, this is equivalent to *fixing* ρ at the value then contained in the scalar *rho*. That is, *rho* is a value, not a model parameter name such as *b*1. On the contrary, however, you might wish specifically to use *rho* in your **; Rst** specification. For example, to trace the maximized log likelihood over values of ρ, you might base the study on a command set that includes

```
PROCEDURE
BIVARIATE   ; ....  ; Rst = ..., rho $
...
ENDPROC
EXECUTE     ; rho = 0.0, .90, .10 $
```

This would estimate the bivariate probit model 10 times, with ρ fixed at 0, .1, .2, ..., .9. Presumably, as part of the procedure, you would be capturing the values of *logl* and storing them for a later listing or perhaps a plot of the values against the values of *rho*.

If you use the constraints option, the parameter specification includes ρ. As such, you can use this method to fix ρ to a particular value. For another example, consider the application in Section E33.2.8. This is a model for a voting choice and use of private schools:

$$vote = f_1(one, income, property\_taxes)$$
$$private = f_2(one, income, years, teacher).$$

Suppose it were desired to make the income coefficient the same in the two equations and, in a second model, fix *rho* at 0.4. The commands could be

```
BIVARIATE   ; Lhs  = tax,priv
            ; Rh1 = one,inc,ptax ; Rh2 = one,inc,yrs,tch
            ; Rst  = b10,bi,b12,b20,bi,b22,b23,r $
```

and

```
BIVARIATE   ; Lhs  = tax, priv
            ; Rh1 = one,inc,ptax ; Rh2 = one,inc,yrs,tch
            ; Rst  = b10,bi,b12,b20,bi,b22,b23,0.4 $
```

Choice Based Sampling

Any of the bivariate probit models may be estimated with choice based sampling. The feature is requested with

; Wts = the appropriate weighting variable
; Choice Based

For this model, your weighting variable will take four values, for the four cells (0,0), (0,1), (1,0), and (1,1);

w_{ij} = population proportion / sample proportion, i,j = 0,1.

The particular value corresponds to the outcome that actually occurs. You must provide the values. You can obtain sample proportions you need if you do not already have them by computing a crosstab for the two Lhs variables:

CROSSTAB ; Lhs = y1 ; Rhs = y2 $

The table proportions are exactly the proportions you will need. To use this estimator, it is assumed that you know the population proportions.

Robust Covariance Matrix with Correction for Clustering

The standard errors for all bivariate probit models may be corrected for clustering in the sample. Full details on the computation are given in Chapter R10, so we give only the final result here. Assume that the data set is partitioned into G clusters of related observations (like a panel). After estimation, let **V** be the estimated asymptotic covariance matrix which ignores the clustering. Let $\mathbf{g}_{ij}$ denote the first derivatives of the log likelihood with respect to all model parameters for observation (individual) i in cluster j. Then, the corrected asymptotic covariance matrix is

$$\text{Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \mathbf{V}\left(\frac{G}{G-1}\right)\left[\sum_{i=1}^{G}\left(\sum_{j=1}^{n_i}\mathbf{g}_{ij}\right)\left(\sum_{j=1}^{n_i}\mathbf{g}_{ij}\right)'\right]\mathbf{V}$$

You specify the clusters with

; Cluster = either the fixed number of individuals in a group or the name of a variable which identifies the group membership

Any identifier which is common to all members in a cluster and different from other clusters may be used. The controls for stratified and clustered data may be used as well. These are as follows:

; Cluster = the number of observations in a cluster (fixed) or the name of a stratification variable which gives the cluster an identification. This is the setup that is described above.
; Stratum = the number of observations in a stratum (fixed) or the name of a stratification variable which gives the stratum an identification
; Wts = the name of the usual weighting variable for model estimation if weights are desired. This defines w_{ics}. This is the usual weighting setup that has been used in all previous versions of *LIMDEP*.

; FPC = the name of a variable which gives the number of clusters in the stratum. This number will be the same for all observations in a stratum – repeated for all clusters in the stratum. If this number is the same for all strata, then just give the number.
; Huber Use this switch to request h_s. If omitted, $h_s = 1$ is used.
; DFC Use this switch to request the use of d given above. If omitted, $d = 1$ is used.

Note, these corrections will generally lead to larger standard errors compared to the uncorrected results.

Standard Model Specifications for the Bivariate Probit Model

This is the full list of general options that are applicable to this model estimator.

Controlling Output from Model Commands

; OLS reports initial ordinary least squares estimates of parameters
; Margin displays marginal effects.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Choice uses choice based sampling (sandwich with weighting) estimated matrix.
; Cluster = spec requests computation of the cluster form of corrected covariance estimator.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm (Newton is not available, avoid BHHH).
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level ‘**n**’ is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values of y_1 as a new (or replacement) variable in data set.
; Res keeps a fitted value for y_2.
; Fill fills missing values (outside estimating sample) for fitted values.
; Prob keeps a fitted probability for observed joint y_1, y_2 outcome.
; Density keeps a fitted bivariate normal density for observed outcome.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

Fitted values for the bivariate probit model are treated a bit differently from other single equation models. Note that the fitted value is the prediction for y_1 while the 'residual' is the prediction for y_2. Since this is a two equation model, there is no residual as such.

E33.2.2 Starting values

You may provide starting values for $\boldsymbol{\beta}_1$ and $\boldsymbol{\beta}_2$. (A starting value for ρ is optional, even if you give the values for $\boldsymbol{\beta}_1$ and $\boldsymbol{\beta}_2$.) Since estimation of this model is a bit more difficult than the univariate probit model – the log likelihood is not globally concave because of ρ – a good set of starting values may be helpful. Since the single equation estimators are consistent, one way to proceed would be

```
NAMELIST    ; x1 = the Rhs variables in equation 1
            ; x2 = the Rhs variables in equation 2 $
PROBIT      ; Lhs = y1 ; Rhs = x1 ... ; ... any other options $
MATRIX      ; b1 = b $
PROBIT      ; Lhs = y2 ; Rhs  = x2 ... ; ... any other options $
MATRIX      ; b2 = b $
BIVARIATE   ; Lhs = y1,y2 ; Rh1 = x1 ; Rh2 = x2 ; Start = b1,b2 $
```

where *y*1 and *y*2 are the two binary variables, *x*1 and *x*2 are lists of variable names for the two regressor vectors, and *b*1 and *b*2 are the two column vectors of starting values in your matrix work area. There must be an exact correspondence between the values in *b*1 and *b*2 and the variables in *x*1 and *x*2.

If a starting value for ρ is present, it must be last in your list of starting values. If you do not provide starting values for $\boldsymbol{\beta}_1$ and $\boldsymbol{\beta}_2$, the OLS results of regressing *y*1 on *x*1 and *y*2 on *x*2 are used. The starting value for ρ is obtained as follows: The conditional mean function $E[z_{i1}|y_{i2}, \mathbf{x}_{i2}]$ is

$$E[z_{i1}|y_{i2}, \mathbf{x}_{i2}] = \boldsymbol{\beta}_2'\mathbf{x}_{i2} + \rho\lambda_{i2}$$

where $$\lambda_{i2} = (2y_{i2}-1)\phi(\boldsymbol{\beta}_1'\mathbf{x}_{i2}) / \Phi[(2y_{i2}-1)\boldsymbol{\beta}_1'\mathbf{x}_{i2}].$$

Thus, if z_{i1} and $\boldsymbol{\beta}_1$ were observed, ρ could be estimated by a linear regression of z_{i1} on $\mathbf{x}_{i2}$ and λ_{i2}. In order to approximate this result, we use y_{i1} for z_{i1} and the starting values for the parameters in this regression. The resulting estimator is inconsistent, but generally closer to the final result than the obvious alternative, zero.

E33.2.3 Proportions Data

Like other discrete choice models, this one may be fit with proportions data. Since this is a bivariate model, you must provide the full set of four proportions variables, in the order

; Lhs = p00, p01, p10, p11.

(You may use your own names). Proportions must be strictly between zero and one, and the four variables must add to 1.0.

NOTE: When you fit the model using proportions data, there is no cross tabulation of fitted and actual values produced, and no fitted values or 'residuals' are computed.

E33.2.4 Heteroscedasticity

All bivariate probit specifications, including the basic two equation model, the sample selection model (Section E33.4), and the Meng and Schmidt partial observability model (Section E33.7), may be fit with a multiplicative heteroscedasticity specification. The model is the same as the univariate probit model (Section E27.11);

$$\varepsilon_i \sim N\{0, [\exp(\boldsymbol{\gamma}_i'\mathbf{z}_i)]^2\},\ i = 1 \text{ and/or } 2.$$

Either or both equations may be specified in this fashion. Use

; Hf1 = list of variables if you wish to modify the first equation
; Hf2 = list of variables if you wish to modify the second equation

NOTE: Do not include *one* in either list. The model will become inestimable.

The model is unchanged otherwise, and the full set of options given earlier remains available. To give starting values with this modification, supply the following values in the order given:

$$\boldsymbol{\Theta} = [\boldsymbol{\beta}_1, \boldsymbol{\beta}_2, \boldsymbol{\gamma}_1, \boldsymbol{\gamma}_2, \rho].$$

As before, all starting values are optional, and if you do provide the slopes, the starting value for ρ is still optional. The internal starting values for the variance parameters are zero for both equations. (This produces the original homoscedastic model.)

E33.2.5 Specification Tests

Wald, LM, and LR tests related to the slope parameters would follow the usual patterns discussed in previous chapters. One might be interested in testing hypotheses about the correlation coefficient. The Wald test for the hypothesis that ρ equals zero is part of the standard output for the model – see the results below which include a 't' statistic for this hypothesis. Likelihood ratio and LM tests can be carried out as shown below:

The following routine will test the specification of the bivariate probit model against the null hypothesis that two separate univariate probits apply. The test of the hypothesis that ρ equals zero is sufficient for this. The first group of commands computes and saves the univariate probit coefficients and log likelihoods.

```
NAMELIST    ; x1 = ... Rhs for the first equation
            ; x2 = ... Rhs for the second equation $
PROBIT      ; Lhs = y1 ; Rhs = x1 $
MATRIX      ; b1 = b $
CALC        ; l1 = logl $
PROBIT      ; Lhs = y2 ; Rhs = x2 $
MATRIX      ; b2 = b $
CALC        ; l2 = logl $
```

To carry out the likelihood ratio test, we now fit the bivariate model, which is the unrestricted one. The restricted model, with ρ = 0, is the two univariate models. The restricted log likelihood is the sum of the two univariate values. The **CALC** command carries out the test. The **BIVARIATE** command also produces a t statistic in the displayed output for the hypothesis that ρ = 0. To automate the test, we can also use the automatically retained values *rho* and *varrho*. The second **CALC** command carries out this test.

```
BIVARIATE   ; Lhs  = y1,y2 ; Rh1 = x1 ; Rh2 = x2 $
CALC        ; lrtest = 2*(l1 + l2 - logl)
            ; pvalue = 1 - Chi(lrtest,1) $
CALC        ; waldtest = rho^2 / varrho
            ; pvalue = 1 - Chi(waldtest,1) $
```

The Lagrange multiplier test is also simple to carry out using the built in procedure, as we have already estimated the restricted model. The test is carried out with the model command that specifies the starting values from the restricted model and restricts the maximum iterations to zero.

```
NAMELIST    ; x1 = ... Rhs for the first equation
            ; x2 = ... Rhs for the second equation $
PROBIT      ; Lhs = y1 ; Rhs = x1 $
MATRIX      ; b1 = b $
PROBIT      ; Lhs = y2 ; Rhs = x2 $
MATRIX      ; b2 = b $
BIVARIATE   ; Lhs = y1,y2 ; Rh1 = x1 ; Rh2 = x2
            ; Start = b1,b2,0 ; Maxit = 0 $
```

You can test the heteroscedasticity assumption by any of the three classical tests as well. The LM test will be the simplest since it does not require estimation of the model with heteroscedasticity. You can carry out the LM test as follows:

```
NAMELIST    ; x1 = ... ; x2  = ... ; z1  = ... ; z2  = ... $
BIVARIATE   ; Lhs = ...  ; Rh1 = x1 ; Rh2 = x2 $
CALC        ; h1 = Col(z1) ; h2 = Col(z2)
            ; k1 = Col(x1) ; k2 = Col(x2) ; k12 = k1+k2 $
MATRIX      ; b1_b2 = b(1:k12) $
BIVARIATE   ; Lhs  = ...
            ; Rh1 = x1 ; Rh2 = x2 ? specify the two probit equations
            ; Hf1  = z1 ; Hf2 = z2  ? variables in the two variances
            ; Start = b1_b2, h1_0, h2_0, rho
            ; Maxit = 0 $
```

In this instance, the starting value for *rho* is the value that was estimated by the first model, which is retained as a scalar value.

E33.2.6 Model Results for the Bivariate Probit Model

The initial output for the bivariate probit models consists of the ordinary least squares results if you request them with

; OLS

Final output includes the log likelihood value and the usual statistical results for the parameter estimates.

The last output, requested with

; Summary

is a joint frequency table for four cells, with actual and predicted values shown. The predicted outcome is the cell with the largest probability. Cell probabilities are computed using

$$P_{i00} = 1 - P_{i11} - P_{i10} - P_{i01} \qquad P_{i01} = \Phi\ [\boldsymbol{\beta}_2'\mathbf{x}_{i2}] - P_{i11}$$

$$P_{i10} = \Phi\ [\boldsymbol{\beta}_1'\mathbf{x}_{i1}] - P_{i11} \qquad P_{i11} = \Phi_2[\boldsymbol{\beta}_1'\mathbf{x}_{i1}, \boldsymbol{\beta}_2'\mathbf{x}_{i1}, \rho]$$

A table which assesses the success of the model in predicting the two variables is presented as well. An example appears below. The predictions and residuals are a bit different from the usual setup (because this is a two equation model):

; Keep = name to retain the predicted y_1
; Res = name to retain the predicted y_2
; Prob = name to retain the probability for observed y_1, y_2 outcome
; Density = fitted bivariate normal density for observed outcome

Matrix results kept in the work areas automatically are *b* and *varb*. An extra matrix named *b_bprobt* is also created. This is a two column matrix that collects the coefficients in the two equations in a parameter matrix. The number of rows is the larger of the number of variables in *x*1 and *x*2. The coefficients are placed at the tops of the respective columns with the shorter column padded with zeros.

NOTE: There is no correspondence between the coefficients in any particular row of *b_bprobt*. For example, in the second row, the coefficient in the first column is that on the second variable in *x*1 and the coefficient in the second column is that on the second variable in *x*2. These may or may not be the same.

The results saved by the binary choice models are:

Matrices: *b* = estimate of $(\boldsymbol{\beta}_1',\boldsymbol{\beta}_2',\rho)'$
varb = asymptotic covariance matrix

Scalars: *kreg* = number of parameters in model
nreg = number of observations
logl = log likelihood function

Variables: *logl_obs* = individual contribution to log likelihood

Last Model: *b1_variables*, *b2_variables*, *c1_variables*, *c1_variables*, *r12*

Last Function: $\text{Prob}(y_1 = 1, y_2 = 1|\mathbf{x}_1, x_2) = \Phi_2(\mathbf{b}_1'\mathbf{x}_1, \mathbf{b}_2'\mathbf{x}_2, r)$

The saved scalars are *nreg*, *kreg*, *logl*, *rho*, *varrho*. The *Last Model* labels are *b_variables* and *b*2*_variables*. If the heteroscedasticity specification is used, the additional coefficients are *c*1*_variables* and *c*2*_variables*. To extract a vector that contains only the slopes, and not the correlation, use

```
MATRIX      ; {kb = kreg-1} ; b1b2 = b(1:kb) $
```

To extract the two parameter vectors separately, after defining the namelists, you can use

```
MATRIX      ; {k1 = Col(x1) ; k12 = k1+1 ; kb = kreg-1}
            ; b1 = b(1:k1) ; b2 = b(k12:kb) $
```

You may use other names for the matrices. (Note that the **MATRIX** commands contain embedded **CALC** commands contained in {}.) If the model specifies heteroscedasticity, similar constructions can be used to extract the three or four parts of *b*.

E33.2.7 Partial Effects

Because it is a two equation model, it is unclear what should be an appropriate 'marginal effect' in the bivariate probit model. (This is one of our frequently asked questions, as users are often uncertain about what it is that they are looking for when they seek the 'partial effects' in the model – effect of what? on what?) The literature is not necessarily helpful in this regard. The one published result in the econometrics literature, Christofides, Stengos and Swidinsky (1997), plus an error correction in a later issue, focuses on the joint probability of the two outcome variables equaling one – which is not a conditional mean. The probability might be of interest. It can be examined with the **PARTIAL EFFECTS** program. An example appears in Section E33.2.8. The *marginal* means in the model are the univariate probabilities that the two variables equal one. These are also not necessarily interesting, but, in any event, they can be computed using the univariate models.

LIMDEP analyzes the conditional mean function

$$E[y_1 \mid y_2 = 1, \mathbf{x}_1, \mathbf{x}_2] = \text{Prob}[y_1 = 1, y_2 = 1 \mid \mathbf{x}_1, \mathbf{x}_2, \rho) \,/\, \text{Prob}[y_2 = 1 \mid \mathbf{x}_1].$$

This is the function analyzed in the bivariate probit marginal effects processor. The bivariate probit estimator in *LIMDEP* allows either or both of the latent regressions to be heteroscedastic. The reported effects for this model include the decomposition of the marginal effect into all four terms, the regression part and the variance part, in each of the two latent models.

The computations of the following marginal effects in the bivariate probit model are included as an option with the estimator. There are two models, the base case of y_1,y_2 a pair of correlated probit models, and $y_1|y_2 = 1$, the bivariate probit with sample selection. (See Section E33.4 below.) The conditional mean computed for these two models would be identical,

$$\text{E}[y_1|y_2 = 1] = \Phi_2\,[w_1, w_2\,, \rho\,] \,/\, \Phi(\,w_2\,)$$

where Φ_2 is the bivariate normal CDF and Φ is the univariate normal CDF. This model allows multiplicative heteroscedasticity in either or both equations, so

$$w_1 = \boldsymbol{\beta}_1'\mathbf{x}_1 \,/\, \exp(\boldsymbol{\gamma}_1'\mathbf{z}_1)$$

and likewise for w_2. In the homoscedastic model, $\boldsymbol{\gamma}_1$ and/or $\boldsymbol{\gamma}_2$ is a zero vector. Four full sets of marginal effects are reported, for $\mathbf{x}_1$, $\mathbf{x}_2$, $\mathbf{z}_1$, and $\mathbf{z}_2$. Note that the last two may be zero. The four vectors may also have variables in common. For any variable which appears in more than one of the parts, the marginal effect is the sum of the individual terms. A table is reported which displays these total effects for every variable which appears in the model, along with estimated standard errors and the usual statistical output. Formulas for the parts of these marginal effects are given below with the technical details. For further details, see Greene (2011). Commands and suggestions for how to do these computations are given in Section E33.2.8.

Note that you can get marginal effects for $y_2|y_1$ just by respecifying the model with y_1 and y_2 reversed (y_2 now appears first) in the Lhs list of the command. You can also trick *LIMDEP* into giving you marginal effects for $y_1|y_2 = 0$ (instead of $y_2 = 1$) by computing $z_1 = 1\text{-}y_1$ and $z_2 = 1\text{-}y_2$, and fitting the same bivariate probit model but with Lhs = z_1,z_2. *You must now reverse the signs of the marginal effects (and all slope coefficients) that are reported.*

The example below was produced by a sampling experiment: Note that the model specifies heteroscedasticity in the second equation though, in fact, there is none.

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-500 $
CREATE      ; u1 = Rnn(0,1)  ; u2 = u1 + Rnn(0,1)
            ; z  = Rnu(.2,.4) ; x1 = Rnn(0,1) ; x2 = Rnn(0,1)
            ; x3 = Rnn(0,1)  ; y1 = (x1 + x2 + u1) > 0 ; y2 = (x1 + x3 + u2) > 0 $
BIVARIATE   ; Lhs  = y1,y2
            ; Rh1 = one,x1,x2 ; Rh2 = one,x1,x3
            ; Hf2  = z ; Partial Effects $
```

The first set of results is the model coefficients.

------------------------------------------------------------------------------
```

The marginal effects processor in the bivariate probit model detects when a regressor is a dummy variable. In this case, the marginal effect is computed using differences, not derivatives. The model results will contain a specific description. To illustrate this computation, we revisit the German health care data. A description appears in Chapter E2. Here, we analyze the two health care utilization variables, *doctor* = 1(*docvis* > 0) and *hospital* = 1(*hospvis* > 0) in a bivariate probit model. The model command is

SAMPLE ; All $
CREATE ; doctor = docvis > 0 ; hospital = hospvis > 0 $
BIVARIATE ; Lhs = doctor,hospital
; Rh1 = one,age,educ,hhninc,hhkids
; Rh2 = one,age,hhninc,hhkids
; Partial Effects $

The variable *hhkids* is a binary variable for whether there are children in the household. The estimation results are as follows. This is similar to the preceding example. The final table contains the result for the binary variable. In fact, the explicit treatment of the binary variable results in very little change in the estimate.

```

E33.2.8 Application

The following are a subset of the variables and observations of a data set given by Pindyck and Rubinfeld (1991). The variables in the data set are:

priv = decision whether to have at least one child in private school.
yrs = years lived in the community.
inc = log of income. Read in as a code, then recoded.
ptax = log of property taxes paid. Read in as a code, then recoded.
tax = vote (0=no) on a property tax.

The data were entered and transformed as follows:

READ ; Nvar = 5 ; Nobs = 80 ; By Variables
; Names = priv,yrs,inc,ptax,tax $

```

A bivariate probit model using these data was estimated by Greene (1984). The following is a version of that application. We fit the model

$$vote = f_1(income, property\ taxes),$$
$$private = f_2(income, years, property\ taxes).$$

In the first model, the coefficients are unrestricted. In the second, the income coefficients in the two equations are forced to be equal.

```

The preceding examined the conditional mean function, $\Phi_2(\mathbf{b}_1'\mathbf{x}_1,\mathbf{b}_2'\mathbf{x}_2,\rho)/\Phi(\mathbf{b}_2'\mathbf{x}_2)$. The **PARTIAL EFFECTS** (or just **PARTIALS**) command will produce effects for the joint probability instead. The default computation is the average partial effect. The following shows the computation at the data means for comparison.

PARTIALS ; Effects: ptax $
PARTIALS ; Effects: ptax ; Means $

```
---------------------------------------------------------------------
Partial Effects  Analysis for Bivariate Probit Prob. Function
---------------------------------------------------------------------
Effects on function with respect to PTAX
Results are computed by average over sample observations
Partial effects for continuous PTAX     computed by differentiation
Effect is computed as derivative     = df(.)/dx
---------------------------------------------------------------------
df/dPTAX           Partial    Standard
(Delta method)     Effect      Error     |t|  95% Confidence Interval
---------------------------------------------------------------------
APE. Function      -.10264     .11275     .91     -.32363      .11834
--> partials ; effects: ptax; means $
---------------------------------------------------------------------
```

```
----------------------------------------------------------------------
Partial Effects  Analysis for Bivariate Probit Prob. Function
----------------------------------------------------------------------
Effects on function with respect to PTAX
Results are computed at sample means of all variables
Partial effects for continuous PTAX     computed by differentiation
Effect is computed as derivative     = df(.)/dx
----------------------------------------------------------------------
df/dPTAX             Partial    Standard
(Delta method)       Effect      Error     |t|  95% Confidence Interval
----------------------------------------------------------------------
PE.Func(means)      -.10940     .11724     .93     -.33918      .12039
```

The function in the **PARTIALS** command can be changed, for example, to analyze the same conditional mean function as above. We would do this as follows:

```
PARTIALS    ; Effects: ptax
            ; Function = bx1 = b1+b2*inc+b3*ptax |
                         bx2 = c1+c2*inc+c3*yrs+c4*ptax |
                         Bvn(bx1,bx2,ro)/Phi(bx2)
            ; Labels = b1,b2,b3,c1,c2,c3,c4,ro  $
```

Adding

```
            ; Means $
```

would then replicate the computations done with the **; Partial Effects** specification in the model command. The -.84124 and standard error of .37127 appear in the earlier table of total effects for the bivariate probit model.

```
----------------------------------------------------------------------
Partial Effects  Analysis for User Specified Function

```

The advantage of the latter computations is that the partial effect can be computed for a variety of values of the variable of interest. For example,

```
PARTIALS    ; Effects: ptax & ptax = 6(.1)8 ; Plot(ci)
            ; Function = bx1 = b1+b2*inc+b3*ptax |
                         bx2 = c1+c2*inc+c3*yrs+c4*ptax |
                         Bvn(bx1,bx2,ro)/Phi(bx2)
            ; Labels = b1,b2,b3,c1,c2,c3,c4,ro $
```

```
----------------------------------------------------------------------

E33.2.9 Technical Details

Let

$$q_{im} = 2y_{im} - 1,\ m = 1,2.$$

The log likelihood function for the bivariate probit model is

$$\log L = \Sigma_i \log \Phi_2[q_{i1}\boldsymbol{\beta}_1'\mathbf{x}_{i1},\ q_{i2}\boldsymbol{\beta}_2'\mathbf{x}_{i2},\ q_{i1}q_{i2}\rho],$$

where we use Φ_2 to denote the bivariate standard normal CDF. We will also use $\phi_2[.,.,.]$ to denote the bivariate normal density function. We use ϕ and Φ, without subscripts, to denote the univariate standard normal density and CDF, respectively. For convenience in what follows, we will drop the observation subscript. Let

$$z_m = \boldsymbol{\beta}_m'\mathbf{x}_m,\ m = 1,2,$$

$$w_m = q_m z_m,\ m = 1,2,$$

$$\rho_* = q_1 q_2 \rho \text{ (note that the sign is the same if } y_1 = y_2\text{)},$$

$$g_1 = \phi(w_1)\Phi[(w_2 - \rho_* w_1)/(1 - \rho_*^2)^{1/2}],$$

$$g_2 = \phi(w_2)\Phi[(w_1 - \rho_* w_2)/(1 - \rho_*^2)^{1/2}].$$

Then, $\partial \log L/\partial\boldsymbol{\beta}_j = \Sigma_i (q_j g_j/\Phi_2)\mathbf{x}_j,\ j = 1,2$

and $\partial \log L/\partial\rho = \Sigma_i q_1 q_2 \phi_2/\Phi_2.$

NOTE: A corollary to this result is the marginal effect for the conditional mean function. Define **x** to be the union of $\mathbf{x}_1$ and $\mathbf{x}_2$, and define $\boldsymbol{\theta}_1$ and $\boldsymbol{\theta}_2$ conformably with zeros in the appropriate places so that $z_1 = \boldsymbol{\theta}_1'\mathbf{x} = \boldsymbol{\beta}_1'\mathbf{x}_1$ and $z_2 = \boldsymbol{\theta}_2'\mathbf{x} = \boldsymbol{\beta}_2'\mathbf{x}_2$. Then,

$$\frac{\partial\Phi_2(z_1,z_2,\rho)/\Phi(z_2)}{\partial\mathbf{x}} = \frac{g_1}{\Phi(z_2)}\boldsymbol{\theta}_1 + \left[\frac{g_2}{\Phi(z_2)} - \frac{\Phi_2(z_1,z_2,\rho)\phi(z_2)}{[\Phi(z_2)]^2}\right]\boldsymbol{\theta}_2$$

These are the parts that appear in the tables in the earlier applications, with zeros placed appropriately. (The computation is similar, albeit much more tedious, for a model with heteroscedasticity.)

During estimation, we use a transformation of ρ to avoid problems resulting from invalid correlation coefficients in computing the log likelihood. We define

$$\tau = \log[(1 + \rho)/(1 - \rho)]$$

Then, $\rho = [\exp(\tau) - 1] / [\exp(\tau) + 1].$

The range of τ is unrestricted. The model is viewed as a function of τ. During any computation of the log likelihood or its derivatives, we compute ρ from τ, then use ρ. Derivatives are then corrected to accommodate the transformation. The end result for your estimation of the model is that you will not receive diagnostics about ρ going out of the allowable range, again, since τ is unrestricted. Of course, it is possible for τ to become extremely large or small, which would imply that the model is gravitating toward the polar values of ρ. This signals a problem with your model, such as when the two Lhs variables are too highly correlated, or if an independent variable in one equation is a perfect predictor of the Lhs variable in the other. One point to note is that if your model command contains **; Output = 3**, the displayed output will show you the transient value of τ, not of ρ. For example, in estimating the unrestricted model above, the technical output at the last iteration shows

```
1st derivs.      .32279D-07   .33001D-06   .24128D-06   .29297D-07   .30245D-06
   .77385D-07   .21848D-06  -.48524D-08
Parameters:     -.20420D+01   .16462D+01  -.20155D+01  -.38604D+01   .35280D+00
  -.16221D-01  -.99484D-01  -.67176D+00
```

The last parameter in the list is τ, which appears above as the value -0.67176. But, the model output shows

```
RHO(1,2)|    -.32379          .29914    -1.08  .2791     -.91009    .26251
```

The value given is [exp(-.67176) - 1]/[exp(-.67176) + 1] = -.3237943.

Some of these results are produced as part of the output from your estimation. But, you may wish to do these computations for other purposes. The **CALC** and **CREATE** functions Bvn, Bvd, Bv1, and Bv2 are provided for this purpose. To use these, you must first compute either the variables z_1 and z_2 or the scalars, we'll call them c_1 and c_2, and obtain the value of ρ that you wish to use, which we'll call r. Then, use

```
NAMELIST   ; z = z1,z2 $
CREATE     ; phi2 = Bvn(z,r)       ? to compute the probability
           ; f2  = Bvd(z,r)        ? to compute the density
           ; g1 = Bv1(z,r)         ? to compute the g1 function
           ; g2 = Bv2(z,r)         $ to compute the g2 function
```

The same functions are available in **CALC**, except that in **CALC**, instead of the namelist with two names, you give both arguments. Thus,

```
CALC       ; cphi2 = Bvn(z1,z2,r)  ? to compute the probability
           ; cf2 = Bvf(z1,z2,r)    ? to compute the density
           ; cg1= Bv1(z1,z2,r)     ? to compute the g1 function
           ; cg2= Bv2(z1,z2,r)     $ to compute the g2 function
```

computes these functions for the single values given. Here are three applications. In all cases, we precede the computations with

```
NAMELIST   ; x1 =  ... Rhs for equation 1
           ; x2 =  ... Rhs for equation 2 $
```

Conditional Mean Predictions

```
BIVARIATE   ; Lhs = y1 ; Rh1 = x1 ; Rh2 = x2 $

            ; cz2 = Xbr(z2) ?  of E[y1|y2=1] wrt x1 and x2
            ; me1 =  Bv1(cz1,cz2,rh0) / Phi(cz2)
            ; me2 = (Bv2(cz1,cz2,rho)  -
                      Bvn(cz1,cz2,rho) * N01(cz2) / Phi(cz2) ) / Phi(cz2) $
```

Lambda Variables for the Sample Selection Model

(This is another frequently asked question.) Section E55.3.3 describes the following sample selection model:

(y_1, y_2) determined by the bivariate probit model of this chapter

$$y = \delta'\mathbf{x} + u$$

$\text{Corr}(u,\varepsilon_1) = \rho_{u1}$, $\text{Corr}(u,\varepsilon_2) = \rho_{u2}$. But, $(y,\mathbf{x})$ are only observed when $(y_1 = 1, y_2 = 1)$. Estimation of this model is done by a two step extension of Heckman's method for a single probit selection model. The linear regression is computed using the observed data, with regression of y on $\mathbf{x}$, λ_1 and λ_2 where the two 'lambda' variables are, in fact, g_1/Φ_2 and g_2/Φ_2 as defined above. These variables are computed internally during estimation, but not retained anywhere accessible. We are often asked how these can be computed and, moreover, can they be computed for the 'nonselected' observations. Using what is already done above, the computation is actually simple. The full set of computations would be as follows: (This is generic. Only the first command would be specific to any application.)

```
CREATE      ; y1 = equation 1 Lhs variable ; y2 = equation 2 Lhs variable $
BIVARIATE   ; Lhs = y1, y2 ; Rh1 = x1 ; Rh2 = x2 $
CREATE      ; q1 = 2*y1 – 1; q2 = 2*y2 - 1 $
CALC        ; k1 = Col(x1)  ; k21 = k1 + 1 ; kvar = Col(b) $
MATRIX      ; b1 = b(1:k1)  ; b2 = b(k21:kvar) $
CREATE      ; v1 = q1*x1'b1 ; v2 = q2 * x2'b2 ; rs  = q1*q2*rho $
NAMELIST    ; v = v1,v2 $
CREATE      ; lambda1 = q1*Bv1(v,rs) / Bvn(v,rs)
            ; lambda2 = q2*Bv2(v,rs) / Bvn(v,rs) $
```

Finally, let

$$\delta = 1 / (1 - \rho_*^2)^{1/2},$$

$$v_1 = \delta(w_2 - \rho_* w_1) \text{ so } g_1 = \phi(w_1)\Phi(v_1)$$

and $$v_2 = \delta(w_1 - \rho_* w_2) \text{ so } g_2 = \phi(w_2)\Phi(v_2).$$

Then, $$\partial^2 \ln L/\partial\boldsymbol{\beta}_1\partial\boldsymbol{\beta}_1' = \Sigma_i (-1/\Phi_2)[w_1 g_1 + \rho_*\phi_2 + g_1^2/\Phi_2]\mathbf{x}_1\mathbf{x}_1'$$

and likewise for $\boldsymbol{\beta}_2$. The mixed derivatives are:

$$\partial^2 \ln L/\partial\boldsymbol{\beta}_1\partial\boldsymbol{\beta}_2' = \Sigma_i (q_1 q_2/\Phi_2)[\phi_2 - g_1 g_2/\Phi_2]\mathbf{x}_1\mathbf{x}_2',$$

$$\partial^2 \ln L/\partial\boldsymbol{\beta}_1\partial\rho = \Sigma_i\, q_2(\phi_2/\Phi_2)[\rho_*\delta v_1 - w_1 - g_1/\Phi_2]\mathbf{x}_1,$$

and $$\partial^2 \ln L/\partial\rho^2 = \Sigma_i (\phi_2/\Phi_2)[\delta^2\rho_*(1-\delta^2(w_1^2 + w_2^2 - 2\rho_* w_1 w_2)) + \delta^2 w_1 w_2 - \phi_2/\Phi_2].$$

The derivatives for a model with heteroscedasticity can be easily obtained by modification of the preceding. In the derivation above, $g_j = \partial\Phi_2(h_1,h_2,\rho)/\partial h_j$, so by making the appropriate modification of h_j, derivatives of the extended model can be obtained by differentiating h_j.

The bivariate normal CDF is approximated with a 15 point Gauss-Laguerre quadrature. The procedure used is as follows. We compute the upper (not the lower) tail area bivariate integral thusly:

$$\text{BVN}'(x_1, x_2, \rho) = \int_{x_1}^{\infty}\int_{x_2}^{\infty} \phi_2(x_1, x_2, \rho)\,dx_2\,dx_1$$

Let $$d_1 = 0.0 \text{ if } x_1 > 0.0, \text{ otherwise, } d_1 = 1,\ d_3 = 1.0 - 2.0 d_1$$

$$d_2 = 0.0 \text{ if } x_2 > 0.0, \text{ otherwise, } d_2 = 1,\ d_4 = 1.0 - 2.0 d_2$$

Then, $$B = \frac{1}{\sqrt{2\pi}}\sum_{h=1}^{15} w_h\Phi(a_h)\exp[z_h - .5(z_h + d_3 x_1)^2]$$

where z_h and w_h = the nodes and weights for the quadrature, and

$$a_h = d_4[\rho(x_1 + d_3 z_h) - x_2] / \sqrt{1-\rho^2}$$

Then, $$\text{BVN}'(x_1, x_2, \rho) \approx d_3 d_4 B - d_1 d_2 + d_1\Phi(-x_2) + d_2\Phi(-x_1).$$

The complementary CDF, integrating from $-\infty$ to the argument, is obtained just by sending $-x_1$ and/or $-x_2$ to this computation.

E33.3 Tetrachoric Correlation

The tetrachoric correlation is a measure of the correlation between two binary variables. The familiar Pearson, product moment correlation is inappropriate as it is used for continuous variables. The tetrachoric correlation coefficient is equivalent to the correlation coefficient in the following bivariate probit model:

$$y_1{}^* = \mu + \varepsilon_1, \qquad y_1 = 1(y_1{}^* > 0)$$

$$y_2{}^* = \mu + \varepsilon_2, \qquad y_2 = 1(y_2{}^* > 0)$$

$$(\varepsilon_1,\varepsilon_2) \sim N_2[(0,0),(1,1,\rho)]$$

The applicable literature contains a number of approaches to estimation of this correlation coefficient, some a bit ad hoc. We proceed directly to the implied maximum likelihood estimator. You can fit this 'model' with

BIVARIATE ; Lhs = y1,y2 ; Rh1 = one ; Rh2 = one $

The reported estimate of ρ is the desired estimate. *LIMDEP* notices if your model does not contain any covariates in the equation, and notes in the output that the estimator is a tetrachoric correlation. The results below based on the German health care data show an example.

```

The preceding suggests an interpretation for the bivariate probit model; the correlation coefficient reported is the *conditional* (on the independent variables) tetrachoric correlation.

The computation in the preceding can be generalized to a set of M binary variables, $y_1,...,y_M$. The tetrachoric correlation matrix would be the $M\times M$ matrix, **R**, whose off diagonal elements are the ρ_{mn} coefficients described immediately above. There are several ways to do this computation, again, as suggested by a literature that contains recipes. Once again, the maximum likelihood estimator turns out to be a useful device.

A direct approach would involve expanding the latent model to

$$y_1^* = \mu + \varepsilon_1, \quad y_1 = 1(y_1^* > 0)$$

$$y_2^* = \mu + \varepsilon_2, \quad y_2 = 1(y_2^* > 0)$$

$$\ldots$$

$$y_M^* = \mu + \varepsilon_M, \quad y_M = 1(y_M^* > 0)$$

$$(\varepsilon_1,\varepsilon_2,...,\varepsilon_M) \sim N_M[\mathbf{0},\mathbf{R}]$$

The appropriate estimator would be *LIMDEP*'s multivariate probit estimator, **MPROBIT**, which can handle up to $M = 20$. The correlation matrix produced by this procedure is precisely the full information MLE of the tetrachoric correlation matrix. However, for any M larger than two, this requires use of the GHK simulator to maximize the simulated log likelihood, and is extremely slow. The received estimators of this model estimate the correlations pairwise, as shown earlier. For this purpose, the FIML estimator is unnecessary. The matrix can be obtained using bivariate probit estimates. The following procedure would be useable:

```
NAMELIST    ; y = y1,y2,...,ym $
CALC        ; m = Col(y) $
MATRIX      ; r = Iden(m) $
PROCEDURE $
DO FOR      ; 20 ; i = 2,m $
CALC        ; i1 = i - 1 $
DO FOR      ; 10 ; j = 1,i1 $
BIVARIATE   ; Lhs = y:i, y:j ; Rh1 = one ; Rh2 = one $
MATRIX      ; r(i,j) = rho $
MATRIX      ; r(j,i) = rho $
ENDDO       ; 10 $
ENDDO       ; 20 $
ENDPROC $
EXECUTE     ; Quietly $
```

A final note, the preceding approach is not fully efficient. Each bivariate probit estimates (μ_m,μ_n) which means that μ_m is estimated more than once when $m > 1$. A minimum distance estimator could be used to reconcile these after all the bivariate probit estimates are computed. But, since the means are nuisance parameters in this model, this seems unlikely to prove worth the effort.

E33.4 Bivariate Probit Model with Sample Selection

In the bivariate probit setting, data on y_1 might be observed only when y_2 equals one. For example, in modeling loan defaults with a sample of applicants, default will only occur among applicants who are granted loans. Thus, in a bivariate probit model for the two outcomes, the observed default data are nonrandomly selected from the set of applicants. The model is

$$z_{i1} = \boldsymbol{\beta}'\mathbf{x}_{i1} + \varepsilon_{i1},\ y_{i1} = \text{sgn}(z_{i1}),$$

$$z_{i2} = \boldsymbol{\beta}'\mathbf{x}_{i2} + \varepsilon_{i2},\ y_{i2} = \text{sgn}(z_{i2}),$$

$$\varepsilon_{i1},\varepsilon_{i2} \sim \text{BVN}(0,0,1,1,\rho),$$

$$(y_{i1},\mathbf{x}_{i1}) \text{ is observed only when } y_{i2} = 1.$$

This is a type of sample selectivity model. The estimator was proposed by Wynand and van Praag (1981). An extensive application which uses choice based sampling as well is Boyes, Hoffman, and Low (1989). (See also Greene (1992 and 2011).) The sample selection model is obtained by adding

; Selection (or just ; Sel)

to the **BIVARIATE PROBIT** command. All other options and specifications are the same as before. Except for the diagnostic table which indicates that this model has been chosen, the results for the selection model are the same as for the basic model.

E33.4.1 Technical Details

The log likelihood for the bivariate probit model with selection is

$$\begin{aligned}\text{Log-}L = &\sum\nolimits_{y_2=1,y_1=1} \log \Phi_2[\boldsymbol{\beta}_1'\mathbf{x}_{i1}, \boldsymbol{\beta}_2'\mathbf{x}_{i2}, \rho] \\ &+ \sum\nolimits_{y_2=1,y_1=0} \log \Phi_2[-\boldsymbol{\beta}_1'\mathbf{x}_{i1}, \boldsymbol{\beta}_2'\mathbf{x}_{i2}, -\rho] \\ &- \sum\nolimits_{y_2=0} \log \Phi[-\boldsymbol{\beta}_2'\mathbf{x}_{i2}].\end{aligned}$$

The necessary first and second derivatives are given in Section E33.6.

NOTE: This is one of several sample selection models estimated by maximum likelihood with *LIMDEP*. In this setting, there is no 'lambda' variable as there is in the regression model with sample selection (see Chapter E52). Heckman's (1979) selection correction variable applies to the linear regression model estimated with two step least squares, but not generally to models fit by maximum likelihood. For testing for selection effects, the appropriate approach is to test the hypothesis of no effects, which results if ρ equals zero.

NOTE: You may code y_1 as 0.0 for the nonselected (nonobserved) observations in this model. The correct value to use (or ignore) is determined by the program during estimation.

Further details on this model, with an application and technical background appear in Section E33.2.9.

The following carries out a sampling experiment that conforms exactly to the assumptions of the model. The lhs variables y1 and y2 are governed by a bivariate probit model with coefficient vectors $\beta_1 = \beta_2 = (0,1,1)$ and $\rho = .5$. However, y1s is missing when y2 equals zero, so the appropriate approach is the selection model. As seen below, estimation proceeds routinely. Partial effects and subsequent analysis would be the same as for the bivariate probit model prior to the selection. The force of the revision of the estimator is to use an approach that produces consistent estimators of the model parameters. It is not a fundamentally different model. For comparison, the full sample results are shown as well. Not surprisingly, they are essentially the same.

```
SAMPLE      ; 1-1000 $
CREATE      ; x1 = Rnn(0,1) ; x2 = Rnn(0,1) ; x3 = Rnn(0,1) $
CREATE      ; u1 = Rnn(0,1) ; u2 = .5*(u1 + Rnn(0,1)) $
CREATE      ; y1 = (x1 + x3 + u1) > 0 ; y2 = (x2 + x3 + u2) > 0 $
BIVARIATE   ; Lhs = y1,y2 ; Rh1=one,x1,x3 ; Rh2 = one,x2,x3 $
CREATE      ; y1s = y1 ; If(y2 = 0)y1s = -999 $
BIVARIATE   ; Lhs = y1s,y2 ; Rh1 = one,x1,x3 ; Rh2 = one,x2,x3 ; Selection $

E33.5 Simultaneity in the Binary Variables

A simultaneous equations sort of model would appear as

$$z_{i1} = \boldsymbol{\beta}_1'\mathbf{x}_{i1} + \gamma_1 y_{i2} + \varepsilon_{i1},\ \ y_{i1} = 1 \text{ if } z_{i1} > 0,\ y_{i1} = 0 \text{ otherwise},$$

$$z_{i2} = \boldsymbol{\beta}_2'\mathbf{x}_{i2} + \gamma_1 y_{i1} + \varepsilon_{i2},\ \ y_{i2} = 1 \text{ if } z_{i2} > 0,\ y_{i2} = 0 \text{ otherwise},$$

$$[\varepsilon_{i1},\varepsilon_{i2}] \sim \text{bivariate normal (BVN) } [0,0,1,1,\rho],\ -1 < \rho < 1,$$

individual observations on y_1 and y_2 are available for all i.

It would follow from the construction that

$$\text{Prob}[y_1 = 1,\ y_2 = 1] = \Phi_2\,(\boldsymbol{\beta}_1'\mathbf{x}_1 + \gamma_1 y_2,\ \boldsymbol{\beta}_2'\mathbf{x}_2 + \gamma_2 y_1,\ \rho]$$

and likewise for the other cells, where y_1 and y_2 are two binary variables. Unfortunately, the model as stated is not internally consistent, and is inestimable. Ultimately, it is not identifiable. As a practical matter, you can verify this by attempting to devise a way to simulate a sample of observations that conforms exactly to the assumptions of the model. In this case, there is none because there is no linear reduced form for this model. (The approach suggested by Maddala (1983) is not consistent.) *LIMDEP* will detect this condition and decline to attempt to do the estimation. For example:

BIVARIATE PROBIT ; Lhs = y1,y2 ; Rh1 = one,x1,x3,y2 ; Rh2 = one,x2,x3,y1 $

produces a diagnostic,

```
Error   809: Fully simultaneous BVP model is not identified
```

NOTE: Unlike the case in linear simultaneous equations models, nonidentifiability does not prevent ‘estimation’ in this model. (2SLS estimates cannot be computed when there are too few instrumental variables, which is the signature of nonidentifiability in a linear context.) With the ‘fully simultaneous bivariate probit model,’ it is possible to maximize what purports to be a log likelihood function – numbers will be produced that might even look reasonable. However, as noted, the model itself is nonsensical – it lacks internal coherency.

To illustrate the effect, the following program attempts to estimate a fully simultaneous bivariate probit model. In the first version, the optimizer appears to find a solution, though the theoretical result is that the results are not meaningful. In the second version, the coefficient on $y1$ in the second equation is constrained to equal zero. This produces the generally useable recursive model described in the next section. We use the built in **MAXIMIZE** command to construct our own log likelihood maximizer for this model, as *LIMDEP* will refuse it. The optimization trace for the model is punctuated with error messages. But, ultimately a set of ordinary looking results is produced. The correlation coefficient of .99334 is suspiciously large, however. (This application also demonstrates using **MAXIMIZE** to construct an estimator. **MAXIMIZE** is described in Chapter E66.)

The commands are:

```
NAMELIST   ; y = tax, priv
           ; x1 = one,inc,ptax ; x2  = one,inc,yrs,ptax $
CREATE     ; y1 = tax ; y2 = priv

E33.6 Recursive Bivariate Probit Model

A slight modification of the model in the previous section is identified and used in many recent applications. Consider the model for the probability of the event y_1 = 0/1 and y_2 = 0/1 assuming $\gamma_2 = 0$.

$$\text{Prob}[y_1 = 1, y_2 = 1 \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2(\boldsymbol{\beta}_1'\mathbf{x}_1 + \gamma_1, \; \boldsymbol{\beta}_2'\mathbf{x}_2, \rho)$$

$$\text{Prob}[y_1 = 1, y_2 = 0 \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2(\boldsymbol{\beta}_1'\mathbf{x}_1, \; -\boldsymbol{\beta}_2'\mathbf{x}_2, -\rho)$$

$$\text{Prob}[y_1 = 0, y_2 = 1 \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2(-\boldsymbol{\beta}_1'\mathbf{x}_1 + \gamma_1, \; \boldsymbol{\beta}_2'\mathbf{x}_2, -\rho)$$

$$\text{Prob}[y_1 = 0, y_2 = 0 \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2(-\boldsymbol{\beta}_1'\mathbf{x}_1, \; -\boldsymbol{\beta}_2'\mathbf{x}_2, \rho)$$

This is a recursive simultaneous equations model. Surprisingly enough, it can be estimated by full information maximum likelihood *ignoring the simultaneity* in the system;

```
BIVARIATE   ; Lhs =  y1, y2
            ; Rh1 =  x1,y2 ; Rh2 = x2 $
```

(A proof of this result is suggested in Maddala (1983, p. 123) and pursued in Greene (1998).) An application of the result to the gender economics study is given in Greene (1998). Some extensions are presented in Greene (2003, 2011).

This model presents the same ambiguity in the conditional mean function and marginal effects that were noted earlier in the bivariate probit model. The conditional mean for y_1 is

$$E[y_1 \mid y_2 = 1, \mathbf{x}_1, \mathbf{x}_2] \;=\; \Phi_2\,(\boldsymbol{\beta}_1'\mathbf{x}_1 + \;\gamma_1, \boldsymbol{\beta}_2'\mathbf{x}_2, \rho)\;/\;\Phi(\boldsymbol{\beta}_2'\mathbf{x}_2)$$

for which derivatives were given earlier. Given the form of this result, we can identify *direct* and *indirect* effects in the conditional mean:

$$\frac{\partial E[y_1 \mid y2 = 1, \mathbf{x}_1, \mathbf{x}_2]}{\partial \mathbf{x}_1} = \frac{g_1}{\Phi(\boldsymbol{\beta}'\mathbf{x}_2)}\boldsymbol{\beta}_1 \;=\; \text{direct effects}$$

$$\frac{\partial E[y_1 \mid y_2 = 1, \mathbf{x}_1, \mathbf{x}_2]}{\partial \mathbf{x}_2} = \left[\frac{g_2}{\Phi(\boldsymbol{\beta}'\mathbf{x}_2)} - \frac{\Phi_2(\boldsymbol{\beta}'\mathbf{x}_1, \boldsymbol{\beta}'\mathbf{x}_2, \rho)\phi(z_2)}{\left[\Phi(\boldsymbol{\beta}'\mathbf{x}_2)\right]^2}\right]\boldsymbol{\beta}_2 \;=\; \text{indirect effects}$$

The unconditional mean function is

$$\begin{aligned} \mathrm{E}[y_1 \mid \mathbf{x}_1, \mathbf{x}_2] &= \Phi(\boldsymbol{\beta}_2'\mathbf{x}_2)\,\mathrm{E}[y_1 \mid y_2 = 1, \mathbf{x}_1, \mathbf{x}_2] + [1\text{-}\Phi(\boldsymbol{\beta}_2'\mathbf{x}_2)]\,\mathrm{E}[y_1 \mid y_2 = 0, \mathbf{x}_1, \mathbf{x}_2] \\ &= \Phi_2\,(\boldsymbol{\beta}_1'\mathbf{x}_1 + \;\gamma_1, \boldsymbol{\beta}_2'\mathbf{x}_2, \rho) + \Phi_2\,(\boldsymbol{\beta}_1'\mathbf{x}_1, -\boldsymbol{\beta}_2'\mathbf{x}_2, -\rho) \end{aligned}$$

Derivatives for marginal effects can be derived using the results given earlier. Analysis appears in Greene (1998). The decomposition is done automatically when you specify a recursive bivariate probit model – one in which the second Lhs variable appears in the Rhs of the first equation.

The following demonstrates this by extending the model in Section E33.2.8. Note the appearance of *priv* on the Rhs of the first equation, *x1*.

```
NAMELIST    ; y = tax, priv
            ; x1 = one,inc,ptax,priv ; x2 = one,inc,yrs,ptax $
BIVARIATE   ; Lhs = tax,priv ; Rh1 = x1 ; Rh2 = x2 ; Partial Effects $
```

Partial effects for continuous variables are derivatives.
Partial effects for dummy variables (*) are first differences.
Direct effect is wrt x2, indirect is wrt x1, total is the sum.
---------------------------------------------------------------
Variable   Direct Effect   Indirect Effect    Total Effect
---------+---------------+----------------+-------------------
     INC |   .4787001        .0169062          .4956064
    PTAX |  -.6362002        .0047864         -.6314138
     YRS |   .0000000       -.0036217         -.0036217
---------+-----------------------------------------------------
```

The decomposition of the partial effects accounts for the direct and indirect influences. Note that there is no partial effect given for *priv* because this variable is endogenous. It does not vary ‘partially.’

E33.7 Bivariate Probit Models with Partial Observability

We consider a bivariate probit model in which, instead of observing both y_{i1} and y_{i2}, we observe the product, $y_i = y_{i1}y_{i2}$. The situation arises when we observe the final outcome of two decision processes which lead to a single conclusion. Basic references are Poirier (1980), Abowd and Farber (1982), and Meng and Schmidt (1985). There are three variants available:

Poirier

In the Poirier model, y_1 and y_2 are simultaneously determined, and ε_1 and ε_2 are correlated. Then,

$$\text{Prob}[y = 1] = \Phi_2[\boldsymbol{\beta}_1'\mathbf{x}_1,\boldsymbol{\beta}_2'\mathbf{x}_2,\rho],$$

$$\text{Prob}[y = 0] = 1 - \text{Prob}[y = 1].$$

As an example, Poirier cites the case of a joint decision made by two people each of whom has veto power.

Abowd and Farber

In the Abowd and Farber model, y_1 and y_2 are determined sequentially, and ε_1 and ε_2 are uncorrelated. The model is

$$\text{Prob}[y = 1] = \text{Prob}[y_1 = 1]\ \text{Prob}[y_2 = 1] = \Phi(\boldsymbol{\beta}_1'\mathbf{x}_1)\ \Phi(\boldsymbol{\beta}_2'\mathbf{x}_2),$$

$$\text{Prob}[y = 0] = 1 - \text{Prob}[y = 1].$$

The Abowd and Farber variant results from the Poirier model when ρ equals zero. Abowd's example is that of an individual who decides to enter a queue, then subsequently decides whether or not to accept an offer upon reaching his or her turn in the queue. *LIMDEP* produces full information maximum likelihood estimates of all parameters in both of these models. Since they have only a single dependent variable (the product, $y_1 \times y_2$), these partial observability models are estimated as probit models, not bivariate probit models. The Poirier variant is requested simply by adding the second list of exogenous variables to the **PROBIT** command. I.e.,

PROBIT ; Lhs = y ; Rh1 = x1list ; Rh2 = x2list $

The Abowd and Farber variant is requested by adding

; Selection

to the Poirier variant.

Starting values for both of these models are the ordinary least squares estimates and ρ equal to zero for the Poirier variant. As always, you may provide your own starting values if you like. If so, you must provide a value of ρ for the Poirier variant. In both models, the full set of parameters involves $[\boldsymbol{\beta}_1,\boldsymbol{\beta}_2]$. You may use **; Rst** in the example at the end of Section E33.2.8, to impose both within and cross equation restrictions on the models. For the listing of predictions and residuals, **; Keep** and **; Res**, the same prediction rule as in the univariate probit model is used. That is, for each observation, we compute Prob[y = 1], then predict y = 1 if the probability is greater than .5.

Meng and Schmidt

In the Meng and Schmidt model, y_1 and y_2 are defined by separate probit models;

if $y_1 = 1$, both y_1 and y_2 are observed,

if $y_1 = 0$, then only $y_1 \times y_2$ is observed.

The setup involves both Lhs variables, so it is estimated as a bivariate probit model.

NOTE: When y_1 is zero, you should code y_2 as zero also.

The command for the Meng and Schmidt model is

```
BIVARIATE   ; Lhs  = y1,y2
            ; Rh1 = Rhs for first equation
            ; Rh2 = Rhs for second equation
            ; Model = Partial $
```

All other options are the same as for other bivariate probit models.

NOTE: The Meng and Schmidt model is identical to the bivariate probit model with sample selection, with the two variables reversed.

E33.7.1 Example

The following experiment will illustrate the computations in the partial observability models: The data are simulated, and correspond exactly to the assumptions of the models.

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-500 $
CREATE      ; x1 = Rnn(0,1) ; x2 = Rnn(0,1)
            ; y1 = x1 + Rnn(0,1) ; y1 = y1 > 0
            ; y2 = x2 + Rnn(0,1) ; y2 = y2 > 0 ; y2 = y2*y1 $
CREATE      ; y = y1*y2 $
```

Estimate the Meng and Schmidt model.

```
BIVARIATE   ; Lhs = y1,y2 ; Rh1 = one,x1 ; Rh2 = one,x2 ; Model = Partial $
```

Estimate the Poirier model.

```
PROBIT      ; Lhs = y ; Rh1 =one,x1 ; Rh2 = one,x2 ; Partial Effects $
```

Estimate the Abowd and Farber model.

```
PROBIT      ; Lhs = y ; Rh1 =one,x1 ; Rh2  = one,x2
            ; Selection ; Partial Effects $
```

Meng and Schmidt Model

E33.7.2 Technical Details

The log likelihood for Poirier's variant of the partial observability model is

$$\text{Log } L = \Sigma_{y=1} \log \Phi_2 (\boldsymbol{\beta}_1'\mathbf{x}_1, \boldsymbol{\beta}_2'\mathbf{x}_2, \rho) + \Sigma_{y=0} \log [1 - \Phi_2(\boldsymbol{\beta}_1'\mathbf{x}_1, \boldsymbol{\beta}_2'\mathbf{x}_2, \rho)].$$

The log likelihood for Abowd and Farber's variant of the partial observability model is derived from Poirier's by setting $\rho = 0$. The bivariate CDF then factors into the product of two univariate CDFs. The derivatives of this function are given above in Section E33.2.9. For the Poirier and Abowd/Farber models, the conditional mean function is

$$E[y \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2 (\boldsymbol{\beta}_1'\mathbf{x}_1, \boldsymbol{\beta}_2'\mathbf{x}_2, \rho)$$

Using the results from Section E33.2.9 once again, it follows that the marginal effects are

$$\boldsymbol{\delta} = \partial E[y \mid \mathbf{x}_1, \mathbf{x}_2] / \partial \mathbf{x}$$

$$= g_1 \boldsymbol{\gamma}_1 + g_2 \boldsymbol{\gamma}_2$$

where

$\mathbf{x}$ = the union of $\mathbf{x}_1$ and $\mathbf{x}_2$

$\boldsymbol{\gamma}_m = \boldsymbol{\beta}_m$ augmented with zeros to correspond to $\mathbf{x}$

$$w_m = \boldsymbol{\gamma}_m' \mathbf{x},\ m = 1,2$$

$$a_1 = (w_2 - \rho w_1)/(1 - \rho^2)^{1/2}$$

$$a_2 = (w_1 - \rho w_2)/(1 - \rho^2)^{1/2}$$

$$g_1 = \phi(w_1)\Phi[(w_2 - \rho w_1)/(1 - \rho^2)^{1/2}] = \phi(w_1)\Phi(a_1)$$

$$g_2 = \phi(w_2)\Phi[(w_1 - \rho w_2)/(1 - \rho^2)^{1/2}] = \phi(w_2)\Phi(a_2)$$

The Abowd and Farber case is produced by setting $\rho = 0$. To compute standard errors for the marginal effects, we use the delta method. The necessary derivatives are as follows: We will require

$$\phi'(w_1) = -w_1\phi(w_1) \text{ and likewise for } w_2.$$

Then,

$$\frac{\partial \boldsymbol{\delta}}{\partial \boldsymbol{\gamma}_1} = g_1\mathbf{I} + \left(\phi'(w_1)\Phi(a_1) + \frac{-\rho\phi(w_1)\phi(a_1)}{\sqrt{1-\rho^2}} \right)\boldsymbol{\gamma}_1\mathbf{x}' + \phi(w_2)\phi(a_2)\frac{1}{\sqrt{1-\rho^2}}\boldsymbol{\gamma}_2\mathbf{x}'$$

$$\partial\boldsymbol{\delta}/\partial\rho = \boldsymbol{\gamma}_1\, \phi(w_1)\phi(a_1)\partial a_1/\partial\rho + \gamma_2\phi(w_2)\phi(a_2)\partial a_2/\partial\rho$$

$$\partial a_1/\partial\rho = (\rho a_1/(1 - \rho^2)^{1/2} - w_1) / (1 - \rho^2)^{1/2}$$

The remaining derivatives, $\partial\boldsymbol{\delta}/\partial\boldsymbol{\gamma}_2$ and $\partial a_2/\partial\rho$ are obtained by reversing subscripts in the preceding.

For the Meng and Schmidt model, the log likelihood is

$$\begin{aligned}\text{Log } L \;=\;& \Sigma_{y=1,y2=1} \log \Phi_2[\boldsymbol{\beta}_1'\mathbf{x}_1,\boldsymbol{\beta}_2'\mathbf{x}_2,\rho] && \text{(both variables observed)}\\ &+ \Sigma_{y1=1,y2=0} \log \Phi_2[\boldsymbol{\beta}_1'\mathbf{x}_1,-\boldsymbol{\beta}_2'\mathbf{x}_2,-\rho] && \text{(both variables observed)}\\ &+ \Sigma_{y1=0} \log [1-\Phi(\boldsymbol{\beta}_1'\mathbf{x}_1)] && \text{(only } y_1 \text{ observed)}\end{aligned}$$

(Note that save for a reversal of subscripts and a minor change in interpretation, the Meng and Schmidt log likelihood is the same as that for the bivariate probit with sample selection – in fact, the models are identical.) The various first and second derivatives can be obtained from the terms given earlier. Since there are two outcomes and no natural conditional mean function, marginal affects are not computed for the Meng and Schmidt model.

For all of these models, the BFGS method is used for estimation. BHHH and Newton (based on the BHHH estimator of the Hessian) will probably perform very poorly. We have also found that iteration with the Hessian as opposed to the BHHH estimator for the bivariate probit models performs, likewise, very poorly. The choice based sampling estimator uses the Hessian in order to construct the adjusted covariance matrix.

E33.8 Panel Data Bivariate Probit Models

The four bivariate probit models, bivariate probit, bivariate probit with selection, Poirier's partial observability and Abowd's partial observability model have all been extended to the random parameters form of the panel data models. (The fixed effects and latent class models are not available.) Use of the random parameters formulation is described in detail in Chapter R24. We will only sketch the extension here. The commands for the models are as follows, where [...] indicates an optional part of the specification:

```
        BIVARIATE   ; Lhs  = y1, y2              ? Bivariate probit
                    ; Rh1  = Rhs for equation 1
                    ; Rh2  = Rhs for equation 2
                    [ ; Selection ]              ? Partial observability

or      PROBIT      ; Lhs  = y                   ? Probit model
                    ; Rh1  = Rhs for equation 1
                    ; Rh2  = Rhs for equation 2 ? Partial observability (Poirier)
                    [ ; Selection ]              ? Abowd and Farber

Then,               ; RPM [ = list for heterogeneity in the mean ]
                    ; Pds  = panel specification ? Optional if cross section
                    [ ; Pts = number of replications ]
                    [ ; Halton and other controls for the estimation ]
                    ; Fcn  = designation of random parameters $
```

For the random parameters specification, use

; name (distribution) distribution = *n*, *u*, *t*, *l*, *c* for the first equation

or **; name [distribution]** for the second equation.

Note that random parameters in the second equation are designated by square brackets rather than parentheses. This is necessary because the same variables can appear in both equations. Two other specifications should be useful

; Cor allows the random parameters to be correlated.
; AR1 allows the random terms to evolve according to an AR(1) process rather than be time invariant.

The two equation random parameters save the matrices *b* and *varb* and the scalar logl after estimation. No other variables, partial effects, etc. are provided internally to the command. But, you can use the estimation results directly in the **SIMULATION**, **PARTIAL EFFECTS** commands, and so on. An example appears after the results of the simulation below.

E33.8.1 Application

To demonstrate this model, we will fit a true random effects model for a bivariate probit outcome. Each equation has its own random effect, and the two are correlated. The model structure is

$$z_{it1} = \boldsymbol{\beta}_1'\mathbf{x}_{it1} + \varepsilon_{it1} + u_{i1},\quad y_{it1} = 1 \text{ if } z_{it1} > 0,\ y_{it1} = 0 \text{ otherwise,}$$

$$z_{it2} = \boldsymbol{\beta}_2'\mathbf{x}_{it2} + \varepsilon_{it2} + u_{i2},\quad y_{it2} = 1 \text{ if } z_{it2} > 0,\ y_{it2} = 0 \text{ otherwise,}$$

$$[\varepsilon_{it1},\varepsilon_{it2}] \sim \text{Bivariate normal (BVN) } [0,0,1,1,\rho],\ -1 < \rho < 1,$$

$$[u_{i1},u_{i2}] \sim \text{Bivariate normal (BVN) } [0,0,1,1,\theta],\ -1 < \theta < 1,$$

Individual observations on y_1 and y_2 are available for all i. Note, in the structure, the idiosyncratic ε_{itj} creates the bivariate probit model, whereas the time invariant common effects, u_{ij} create the random effects (random constants) model. Thus, there are two sources of correlation across the equations, the correlation between the unique disturbances, ρ, and the correlation between the time invariant disturbances, θ. The data are generated artificially according to the assumptions of the model.

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-200 $
CREATE      ; x1 = Rnn(0,1) ; x2 = Rnn(0,1) ; x3 = Rnn(0,1) $
MATRIX      ; u1i = Rndm(20) ; u2i = .5* Rndm(20) + .5* u1i $
CREATE      ; i  = Trn(10,0) ; u1 = u1i(i) ; u2 = u2i(i) $
CREATE      ; e1 = Rnn(0,1) ; e2 = .7*Rnn(0,1) + .3*e1 $
CREATE      ; y1 = (x1+e1 + u1) > 0
            ; y2 = (x2+x3+e2+u2) > 0  ; y12 = y1*y2 $
BIVARIATE   ; Lhs = y1,y2 ; Rh1 = one,x1 ; Rh2 = one,x2,x3
            ; RPM ; Pds = 10 ; Pts = 25 ; Cor ; Halton
            ; Fcn = one(n), one[n] $
PROBIT      ; Lhs = y12 ; Rh1 = one,x1 ; Rh2 = one,x2,x3
            ; RPM ; Pds = 10 ; Pts = 25 ; Cor ; Halton
            ; Fcn  = one(n), one[n] ; Selection $
PROBIT      ; Lhs  = y12 ; Rh1 = one,x1 ; Rh2 = one,x2,x3
            ; RPM ; Pds = 10 ; Pts = 25 ; Cor ; Halton
            ; Fcn  = one(n), one[n] $
```

Note that by construction, most of the cross equation correlation comes from the random effects, not the disturbances. The second model is the Abowd/Farber version of the partial observability model. The Poirier model is not estimable for this setup. It is easy to see why. The correlations in the Poirier model are overspecified. Indeed, with **; Cor** for the random effects, the Poirier model specifies two separate sources of cross equation correlation. This is a weakly identified model. The implication can be seen in the results below, where the estimator failed to converge for the probit model, and at the exit, the estimate of ρ was nearly -1.0. This is the signature of a weakly identified (or unidentified) model.

These are the estimates of the Meng and Schmidt model.

E33.8.2 Simulation and Partial Effects

This is the model estimated at the beginning of the previous section.

$$y1^* = a1 + b11\,x1 + u1 + e1$$

$$y2^* = a2 + b22\,x2 + b23\,x3 + u2 + e2.$$

The random effects, $u1$ and $u2$, are time invariant – the same value appears in each of the 10 periods of the data. The model command is

BIVARIATE ; Lhs = y1,y2
; Rh1 = one,x1 ; Rh2 = one,x2,x3
; RPM ; Pds = 10 ; Pts = 25 ; Cor ; Halton
; Fcn = one(n), one[n] $

```

Figure E33.3 Matrix Results

The estimator does not support predictions or partial effects. But, we can use the template **SIMULATE** and **PARTIAL EFFECTS** programs to create our own by supplying our function and estimates.. We will use the model exactly as shown in the results, with labels for the estimates in order of their appearance: **b11,b22,b23,a1,a2,c11,c22,c21,ro.** For purposes of the exercise, we will examine the bivariate normal probability P(y1=1,y2=1). With all the parts in place, other functions, such as the conditional means, can be examined by making minor changes in the function definition. For example, in the program below, partial effects are obtained simply by changing the command to **PARTIALS** and changing **; Scenario: to ; Effects: x1**.

? Create time invariant random effects. Used to create correlated u1 and u2

```
MATRIX      ; mv1 = Rndm(20,1) ; mv2 = Rndm(20,1) $
CREATE      ; index = Trn(10,0) $
CREATE      ; v1 = mv1(index) ; v2 = mv2(index) $
```

? Simulate the joint probability and examine its behavior as x1 varies

```
SIMULATE    ; Labels = b11,b22,b23,a1,a2,c11,c22,c21,ro
            ; Parameters = b
            ; Covariance = varb

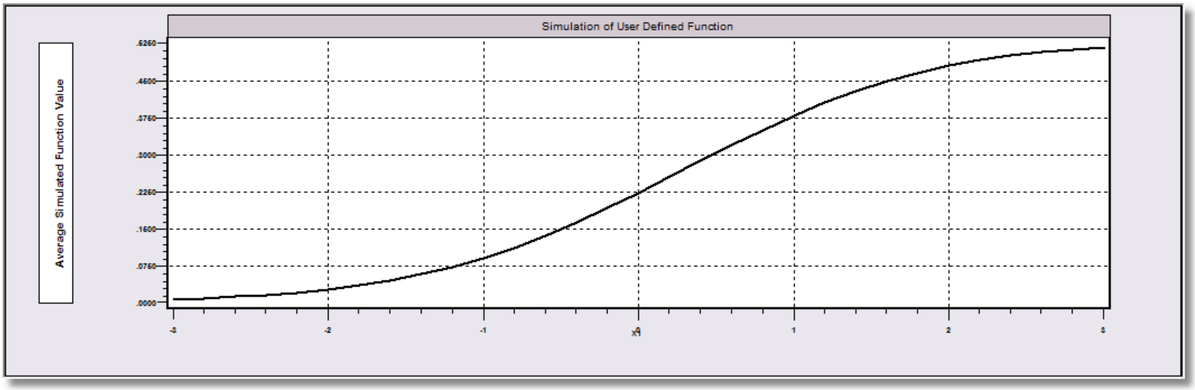

Figure E33.4 Simulation of Estimated Model

E33.9 Simultaneous Equations Models

Sections E33.5 and E33.6 suggested some results for simultaneous equations models involving binary variables. For present purposes, the important feature is the appearance of the actual binary outcomes in the structural equations. A number of models have been developed that involve not the outcome variables, but the underlying, unobserved continuous utilities. A familiar source for some of these is Maddala (1983, Chapter 8). His structural model is

$$y_1^* = \gamma_1 y_2^* + \boldsymbol{\beta}_1'\mathbf{x}_1 + \varepsilon_1,\ y_1 = 1(y_1^* > 0) \text{ in the probit formulations,}$$

$$y_2^* = \gamma_2 y_1^* + \boldsymbol{\beta}_2'\mathbf{x}_2 + \varepsilon_2,\ y2 = 1(y2^* > 0) \text{ in the probit formulations,}$$

$$[\varepsilon_1,\varepsilon_2] \sim \text{BVN}[(0,0), \sigma_1^2, \sigma_2^2, \rho] \ (\rho \text{ is the correlation, } \sigma_j \text{ is a standard deviation).}$$

Maddala's Section 8.8 lists numerous permutations of the model based on different censoring mechanisms, that is, whether y_j^* or y_j is observed, or perhaps somewhere between, a censored version, $y_j^+ = y_j y_{j^*}$. A crucial element of this model is that the underlying structure involves the latent, uncensored variables. One might easily imagine that the observed data, rather than the latent variables appear in the model. Consider Greene's (1998) model (based on Burnett (1997)) of whether a liberal arts college offers a gender economics course. Its structure has the form:

$$\text{Prob[Women's studies program]} = F_1(\boldsymbol{\beta}_1'\mathbf{x}_1)$$

$$\text{Prob[Gender economics course]} = F_2(\boldsymbol{\beta}_2'\mathbf{x}_2 + \gamma\text{Women's studies program).}$$

This is a simultaneous equations (albeit a recursive one), but with the crucial difference that the observed binary variable from the first equation, not the latent continuous variable, appears in the second equation. We reconsider this model below. Estimation of the two formulations must be handled differently. The second case was developed in Sections E33.5 and E33.6.

E33.9.1 Maddala's Models

The fundamental aspect of Maddala's models (which may or may not be appropriate in a given application) is that there exists a reduced form

$$y_1^* = \pi_1'\mathbf{x} + v_1,$$

$$y_2^* = \pi_2'\mathbf{x} + v_2,$$

$$[v_1,v_2] \sim \text{BVN}[(0,0), \theta_1^2, \theta_2^2, \tau] \text{ (τ is the correlation, θ_j is a standard deviation)},$$

where $\mathbf{x}$ is the union of the variables in $\mathbf{x}_1$ and $\mathbf{x}_2$. The observation mechanism that translates the latent variables into the observed ones thus operates on the reduced form as well as on the structure. This turns out to be a (very) large convenience. We consider two of the models given in Maddala (1983). The others can be handled similarly. We note, most of Maddala's formulations of these estimation problems, although correct, are probably more complicated than necessary. The manipulation of variance parameters that are unidentified, rather than normalization of them to one at the outset, unnecessarily complicates some of the analyses as well. Also, in some cases, the Murphy-Topel result for correcting covariance matrices for two step estimators can be used to some advantage to simplify Maddala's results. (Interestingly, Maddala (1983) gives, on page 243 the basic result to generate Murphy and Topel's (1985) formulas, but he does not take full advantage of it in his derivations.) Also, it is important to note that given the way these models are formulated, all can be estimated by full information maximum likelihood. Imposition of the overidentifying restrictions will complicate the development, which is a reasonable motivation for the two step methods considered here. In these cases, the models are estimated using the method of moments and two step estimators sometimes using single equation MLE at the first step.

E33.9.2 Model 3: y_1* Observed Directly, y_2* Observed as Binary y_2

The steps in the estimation involve fitting the two equations of the reduced form, by least squares for the first equation and univariate probit for the second. Fitted values for the latent variables from the two equations are then inserted into the structural forms. The structures are then fit by least squares and maximum likelihood probit, respectively, and the asymptotic covariance matrices are corrected after estimation. This *LIMDEP* routine estimates Maddala's Model 3, page 245. A few algebraic errors are corrected in what follows. Also, Maddala carries σ_2 around his derivation, but σ_2 must equal one. We just impose the normalization outright. The implied equation system is

$$y_1^* = \gamma_1\, y_2^* + \boldsymbol{\beta}_1'\mathbf{x}_1 + u_1,\;\; y_1 = y_1^*,$$

$$y_2^* = \gamma_2\, y_1^* + \boldsymbol{\beta}_2'\mathbf{x}_2 + u_2,\;\; y_2 = \mathbf{1}(y_2^* > 0).$$

The first variable, y_1* is directly observed, but only the sign of y_2* is observed. The variance of u_1 is σ_1^2 squared. Since y_2* is not observed, save for sign, σ_2^2 squared is normalized to 1.0. The correlation is ρ_{12}.

In the following, $\mathbf{x}$ is the union of $\mathbf{x}_1$ and $\mathbf{x}_2$. The reduced form for the structural system is

$$y_1^* = \boldsymbol{\pi}_1'\mathbf{x} + v_1,\ \mathrm{Var}[v_1] = \theta_1^2 = (\sigma_1^2 + \gamma_1^2 + 2\rho_{12}\gamma_1\sigma_1) / (1 - \gamma_1\gamma_2)^2$$

$$y_2^* = \boldsymbol{\pi}_2'\mathbf{x} + v_2,\ \mathrm{Var}[v_2] = \theta_2^2 = (\ 1\ + \gamma_2\sigma_1^2 + 2\rho\gamma_2\ ) /\ (1 - \gamma_1\gamma_2)^2$$

We note before proceeding that there is a huge gap in Maddala's derivation. The parameter ρ_{12} is crucial in the derivation, and Maddala offhandedly claims that σ_{12}/σ_2 is estimable. In fact, σ_2 is not estimable – it must be normalized to 1.0. That leaves σ_{12} which is the needed calculation, since $\rho_{12} = \sigma_{12}/\sigma_1$. But, in his derivation, he never presents the estimator for σ_{12} and it is far from obvious where one should get it. We see two possibilities: (1) Since σ_1, γ_1 and θ_1^2 are estimated in the OLS regression of the first reduced form, the value of ρ_{12} that equates the left and right hand sides can be used. (2) Since the variance in a probit equation must equal one, we can find the ρ_{12} that makes θ_2^2 equal one. Both of these candidates are method of moments estimators that can produce nonsense estimates of ρ_{12}. Based on his specification, there is no other way out of this quandary.

Only this setup is needed for use of this program. The remainder is generic. This defines the exogenous variables in the structural equations. For convenience, we also make copies of the two left hand side variables.

```
NAMELIST    ; x1 = ... ; x2 = ... $
CREATE      ; y1 = ... ; y2 = ... $
```

The procedure will now be generic. This can be called by name, supplying only the names of the left and right hand side variables.

```
PROC = Model3(y1,y2,x1,x2) $
NAMELIST    ; xm3 = OR(x1,x2) $ Forms the union of the two right hand sides.
```

This is the first reduced form regression. Regress y_1 on $\mathbf{x}$. This estimates $\boldsymbol{\pi}_1$ and θ_1^2. The fitted values are $\boldsymbol{\pi}_1'\mathbf{x}$. Retrieve the reduced form variance, s^2; this is the estimate of θ_1^2.

```
REGRESS     ; Lhs = y1 ; Rhs = xm3 ; Keep = p1x $
CALC        ; t1sq = ssqrd $
```

The second reduced form is the probit equation to estimate $\boldsymbol{\pi}_2$. We use these to compute $\boldsymbol{\pi}_2'\mathbf{x}$.

```
PROBIT      ; Lhs = y2 ; Rhs = xm3 $
CREATE      ; p2x = xm3'b $
MATRIX      ; v0 = varb $
```

The fitted values are used on the right hand sides of the structural equation estimators. Estimate the first structural equation by least squares regression of y_1 on $(\boldsymbol{\pi}_2'\mathbf{x})$ and $\mathbf{x}_1$. Pick up the estimates of γ_1 and σ_1^2 and the full coefficient vector $\alpha_1 = (\gamma_1,\boldsymbol{\beta}_2)$. Estimate the second structural equation by probit estimation of y_2 on $\boldsymbol{\pi}_1'\mathbf{x}$ and x_2. Pick up the estimate of γ_2 and $\boldsymbol{\alpha}_2 = (\gamma_2,\boldsymbol{\beta}_2)$

```
NAMELIST    ; z1 = p2x,x1 ; z2 = p1x,x2 $
REGRESS     ; Lhs = y1 ; Rhs = z1 $  First structural equation
MATRIX      ; alpha1 = b ; vols = varb $
CALC        ; gamma1 = b(1) ; sigmasq1 = ssqrd ; sigma1 = s $
PROBIT      ; Lhs = y2 ; Rhs = z2 $  Second structural equation
MATRIX      ; alpha2 = b ; vprobit = varb  $
CALC        ; gamma2 = b(1) $
```

Use the estimates of θ_1, γ_1, γ_2, and σ_1^2 to estimate ρ_{12}. We first compute the possibly problematic method of moments estimator of ρ_{12}. Then compute the two scalars used in the computation, $c = \sigma_1^2 - 2\sigma_1\gamma_1\rho_{12}$ and $d = \gamma_2^2\sigma_1^2 - 2\sigma_1\gamma_2\rho_{12}$.

```
CALC        ; rho12 = ((1-gamma1*gamma2)^2*t1sq - gamma1^2 - sigmasq1)
                          / (2*gamma1*sigma1)
            ; c = sigmasq1 - 2* sigma1*gamma1*rho12
            ; d = gamma2^2 * sigmasq1 - 2*sigma1*gamma2*rho12 $
```

Now compute the adjusted asymptotic covariance matrices and correct the results. He carries σ_2 through all the computations, but σ_2 must equal one. Finish the covariance matrices and show the results.

```
MATRIX      ; z1z1i  =<z1'z1> ; va1 = c*z1z1i
                + {gamma1^2} * z1z1i * z1'XM3 * v0 * xm3'z1 * z1z1i
            ; z2xvi  = z2'xm3 * v0 * xm3'z2 ; z2xvi  = <z2xvi>
            ; va2 = z2xvi + d*z2xvi * z2'xm3 * v0 * <xm3'xm3> * v0 * xm3'z2 * z2xvi
            ; Stat(alpha1,va1,z1) ; Stat (alpha1,vols,z1)
            ; Stat(alpha2,va2,z2) ; Stat(alpha2,vprobit,z2) $
ENDPROCEDURE $
```

To use the procedure, the command is where the arguments are the variables and namelists that you have defined earlier.

```
EXECUTE     ; Proc = Model3(y1, y2, x1, x2) $
```

E33.9.3 Model 6: Both y_1^* and y_2^* Observed as Binary y_1 and y_2

This model involves only the binary variables. Neither structural variance is identified, so the only variance parameter the model produces is the correlation coefficient, ρ. The setup for the two sets of variables in the system is the same as above in the Model 3 procedure.

```
PROCEDURE  = Model6(y1,y2,x1,x2) $
NAMELIST    ; xm6 = OR(x1,x2) $
```

Estimate the reduced form probits and save the coefficients

```
PROBIT      ; Lhs = y1 ; Rhs = xm6 $
MATRIX      ; pi1 = b ; v1 = varb  $
PROBIT      ; Lhs = y2 ; Rhs = xm6 $
MATRIX      ; pi2 = b ; v2 = varb  $
CREATE      ; y1f = x'pi1 ; y2f = xm6'pi2 $
```

Estimate the structural probits using the fitted values from above.

```
NAMELIST    ; z1 = y2f,x1 ; z2 = y1f,x2 $
PROBIT      ; Lhs = y1 ; Rhs = z1 $
MATRIX      ; alpha1 = b ; vp1 = varb $
PROBIT      ; Lhs = y2 ; Rhs = z2 $
MATRIX      ; alpha2 = b ; vp2 = varb $
```

Calculate the covariance matrices, first for α_1 then, symmetrically, for α_2

```
CREATE      ; q1= z1'alpha1 ; q2 = xm6'pi2
            ; a1 = Lmp(q1)/Phi(q1) ; a2 = Lmp(q2)/Phi(q2)
            ; capa1 = N01(q1) * a1
            ; u1 = y1 - Phi(q1) ; u2 = y2 - Phi(q2) ; v = a1 * a2 * u1 * u2 $
MATRIX      ; w1 = z1'[capa1]z1 ; w2 = v1 ; w3 = alpha1(1) * z1'[capa1]xm6
            ; w4 = xm6'[v]z1 ; w324 = w3 * w2 * w4  ; w323 = w3 * w2 * w3'
            ; va1 = w1 - w324 - w324' + w323 ; va1 = <w1> * va1 * <w1> $
CREATE      ; q3 = z2'alpha2 ; q4 = xm6'pi1
            ; a3 = Lmp(q3)/Phi(q3) ; a4 = Lmp(q4)/Phi(q4)
            ; capa3 = N01(q3) * a3
            ; u3 = y2 - Phi(q3) ; u4 = y1 - Phi(q4) ; v = a3 * a4 * u3 * u4 $
MATRIX      ; w1 = z2'[capa3]z2 ; w2 = v2 ; w3 = alpha2(1) * z2'[capa3]xm6
            ; w4 = x '[v]z2  ; w324 = w3 * w2 * w4 ; w323 = w3 * w2 * w3'
            ; va2 =  w1 - w324 - w324' + w323 ; va2 = <w1> * va2 * <w1> $
MATRIX      ; Stat(alpha1,va1,z1) ; Stat(alpha1,vp1,z1)
            ; Stat(alpha2,va2,z2) ; Stat(alpha2,vp2,z2) $
```

To use the procedure, the command is where the arguments are the variables and namelists that you have defined earlier.

```
EXECUTE     ; Proc = Model6(y1, y2, x1, x2) $
```

E33.10 Multivariate Probit Model

The multivariate probit model is the extension to M equations of the bivariate probit model

$$y_{im}^* = \boldsymbol{\beta}_m'\mathbf{x}_{im} + \varepsilon_{im},\ m = 1,\ldots,M$$

$$y_{im} = 1 \text{ if } y_{im}^* > 0, \text{ and 0 otherwise.}$$

$$\varepsilon_{im},\ m = 1,\ldots,M \sim \text{MVN}\,[\mathbf{0},\mathbf{R}]$$

where R is the correlation matrix. Each individual equation is a standard probit model. This generalizes the bivariate probit model for up to M = 20 equations. Specify the model with the same command structure as the SURE model, using the command **MPROBIT**,

MPROBIT ; Lhs = y1,y2,...,ym (list of up to 20 variables)
; Eq1 = list of Rhs variables in the first equation
; Eq2 = list of Rhs variables in the second equation
...
; EqM = list of Rhs variables for Mth equation $

The data for this model must be individual, not proportions and not frequencies. You may use

; Wts = name

as usual. Other options specific for this model in addition to the standard output options are

; Prob = name

which requests the estimator to save the predicted probability for the observed joint outcome, and

; Utility = name

where '**name**' is an existing *namelist* to save the estimated utilities, $\mathbf{X}_m\boldsymbol{\beta}_m$. Restrictions can be imposed with

; Rst = list
and **; CML: specification for constraints**

Note that either of these can be used to specify the correlation matrix. The list for **; Rst** includes the $M(M\text{-}1)/2$ below diagonal elements of **R**. You can use this to force correlations to equal each other, or zero, or other values.

E33.10.1 Other Options

Standard Model Specifications for the Multivariate Probit Model

This is the full list of general that are applicable to this model estimator.

Controlling Output from Model Commands

; Margin displays marginal effects.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Prob = name saves probabilities as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E33.10.2 Retrievable Results

This model keeps the following retrievable results:

Matrices:	*b*	= estimate of $(\boldsymbol{\beta}_1',\boldsymbol{\beta}_2',\ldots,\boldsymbol{\beta}_M')'$ = vector of slopes only
	varb	= asymptotic covariance matrix
	omega	= M×M correlation matrix of disturbances
Scalars:	*kreg*	= number of parameters in model
	nreg	= number of observations
	logl	= log likelihood function
Variables:	*logl_obs*	= individual contribution to log likelihood
Last Model:	None	
Last Function:	None	

E33.10.3 Marginal Effects

You can obtain marginal effects for this model of the following form: The expected value of y_1 given that all other ys equal one is

$$E[y_1|y_2=1,...,y_M=1] = \text{Prob}(y_1=1,...,y_M=1)/\text{Prob}(y_2=1,...,y_M=1) = P_{1...M} / P_{2...M} = E_1.$$

The derivatives of this function are constructed as follows: Let $\mathbf{x}$ equal the union of all of the regressors that appear in the model, and let $\boldsymbol{\gamma}_m$ be such that $\mathbf{z}_m = \mathbf{x}'\boldsymbol{\gamma}_m = \boldsymbol{\beta}_m'\mathbf{x}_m$. ($\boldsymbol{\gamma}_m$ will usually have some zeros in it unless all regressors appear in all equations.) Then,

$$\frac{\partial E_1}{\partial \mathbf{x}} = \sum_{m=1}^{M}\left(\frac{1}{P_{2...M}}\frac{\partial P_{1...M}}{\partial \mathbf{z}_m}\right)\boldsymbol{\gamma}_m - E_1\sum_{m=2}^{M}\left(\frac{1}{P_{2...M}}\frac{\partial P_{2...M}}{\partial \mathbf{z}_m}\right)\boldsymbol{\gamma}_m$$

The relevant parts of this combination of the coefficient vectors are then extracted and reported for the specific equations. Standard errors are obtained using the delta method, and all derivatives are approximated numerically. All effects are computed at the means of the Rhs variables. Use

; Partial Effects

to request this computation. In the display of these results, derivatives with respect to the constant term are set to zero.

Standard errors for these marginal effects cannot be computed directly. We report a bootstrapped approximation computed as follows: Let the estimated set of marginal effects be denoted **d**. This is computed using the parameter estimates from the model as given earlier. Let **V** denote the estimated asymptotic covariance matrix for the coefficient estimates. An estimate of the variance of the estimator of the marginal effects is obtained as the mean squared deviation of 50 random draws from the distribution of the underlying slope parameters. You can set the number of bootstrap replications to use with

; Nbt = number of replications.

The draws are based on the asymptotic normal distribution with mean **b** and variance **V**. (The estimated correlation parameters are taken as fixed.) Thus, the marginal effects at the data means are computed 50 additional times with these new parameters, using

$$Est.Var[d_j] = \frac{1}{50}\sum_{r=1}^{50}\left(d_{jr} - d_j\right)^2$$

Note that the sums are centered at the original estimated marginal effect, not at the means of the random draws.

E33.10.4 Technical Details

The probabilities that enter the log likelihood, its derivatives, and so on are computed using the GHK simulation method described in Section R26.8. The approximation is based on averaging R draws from a certain multivariate normal distribution, for each observation. Each observation has its own seed for the random number generator, so for identical parameter values and fixed R, the draws are repeatable. Increasing R brings greater accuracy, but at the cost of greatly increased computation time. Note, as well, that all derivatives for this model are computed numerically, so it is very time consuming. However, one useful result is that although the amount of time needed to compute the function and the derivatives varies with R and the number of equations, for a given number of equations, the number of right hand side variables has only a very minor influence on the amount of time needed to compute the model. You can control the number of draws with

; Pts = R

where R is the number you desire.

The log likelihood for this model is accumulated as the sum of the logs of the probabilities of the observed outcomes. These are computed using the following construction:

$$\text{Prob}[y_1,y_2,...,y_M|\mathbf{x}_1,\mathbf{x}_2,...,\mathbf{x}_M] = \text{Mvn}\ (\ \mathbf{Tz}\ ,\ \mathbf{TRT}'\ )$$

where $\mathbf{z}$ = the vector of utilities, $z_m = \boldsymbol{\beta}_m'\mathbf{x}_{im}$, $\mathbf{R}$ is the correlation matrix, and $\mathbf{T}$ is a diagonal matrix with $t_{mm} = 2y_m - 1$ (i.e. $t_{mm} = 1$ if $y_m = 1$ and $t_{mm} = -1$ if $y_m = 0$).

E33.10.5 Example

The following example demonstrates estimation of a four equation model. The correlations are actually zero, so in principle, this could be fit with individual probit equations. But, normally, that would not be known a priori.

```
SAMPLE     ; 1-200 $

E33.10.6 Sample Selection Model

There are two modifications of the multivariate probit model built into the estimator. The first is a multivariate version of the selection model in Section E33.4. The model structure is

$$
\begin{aligned}
y_{i1}^* &= \boldsymbol{\beta}_1'\mathbf{x}_{i1} + \varepsilon_{i1},\\
y_{i2}^* &= \boldsymbol{\beta}_2'\mathbf{x}_{i2} + \varepsilon_{i2},\\
&\ldots\\
y_{i,M-1}^* &= \boldsymbol{\beta}_{M-1}'\mathbf{x}_{i,M-1} + \varepsilon_{I,M-1},\\
y_{iM}^* &= \boldsymbol{\beta}_M'\mathbf{x}_{iM} + \varepsilon_{iM},\\
y_{im} &= 1 \text{ if } y_{im}^* > 0 \text{, and 0 otherwise.}\\
\varepsilon_{im}, m &= 1,\ldots,M \ \sim \text{MVN}\,[\mathbf{0},\mathbf{R}]
\end{aligned}
$$

$y_{i,1}, y_{i,2}, \ldots, y_{i,M\text{-}1}$ only observed when $y_{iM} = 1$.

In the same fashion as earlier, the log likelihood is built up from the laws of probability. The different terms in the likelihood function are

$$\text{Prob}(y_{iM} = 1|\mathbf{x}_{im})$$

for the nonselected case, then

$$\text{Prob}(Y_{i1} = y_{i1},\ldots,Y_{i,M\text{-}1} = y_{i,M\text{-}1}\ , y_{iM} = 1|\mathbf{x}_{i1},\ldots,\mathbf{x}_{iM}).$$

The last equation is the selection mechanism. This produces a difference in the likelihood that is maximized (and, to some degree, in the interpretation of the model), but no essential difference in the estimation results.

This form of the model is requested by adding

; Selection

to the **MVPROBIT** command. There are no other changes in the model specification, or the data. Missing data may be coded as zeros or as missing.

E33.10.7 Sequential Selection or Attrition

A second form of the multivariate probit model accommodates exogenous attrition. In this form, the M equations would be a sequence of probit outcomes, in the form of an M period panel. The feature produced here is that the individual is present only for the first T_i of the M periods; T_i might equal M, but could be fewer. For this form of the model, the structure is exactly as above, for all M periods. However, for individual *i*, only a T_i-variate probit model applies. To request this form of the model, use

MVPROBIT ; … all as before
; Pds = the variable that provides T_i $

The remaining features of the model are, once again, all as before. A (probably obvious) restriction is that at least some individuals must be present for all M periods in order for the model to be estimable.

E34: Ordered Choice Models

E34.1 Introduction

The basic ordered choice model is based on the following specification: There is a latent regression,

$$y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ \ \varepsilon_i \sim F(\varepsilon_i\,|\boldsymbol{\theta}),\ \mathrm{E}[\varepsilon_i|\mathbf{x}_i] = 0,\ \mathrm{Var}[\varepsilon_i|\mathbf{x}_i] = 1,$$

The observation mechanism results from a complete censoring of the latent dependent variable as follows:

$$\begin{aligned} y_i &= 0 \text{ if } y_i \le \mu_0,\\ &= 1 \text{ if } \mu_0 < y_i \le \mu_1,\\ &= 2 \text{ if } \mu_1 < y_i \le \mu_2,\\ &\ \ldots\\ &= J \text{ if } y_i > \mu_{J\text{-}1}. \end{aligned}$$

The latent 'preference' variable, y_i^* is not observed. The observed counterpart to y_i^* is y_i. Five stochastic specifications are provided for the basic model shown above. The *ordered probit* model based on the normal distribution was developed by Zavoina and McElvey (1975). It applies in applications such as surveys, in which the respondent expresses a preference with the above sort of ordinal ranking. The variance of ε_i is assumed to be one, since as long as y_i^*, $\boldsymbol{\beta}$, and ε_i are unobserved, no scaling of the underlying model can be deduced from the observed data. (The assumption of homoscedasticity is arguably a strong one. We will relax that assumption in Section E35.2.) Since the μs are free parameters, there is no significance to the unit distance between the set of observed values of y. They merely provide the coding. Estimates are obtained by maximum likelihood. The probabilities which enter the log likelihood function are

$$\mathrm{Prob}[y_i = j] = \mathrm{Prob}[y_i^* \text{ is in the } j\text{th range}].$$

The model may be estimated either with individual data, with $y_i = 0, 1, 2, \ldots$ or with grouped data, in which case each observation consists of a full set of J+1 proportions, $p_{0i},\ldots,p_{Ji}$.

NOTE: If your data are not coded correctly, this estimator will abort with one of several possible diagnostics – see below for discussion. Your dependent variable must be coded 0,1,...,J. We note that this differs from some other econometric packages which use a different coding convention.

There are numerous variants and extensions of this model which can be estimated. The underlying mathematical forms are shown below, where the CDF is denoted $F(z)$ and the density is $f(z)$. (Familiar synonyms are given as well.)

Probit

$$F(z) = \int_{-\infty}^{z} \frac{\exp(-t^2/2)}{\sqrt{2\pi}} dt = \Phi(z), \qquad f(z) = \phi(z)$$

Logit

$$F(z) = \frac{\exp(z)}{1+\exp(z)} = \Lambda(z), \qquad f(z) = \Lambda(z)[1 - \Lambda(z)]$$

Complementary log log or Weibull

$$F(z) = 1 - \exp(-\exp(z)) = C(z), \qquad f(z) = \exp(z)[1 - C(z)]$$

Gompertz or log log or extreme value

$$F(z) = \exp(-\exp(-z)) = G(z), \qquad f(z) = \exp(-z)G(z)$$

Arctangent

$$F(z) = 2/\pi \arctan(z), \qquad f(z) = 2/\pi \times 1/(1 + z^2)$$

The *ordered probit* model is an extension of the probit model for a binary outcome with normally distributed disturbances. The *ordered logit model* results from the assumption that ε has a standard logistic distribution instead of a standard normal. The *ordered Weibull*, *ordered Gompertz* and *ordered arctangent* models are based on asymmetric distributions with skews to the right and left, respectively. A variety of additional specifications and extensions are provided. Basic models are treated in this chapter. Extensions such as censoring and sample selection are given in Chapter E35. Panel data models for ordered choice are discussed in Chapter E36.

E34.2 Command for Ordered Probability Models

The essential command for estimating ordered probability models is

ORDERED ; Lhs = y or p0,p1,...pJ ; Rhs = regressors $

Note that the estimator accepts proportions data for a set of J proportions. The proportions would sum to one at each observation. The probit model is the default specification. To estimate an ordered logit, ordered Weibull, ordered Gompertz or ordered arctangent model instead, add

; Model = Logit

or **; Model = Weibull (this is the extreme value model)**

or **; Model = Gompertz**

or **; Model = Arctangent**

to the command. The standardized logistic distribution (mean zero, standard deviation approximately 1.81) is used as the basis of the model instead of the standard normal. The command builder for this model is found at Model:Discrete Choice/Ordered.

E34.2.1 Data Problems

If you are using individual data, the Lhs variable must be coded 0,1,...,*J*. All the values must be present in the data. *LIMDEP* will look for empty cells. If there are any, estimation is halted. (If value '*j*' is not represented in the data, then the threshold parameter, μ_j is not estimable.) In this circumstance, you will receive a diagnostic such as

```
ORDE,Panel,BIVA PROBIT:A cell has (almost) no observations.
Empty cell: Y        never takes value  2
```

This diagnostic means exactly what it says. The ordered probability model cannot be estimated unless all cells are represented in the data. Users frequently overlook the coding requirement, y = 0,1,... If you have a dependent variable that is coded 1,2,..., you will see the following diagnostic:

```
Models - Insufficient variation in dependent variable.
```

The reason this particular diagnostic shows up is that *LIMDEP* creates a new variable from your dependent variable, say *y*, which equals zero when *y* equals zero, and one when *y* is greater than zero. It then tries to obtain starting values for the model by fitting a regression model to this new variable. If you have miscoded the Lhs variable, the transformed variable always equals one, which explains the diagnostic. In fact, there is no variation in the transformed dependent variable. If this is the case, you can simply use **CREATE** to subtract 1.0 from your dependent variable to use this estimator.

E34.2.2 Other Standard Options

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps ancillary parameters μ_j with main parameter β vector in *b*.
; Margin	displays marginal effects.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix	displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Cluster = spec	requests computation of the cluster form of corrected covariance estimator.
; Stratum = spec	is used with **; Cluster** for stratified and clustered data sets.
; Robust	requests a sandwich estimator or robust VC for TSCS and some discrete choice models.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Prob = name	saves probabilities of outcome as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E34.3 Output from the Ordered Probability Estimators

All of the ordered probit/logit models begin with an initial set of least squares results of some sort. These are suppressed unless your command contains **; OLS**. The iterations are then followed by the maximum likelihood estimates in the usual tabular format. The final output includes a listing of the cell frequencies for the outcomes. When the data are stratified, this output will also include a table of the frequencies in the strata. The log likelihood function, and a log likelihood computed assuming all slopes are zero are computed. For the latter, the threshold parameters are still allowed to vary freely, so the model is simply one which assigns each cell a predicted probability equal to the sample proportion. This appropriately measures the contribution of the nonconstant regressors to the log likelihood function. As such, the chi squared statistic given is a valid test statistic for the hypothesis that all slopes on the nonconstant regressors are zero.

The sample below shows the standard output for a model with six outcomes. These are the German health care data used in several earlier examples. The dependent variable is the self reported health satisfaction rating. For the purpose of a convenient sample application, we have truncated the health satisfaction variable at five by discarding observations – in the original data set, it is coded 0,1,...,10.

HINT: The ordered logit model typically produces the same sort of scaling of the coefficient vector that arises in the binary choice models discussed in Chapter E27. As before, the difference becomes much less pronounced when the marginal effects are considered instead. We are unaware of a convenient specification test for distinguishing between the probit and logit models. A test of normality against the broader Pearson family of distributions is described in Glewwe (1997), but it is not especially convenient. A test for skewness based on the Vuong test seems like a possibility.

Total	445	255	644	1176	1389	4230	8140

Row = actual, Column = Prediction, Model = Probit
Value(j,m)=Sum(i=1,N)y(i,j)*p(i,m).
Column totals may not match cell sums because of rounding error.

The model output is followed by a $(J+1)\times(J+1)$ frequency table of predicted versus actual values. (This table is not given when data are grouped or when there are more than 10 outcomes.) The predicted outcome for this tabulation is the one with the largest predicted probability. Even though the model appears to be highly significant, the table of predictions has seems to suggest a lack of predictive power. Tables such as the one above are common with this model. The driver of the result is the sample configuration of the data. Note in the frequency table that the sample is quite unbalanced, and the highest outcome is quite likely to have the highest probability for every observation. The estimation criterion for the ordered probability model is unrelated to its ability to predict those cells, and you will rarely see a predictions table that closely matches the actual outcomes. It often happens that even in a set of results with highly significant coefficients, only one or a few of the outcomes are predicted by the model. The second table relates more closely to the aggregate predictions of the model. The table entries are the sample proportions that would be predicted for each outcome. For example, the first row of the table shows that 447 individuals in the sample chose outcome 0. For every individual, the model produces a full set of J+1 probabilities. For the 447 individuals, 8140 times the sum of the probabilities of outcome 0 equals 26, 8140 times the sum of the probabilities of outcome 1 equals 15, and so on.

E34.3.1 Robust Covariance Matrix Estimation

The Sandwich Estimator

The standard robust covariance matrix is

$$\text{Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \left[\sum_{i=1}^{n}\left(\frac{\partial^2 \log F_i}{\partial\hat{\boldsymbol{\gamma}}\partial\hat{\boldsymbol{\gamma}}'}\right)\right]^{-1}\left[\sum_{i=1}^{n}\left(\frac{\partial \log F_i}{\partial\hat{\boldsymbol{\gamma}}}\right)\left(\frac{\partial \log F_i}{\partial\boldsymbol{\gamma}}\right)'\right]\left[\sum_{i=1}^{n}\left(\frac{\partial^2 \log F_i}{\partial\hat{\boldsymbol{\gamma}}\partial\hat{\boldsymbol{\gamma}}'}\right)\right]^{-1}$$

where $\hat{\boldsymbol{\gamma}}$ indicates the full set of parameters in the model. To obtain this matrix with any of the forms of the ordered choice models, use

; Robust

in the **ORDERED** command.

Clustering and Stratification

A related calculation is used when observations occur in groups which may be correlated. This is rather like a panel; one might use this approach in a random effects kind of setting in which observations have a common latent heterogeneity. The parameter estimator is unchanged in this case, but an adjustment is made to the estimated asymptotic covariance matrix. Full details on this estimator appear in Chapter R10. To specify this estimator, use

; Cluster = specification

where the specification is either a fixed number of observations or the name of a variable that provides an identifier for the cluster, such as an *id* number. Note that if there is exactly one observation per cluster, then this is $G/(G\text{-}1)$ times the sandwich estimator discussed above. Also, if you have fewer clusters than parameters, then this matrix is singular – it has rank equal to the minimum of G and K, the number of parameters.

The extension of this estimator to stratified data is described in detail in Section R10.3. To use this with the **; Cluster** specification, add

; Stratum = specification

E34.3.2 Saved Results

Computation of predictions and ancillary variables is as follows: For each observation, the predicted probabilities for all J+1 outcomes are computed. Then if you request **; List**, the listing will contain

Predicted Y: Y with the largest probability.

Residual: the largest of the J+1 probabilities (i.e., Prob[y = fitted Y]).

Var1: the estimate of $E[y_i] = \sum_{i=0}^{J} i \times \text{Prob}[Y_i = i]$.
(Note that since the outcomes are only ordinal, this is not a true expected value.)

Var2: the probability estimated for the observed Y.

Estimation results kept by the estimator are as follows:

Matrices: *b* = estimate of $\boldsymbol{\beta}$,
varb = estimated asymptotic covariance,
mu = J-1 estimated μs.

Scalars: *kreg*, *nreg*, and *logl*.

Last Model: The labels are *b_variables*, *mu*1, ...

Last Function: Prob(y = highest outcome | x)

The specification **; Par** adds $\boldsymbol{\mu}$ (the set of estimated threshold values) to *b* and *varb*. The additional matrix, *mu* is kept regardless, but the estimated asymptotic covariance matrix is lost unless the command contains **; Par**. The *Last Function* is used in the **SIMULATE** and **PARTIAL EFFECTS** routines. The default function is the probability of the highest outcome. You can specify a different outcome in the command with

; Outcome = j

where j is the desired outcome. For example, in our earlier application in which outcomes are 0,1,2,3,4,5, the command might specify

PARTIAL EFECTS ; Effects: hhninc ; Outcome = 3 $

and likewise for **SIMULATE**. A full examination of all outcomes is obtained by using

; Outcome = *

E34.4 Model Structure and Data

E34.4.1 Constant Term

This model must include a constant term, *one*, as the first Rhs variable. Since the equation does include a constant term, one of the μs is not identified. We normalize μ_0 to zero. (Consider the special case of the binary probit model with something other than zero as its threshold value. If it contains a constant, this cannot be estimated.) Data may be grouped or individual. (Survey data might logically come in grouped form.) If you provide individual data, the dependent variable is coded 0, 1, 2, ..., J. There must be at least three values. Otherwise, the binary probit model applies. If the data are grouped, a full set of proportions, p_0, p_1, ..., p_J, which sum to one at every observation must be provided. In the individual data case, the data are examined to determine the value of J, which will be the largest observed value of y which appears in the sample. In the grouped data case, J is one less than the number of Lhs variables you provide. Once again, we note that other programs sometimes use different normalizations of the model. For example, if the constant term is forced to equal zero, then one will instead, add a nonzero threshold parameter, μ_0, which equals zero in the presence of a nonzero constant term.

E34.4.2 Censored Data

Suppose that the dependent variable for the ordered probability model is censored for some observations. For example, suppose that Y takes values 0,1,2,...,10. But, for some observations, we observe only a five and an indicator that the dependent variable was actually at least five, though the actual value is unknown. Then, for this observation, the relevant probability is the sum of the probabilities from five to 10, not just the cell probability for $Y = 5$. These sorts of data are likely to occur in the context of the ordered extreme value model for duration described in Chapter E59.3. *LIMDEP* will accommodate this form of censoring, and modify the log likelihood function and all estimates accordingly. Censoring is indicated as in the other duration models. *That is, when data are censored, you can so indicate by including in your model command a second Lhs variable which is the censoring indicator.* Remember that the indicator takes values zero for the censored observations and one for the uncensored observations.

Mathematically, the censored data model is a simple extension of the familiar ordered probability model. Let $y = 0,1,...,J$. The probability that y equals j is

$$\text{Prob}[\text{observed } y = j] \;=\; F[\mu_j - \boldsymbol{\beta}'\mathbf{x}] - F[\mu_{j-1} - \boldsymbol{\beta}'\mathbf{x}].$$

The log likelihood and its derivatives are built up from this relationship. If, however, y is censored, then the observed value $y = j$ contributes a term

$$\text{Prob}[\text{observed } y = j] \;=\; \sum_{i=j}^{J} \{\text{F}[\mu_i - \boldsymbol{\beta}'\mathbf{x}] - \text{F}[\mu_{i-1} - \boldsymbol{\beta}'\mathbf{x}]\}.$$

The log likelihood and its derivatives are obtained just by summing all of the relevant cells.

> **NOTE:** Recall that *LIMDEP* deduces the value of J from the data – the highest value of y_i. Therefore, you must have some uncensored observations, and J is the largest value of y_i observed among these data points. By implication, if a censored y_i exceeds J, there is a problem in the data.

> **NOTE:** (On computation) This additional summation will not add any additional time to fit your model. The reason is that *LIMDEP* already obtains the log likelihood function by taking a weighted sum of all J+1 terms, where in the standard case, the weights are either [0,0,...,1,0,...] for the individual case or [p0,p1,...,pJ] in the grouped data case. For the censored data case, we merely change the weight vector to [0,0,...,1,1,1...], which is a trivial operation.

In the example below, we have randomly censored about 20% of the observations. The commands are

```
SAMPLE    ; All $
REJECT    ; _groupti < 7 $
CREATE    ; censor = Rnu(0,1) > .2 $
ORDERED   ; Lhs = newhsat,censor ; Rhs = one,female,hhninc,hhkids,educ
          ; Logit $
```

The results do reveal an impact of the censoring. For comparison, the same model estimated without censoring is presented with the results.

```

E34.5 Partial Effects and Simulations

There is potentially a large amount of output for the ordered choice model, in addition to the basic model results. There is no single conditional mean because the outcomes are labels, not measures. There are J+1 probabilities to analyze,

$$\text{Prob[cell j]} = F(\mu_j - \boldsymbol{\beta}'\mathbf{x}_i) - F(\mu_{j\text{-}1} - \boldsymbol{\beta}'\mathbf{x}_i).$$

Typically, the highest or lowest cell is of interest. However, the **PARTIAL EFFECTS** (or just **PARTIALS**) and **SIMULATE** commands can be used to examine any or all of them.

Marginal effects in the ordered probability models are also quite involved. Since there is no meaningful conditional mean function to manipulate, we compute, instead, the effects of changes in the covariates on the cell probabilities. These are:

$$\partial\text{Prob[cell } j]/\partial\mathbf{x}_i \;=\; [f(\mu_{j\text{-}1} - \boldsymbol{\beta}'\mathbf{x}_i) - f(\mu_j - \boldsymbol{\beta}'\mathbf{x}_i)] \times \boldsymbol{\beta},$$

where $f(.)$ is the appropriate density for the standard normal, $\phi(\bullet)$, logistic density, $\Lambda(\bullet)(1\text{-}\Lambda(\bullet))$, Weibull, Gompertz or arctangent. Each vector is a multiple of the coefficient vector. But it is worth noting that the magnitudes are likely to be very different. In at least one case, Prob[cell 0], and probably more if there are more than three outcomes, the partial effects have exactly the opposite signs from the estimated coefficients.

NOTE: This estimator segregates dummy variables for separate computation in the marginal effects. The marginal effect for a dummy variable is the difference of the two probabilities, with and without the variable.

Partial effects for the ordered probability models are obtained internally in the command by adding

; Partial Effects

in the command. This produces a table oriented to the outcomes, such as the one below. A second summary that is oriented to the variables rather than the outcomes is requested with

; Partial Effects ; Full

The internal results are computed at the means of the data. Partial effects can also be obtained with the **PARTIALS** command. The third set of results below is obtained with

PARTIALS ; Effects: hhninc ; Outcome = * $

This command produces average partial effects by default, but you can request that they be computed at the data means by adding **; Means** to the command. Probabilities for particular outcomes are obtained with the **SIMULATE** command. An example appears below.

```

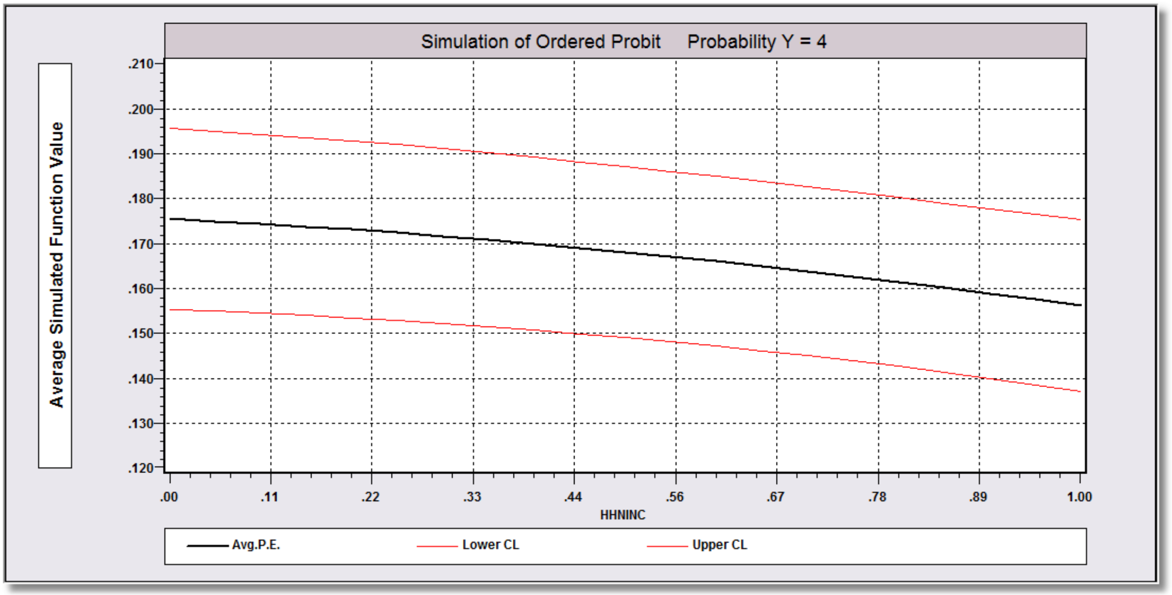

Figure E34.1 Simulated Probabilities

E34.6 Technical Details for Ordered Choice Models

For brevity, we generalize the basic model at this point by integrating both the heteroscedasticity and stratification that are presented in the next two chapters. Either or both can be assumed away. Define the augmented vector of threshold parameters

$$\boldsymbol{\mu} = \mu_{-1}\ \mu_0\ \mu_1\ \ldots\ \mu_{J-1}\ \mu_J, \text{ in which } \mu_{-1} = -\infty,\ \ \mu_0 = 0, \text{ and } \mu_J = +\infty.$$

Then, $\text{Prob}[y_{i,s} = j] = F[(\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i)/w_i] - F[(\mu_{j-1,s} - \boldsymbol{\beta}'\mathbf{x}_i)/w_i],\ j = 0,1,\ldots,J$

where s denotes the stratum, which may be one for all observations, 'w_i' is the individual specific standard deviation, which is 1.0 for all i, or an observed variable, w_i, or $\exp(\boldsymbol{\gamma}'\mathbf{z}_i)$ with unknown parameters $\boldsymbol{\gamma}$ and observed variables $\mathbf{z}_i$ which does not include a constant. Then, let

$F(.)$ = the CDF of the distribution of ε, normal, logistic; Weibull, arctangent or Gompertz.

The log likelihood function is

$$\log L = \Sigma_i \log L_i$$

$$= \Sigma_i \log \text{Prob}[Y_{i,s} = y_{i,s}],$$

where $Y_{i,s}$ = the theoretical random variable

and $y_{i,s}$ = the observed value of $Y_{i,s}$ for observation i in stratum s.

The first derivatives are

$$\frac{\partial \log L_i}{\partial \boldsymbol{\beta}} = \left[\frac{f\left(\dfrac{\mu_{j-1,s} - \boldsymbol{\beta}'\mathbf{x}_i}{w_i}\right) - f\left(\dfrac{\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i}{w_i}\right)}{F\left(\dfrac{\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i}{w_i}\right) - F\left(\dfrac{\mu_{j-1,s} - \boldsymbol{\beta}'\mathbf{x}_i}{w_i}\right)} \right] \frac{1}{w_i}\mathbf{x}_i$$

where $f(.)$ denotes the appropriate density, $\phi(.)$ or $\Lambda(1-\Lambda)$ for normal or logistic, etc. For convenience, denote

$f_{j,s} = f[(\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i)/w_i]$

and $F_{j,s} = F[(\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i)/w_i]$,

and likewise for 'j-1.' By convention,

$f_{-1,s} = F_{-1,s} = f_{J,s} = 0$, and $F_{J,s} = 1$.

Then, $\partial \log L_i/\partial\mu_{j,s} = [f_{j,s} / (F_{j,s} - F_{j-1,s})] / w_i$

and $\partial \log L_i/\partial\mu_{j-1,s} = -[f_{j-1,s} / (F_{j,s} - F_{j-1,s})] / w_i$.

These imply that $\partial \log L_i/\partial\mu_m = 0$ if $m = -1, 0,$ or J.

For the model with multiplicative heteroscedasticity,

$$\frac{\partial \log L_i}{\partial \boldsymbol{\gamma}} = \left[\frac{f\left(a_{j-1,s}\right)a_{j-1,s} - f\left(a_{j,s}\right)a_{j,s}}{F\left(a_{j,s}\right) - F\left(a_{j-1.s}\right)} \right]\mathbf{z}_i,\ a_{j,s} = \frac{\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i}{w_i}$$

For estimation with grouped data and observed proportions $p_0,...,p_J$,

$\log L_j = \Sigma_j\, p_j \log \text{Prob}[Y_{i,s} = j]$.

The preceding expressions are summed over all outcomes. Second derivatives are extremely tedious, but use common expressions and are in principle straightforward. The analytic Hessian is used for computing asymptotic standard errors.

The algorithm used to obtain the maximum likelihood estimates is BFGS. Starting values are obtained by least squares, either ordinary or generalized depending on the type of data. In either case, this initial regression is based on the dichotomy formed by using the binary indicator **1**[y > 0] as if a univariate probit model applied. For grouped data, p_+ and $p_0 = 1-p_+$ provide the dichotomy, and minimum chi squared estimates are obtained. The constant term and the values of the thresholds are then estimated by using the cell frequencies under the assumption that all of the slopes are zero. We segment the real line in such a way that the normal (or other distribution) probabilities corresponding to this partition match the sample cell frequencies. You may provide your own starting values with

; Start = start values for β, start values for $\mu_1,...,\mu_{J-1}$.

The first threshold parameter, μ_0 equals 0.0. If the model contains a constant term, this is not estimable. Note, also, that there is no μ_J. For example, if J = 2, so y = 0,1,2, then only μ_1 is to be estimated. The full parameter vector is

$$\boldsymbol{\Theta} = [\beta_1,...,\beta_K,\mu_1,...,\mu_{J-1}].$$

NOTE: It is necessary for the threshold parameters to be strictly ordered. That is, $\mu_j > \mu_{j-1}$. Occasionally, during the line search, this requirement will be violated by a trial value. A diagnostic will be issued,

```
ORDERED PROBIT - Current estimated thresholds not ordered.
```

but estimation will continue. This is merely a warning, and the line search will continue with a smaller step. But, if your data are such that there are many cells, and some of them are nearly empty, this condition may be persistent, and it is possible that the estimation process will break down.

The partial effects are obtained by a manipulation of the likelihood equations.

$$\frac{\partial \text{Prob}(y_i = j \mid \mathbf{x}_i, \mathbf{z}_i)}{\partial \mathbf{x}_i} = \left[f\left(\frac{\mu_{j-1,s} - \boldsymbol{\beta}'\mathbf{x}_i}{w_i}\right) - f\left(\frac{\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i}{w_i}\right)\right]\frac{1}{w_i}\boldsymbol{\beta}$$

$$\frac{\partial \text{Prob}(y_i = j \mid \mathbf{x}_i, \mathbf{z}_i)}{\partial \mathbf{z}_i} = \left[\frac{f\left(a_{j-1,s}\right)a_{j-1,s} - f\left(a_{j,s}\right)a_{j,s}}{F\left(a_{j,s}\right) - F\left(a_{j-1.s}\right)}\right]\mathbf{z}_i,\; a_{j,s} = \frac{\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i}{\exp(\boldsymbol{\gamma}'\mathbf{z}_i)}.$$

E35: Extended Ordered Choice Models

E35.1 Introduction

The basic ordered choice model is based on the following specification: There is a latent regression,

$$y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ \ \varepsilon_i \sim F(\varepsilon_i\,|\boldsymbol{\theta}),\ \mathrm{E}[\varepsilon_i|\mathbf{x}_i] = 0,\ \mathrm{Var}[\varepsilon_i|\mathbf{x}_i] = 1,$$

The observation mechanism results from a complete censoring of the latent dependent variable as follows:

$$\begin{aligned} y_i &= 0 \text{ if } y_i \le \mu_0, \\ &= 1 \text{ if } \mu_0 < y_i \le \mu_1, \\ &= 2 \text{ if } \mu_1 < y_i \le \mu_2, \\ &\ldots \\ &= J \text{ if } y_i > \mu_{J-1}. \end{aligned}$$

The latent 'preference' variable, y_i^* is not observed. The observed counterpart to y_i^* is y_i. The probabilities which enter the log likelihood function are

$$\mathrm{Prob}[y_i = j] = \mathrm{Prob}[y_i^* \text{ is in the } j\text{th range}].$$

Estimation and analysis of the basic model are presented in Chapter E34. A variety of additional specifications and extensions are supported. The extensions shown in this chapter are:

- heteroscedasticity,
- sample selection and treatment effects,
- generalized ordered, proportional odds and the parallel regressions assumption,
- hierarchical ordered probit models,
- zero inflated ordered probit models,
- bivariate ordered probit and polychoric correlation.

E35.2 Weighting and Heteroscedasticity

An ordered probit model with simple heteroscedasticity,

$$\mathrm{Var}[\varepsilon_i] = w_i^2,$$

may be estimated with

ORDERED ; Rhs = ... ; Lhs = ...
; Wts = your weighting variable, wi
; Heteroscedastic $

Your command gives the name of the variable which carries the *observed* individual specific *standard deviations*. This formulation does not add new parameters to the model, and only instructs the estimator how the weighting variable is to be handled.

This approach is different from estimating the model with weights. Without **; Het**, this model is treated as any other weighted log likelihood, and the estimator maximizes

$$\log L \quad = \quad \sum_{i=1}^{n} w_i \log \mathrm{Prob}(\textit{observed outcome}_i)$$

where $\quad \mathrm{Prob}[\text{cell } j] \; = \; F(\mu_j - \boldsymbol{\beta}'\mathbf{x}_i) - F(\mu_{j-1} - \boldsymbol{\beta}'\mathbf{x}_i).$

With **; Het**, the probabilities are built up from the heteroscedastic random variable, but the terms in the log likelihood are unweighted. With this form of the command, using **; Het**, the model is

$$\mathrm{Prob}[\text{cell } j] \; = \; F[(\mu_j - \boldsymbol{\beta}'\mathbf{x}_i)/w_i] - F[(\mu_{j-1} - \boldsymbol{\beta}'\mathbf{x}_i)/w_i]$$

and $\quad \log L \quad = \quad \sum_{i=1}^{n} \log \mathrm{Prob}(\textit{observed outcome}_i)$

E35.3 Multiplicative Heteroscedasticity

The model with multiplicative heteroscedasticity,

$$\mathrm{Var}[\varepsilon_i] \; = \; [\exp(\boldsymbol{\gamma}'\mathbf{z}_i)]^2,$$

is requested with

```
ORDERED     ; Rhs = ... ; Lhs = ...
            ; Het
            ; Rh2 = list of variables in z $
```

NOTE: Do not include a constant (*one*) in **z**. A variable in **z** which has no variation, such as *one*, will lead to a singular Hessian, and the estimator will fail to converge.

This formulation adds a vector of new parameters to the model. For purposes of starting values, restrictions, and hypothesis tests, the full parameter vector becomes

$$\boldsymbol{\Theta} \; = \; [\beta_1,...,\beta_K,\gamma_1,...,\gamma_L,\mu_1,...,\mu_{J-1}].$$

You can use **; Rst** and **; CML:** for imposing restrictions as usual. As always, restrictions that force ancillary variance parameters (γ_h) to equal parameters in the conditional mean function (β_k) will rarely produce satisfactory results. In the saved results, the estimator of $\boldsymbol{\gamma}$ will always be included in *b* and *varb*. Thus, if you want to extract parts of the parameter vector after estimation, you might use

```
NAMELIST    ; x = ...
            ; z = ... $
ORDERED     ; Lhs  = y ; Rhs = x
            ; Rh2 = z ; Het $
CALC        ; k = Col(x) ; k1 = k+1 ; kt = k + Col(z) $
MATRIX      ; beta = b(1:k)
            ; gamma = b(k1:kt) $
```

The μ threshold parameters are still the ancillary parameters. Marginal effects, fitted values, and so on are requested exactly as before with this extension of the ordered probit model. In the *Last Model* labels list, the variance parameters will be denoted *c_variable*, so with this model, the complete list of labels is

Last Model = [B_...,C_...,MU1,...].

The *Last Function* for the model is the probability including the exponential heteroscedasticity model

$$\text{Prob}(y=1\,|\,\mathbf{x},\mathbf{z}) = F\left(\frac{\mu_j - \boldsymbol{\beta}'\mathbf{x}}{\exp(\boldsymbol{\gamma}'\mathbf{z})}\right) - F\left(\frac{\mu_{j-1} - \boldsymbol{\beta}'\mathbf{x}}{\exp(\boldsymbol{\gamma}'\mathbf{z})}\right)$$

E35.3.1 Testing for Heteroscedasticity

The model with homoscedastic disturbances is nested in this model ($\boldsymbol{\gamma} = \mathbf{0}$) so the standard tests, i.e., LM, likelihood ratio, and Wald, are available for testing the specification. The first two of these will be very convenient. To carry out an LM test, you could use the following: First define the two variable lists.

```
NAMELIST    ; x = ...
            ; z = ... $
```

Fit the model without heteroscedasticity. This command saves *b* and *mu* needed later.

```
ORDERED     ; Lhs = y  ; Rhs = x $
```

Define the zero vector for the variance parameters.

```
MATRIX      ; {h = Col(z)} ; gamma = Init (h,1,0) $
```

Now, fit the heteroscedastic model, but do not iterate. This displays the LM statistic.

```
ORDERED     ; Lhs = y ; Rhs = x ; Rh2 = z ; Het
            ; Start = b,gamma,mu ; Maxit = 0 $
```

To use a likelihood ratio test, instead, the preceding is modified as follows:

1. Add **CALC ; lr = logl $** after the first **ORDERED** command.

2. Omit **; Maxit = 0** from the second **ORDERED** command.

3. Add the command

   ```
   CALC     ; List ; chi = 2*(logl - lr) $
   ```

   after the second **ORDERED** command; *chi* is the chi squared statistic. This can be referred to the table with

   ```
   CALC     ; cstar = Ctb(.95,L) $
   ```

   which provides the necessary critical value.

The following experiment illustrates these computations. We test for heteroscedasticity in the health satisfaction model, using the three standard tests in an ordered logit model as the platform. To simplify it a bit, we use a restricted sample of only those individuals observed in all seven periods.

```
SAMPLE     ; All $
REJECT     ; _groupti < 7 $
ORDERED    ; Lhs = newhsat
           ; Rhs = one,female,hhninc,hhkids,educ
           ; Logit $
CALC       ; lr = logl $
```

This command carries out the LM test. The starting values are from the previous model for β and μ and zeros for the elements of γ. The test is requested with **; Maxit = 0**.

```
ORDERED    ; Lhs = newhsat
           ; Rhs = one,female,hhninc,hhkids,educ
           ; Logit ; Het ; Rh2 = married,univ,working,female,hhninc
           ; Start = b,0,0,0,mu ; Maxit = 0 $
```

This command estimates the full heteroscedastic model. Based on these results, we then carry out the likelihood ratio and Wald tests.

```
ORDERED    ; Lhs = newhsat
           ; Rhs = one,female,hhninc,hhkids,educ
           ; Logit ; Het ; Rh2 = married,univ,working,female,hhninc $
CALC       ; lu = logl $
CALC       ; List ; lrtest = 2*(lu - lr) $
MATRIX     ; gamma = b(6:10) ; vgamma = varb(6:10,6:10) $
MATRIX     ; List
           ; waldstat = gamma'<vgamma>gamma $
```

As might be expected in a sample this large, the three tests give the same answer. The LM, LR and Wald statistics obtained are 84.16200, 84.26808 and 83.90174, respectively.

The first set of results are for the restricted, homoscedastic model.

The next set of results is the computation of the Lagrange multiplier statistic. This next command does not reestimate the model. Note that the coefficient estimates are identical, save for the parameters in the variance function. The estimated standard errors do change, however, because in the restricted model above, the Hessian is computed and inverted just for the parameters estimated. In the results below, the Hessian is computed as if the inserted zeros for $\boldsymbol{\gamma}$ were actually the parameter estimates. These standard errors are not useful.

E35.3.2 Partial Effects in the Heteroscedasticity Model

Partial effects in the ordered choice models with heteroscedasticity appear from two sources, in the latent utility and in the variance function. When variables appear in both places, the total effect is the sum of the two terms.

$$\frac{\partial \text{Prob}(y_i = j \mid \mathbf{x}_i, \mathbf{z}_i)}{\partial \mathbf{x}_i} = \left[f\left(a_{j-1,s}\right) - f\left(a_{j,s}\right)\right]\frac{1}{w_i}\boldsymbol{\beta}, \; a_{j,s} = \frac{\mu_{j,s} - \boldsymbol{\beta}'\mathbf{x}_i}{\exp(\boldsymbol{\gamma}'\mathbf{z}_i)}$$

$$\frac{\partial \text{Prob}(y_i = j \mid \mathbf{x}_i, \mathbf{z}_i)}{\partial \mathbf{z}_i} = \left[\frac{f\left(a_{j-1,s}\right)a_{j-1,s} - f\left(a_{j,s}\right)a_{j,s}}{F\left(a_{j,s}\right) - F\left(a_{j-1.s}\right)}\right]\mathbf{z}_i.$$

Request the partial effects within the command with

; Partial Effects

(In previous versions, the command was **; Marginal Effects**. This form is still supported.)

The following results show the computation for the full model fit earlier. (Effects for outcomes 0 to 7 are omitted below.)

```
+-------------------------------------------+

+----------+----------+----------+----------+
```

The **PARTIAL EFFECTS** (or just **PARTIALS**) and **SIMULATE** commands receive the estimates form the heteroscedastic ordered choice model, so you can use them to analyze the probabilities or partial effects. For example, to replace the preceding results, use

PARTIALS ; Effects: female / hhninc ; Outcome = * $

Three differences are first, this estimator uses average partial effects by default (or means if you request them), second, it uses partial differences for dummy variables while the built in computation uses scaled coefficients and, third, as seen below, the **PARTIAL EFFECTS** command produces standard errors and confidence intervals for the partial effects.

E35.4 Sample Selection and Treatment Effects

The following describes an ordered probit counterpart to the standard sample selection model. This is only available for the ordered probit specification. The structural equations are, first, the main equation, the ordered choice model,

$$
\begin{aligned}
y_i^* &= \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ \ \varepsilon_i \sim F(\varepsilon_i\,|\boldsymbol{\theta}),\ E[\varepsilon_i] = 0,\ \text{Var}[\varepsilon_i] = 1,\\
y_i &= 0 \text{ if } y_i \le \mu_0,\\
&= 1 \text{ if } \mu_0 < y_i \le \mu_1,\\
&= 2 \text{ if } \mu_1 < y_i \le \mu_2,\\
&\ldots\\
&= J \text{ if } y_i > \mu_{J-1}.
\end{aligned}
$$

Second is the selection equation, a univariate probit model,

$$
\begin{aligned}
d_i^* &= \boldsymbol{\alpha}'\mathbf{z}_i + u_i,\\
d_i &= 1 \text{ if } d_i^* > 0 \text{ and } 0 \text{ otherwise},
\end{aligned}
$$

The observation mechanism is

$$[y_i,\mathbf{x}_i] \text{ is observed if and only if } d_i = 1.$$

$$\varepsilon_i,u_i \sim N_2[0,0,1,1,\rho]; \text{ there is 'selectivity' if } \rho \text{ is not equal to zero.}$$

This model is a straightforward generalization of the bivariate probit model with sample selection in Section E33.4.

The treatment effects model includes d_i as an endogenous binary variable in the ordered probit equation;

$$
\begin{aligned}
y_i^* &= \boldsymbol{\beta}'\mathbf{x}_i + \gamma d_i + \varepsilon_i,\ \ \varepsilon_i \sim F(\varepsilon_i\,|\boldsymbol{\theta}),\ E[\varepsilon_i] = 0,\ \text{Var}[\varepsilon_i] = 1,\\
y_i &= j \text{ if } \mu_{j-1} < y_i^* \le \mu_j,\ j = 0,1,\ldots,J\\
d_i^* &= \boldsymbol{\alpha}'\mathbf{z}_i + u_i,\\
d_i &= 1 \text{ if } d_i^* > 0 \text{ and } 0 \text{ otherwise},\\
\varepsilon_i,u_i &\sim N_2[0,0,1,1,\rho];\ d_i \text{ is endogenous if } \rho \text{ is not equal to zero.}
\end{aligned}
$$

This model is a generalization of the recursive bivariate probit model in Section E33.6.

E35.4.1 Command

These models require two passes to estimate. In the first, you fit a probit model for the selection (or treatment) variable, *d*. You then pass these values to the ordered probit model using a standard command for this operation, the **; Hold** parameter in the probit command. The two commands would be as follows: (This model is requested in the same fashion as *LIMDEP*'s other sample selectivity models.) Estimate first stage probit model and hold results for next step in the estimation.

PROBIT ; Lhs = d ; Rhs = Z list ; Hold $

Second, estimate the ordered probit model with selectivity

ORDERED ; Lhs = y ; Rhs = X ; ... as usual ; Selection $

You need not make any other changes in the ordered probit command. For the treatment effects case, the probit model is unchanged while the **ORDERED** command becomes

ORDERED ; Lhs = y ; Rhs = X,d ; ... as usual ; Selection ; All $

Note that the treatment variable now appears on the right hand side of the ordered choice model.

The **; Rst = ...** and **; CML:** options for imposing restrictions can be used freely with this model to constrain $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$. The parameter vector is

$$\boldsymbol{\Theta} = [\beta_1,\ldots,\beta_K,\alpha_1,\ldots,\alpha_L,\mu_1,\ldots,\mu_{J-1},\rho].$$

The usual warning about cross equation restrictions apply. You may also give your own starting values with **; Start = list ...**, though the internal values will usually be preferable.

E35.4.2 Saved Results

All results kept for the basic model are also kept; *b* and *varb* still include only $\boldsymbol{\beta}$, but **; Par** adds all of $[\boldsymbol{\mu},\boldsymbol{\alpha},\rho]$ to the parameter vector. This model adds two additional scalars:

rho = estimate of ρ,
varrho = estimate of asymptotic variance of estimated ρ.

NOTE: The estimates of $\boldsymbol{\alpha}$ update the estimates you stored with **; Hold** when you fit the probit model. Thus, for example, if you were to follow your **ORDERED** command immediately with the identical command, the starting values used for $\boldsymbol{\alpha}$ would be the MLEs from the prior ordered probit command, not the ones from the original probit model that you fit earlier. Also, if you were to follow this model command with a **SELECTION** model command, this estimate of $\boldsymbol{\alpha}$ would be used there, as well.

With the corrected estimates of [β,μ] in hand, predictions for this model are computed in the same manner as for the basic model without selection. The only difference is that no prediction for *y* is computed in the selection model if $d = 0$.

The **PARTIAL EFFECTS** and **SIMULATE** commands are not available for these two specifications (because they only operate on single equation models). An internal program for partial effects is provided. An application below illustrates.

E35.4.3 Applications

To illustrate the computations of this model, we have fit an equation for insurance purchase, then followed with an equation for health satisfaction in which insurance is taken to be a selection mechanism. The treatment effects formulation is shown later.

```
PROBIT      ; Lhs = public ; Rhs = one,age,hhninc,hhkids ; Hold $
ORDERED     ; Lhs = newhsat ; Rhs = one,age,educ,hhninc,female
            ; Selection
            ; Partial Effects $
```

This is the initial probit equation.

The FIML results provide two test statistics for 'selectivity.' The z statistic on the estimate of ρ is 3.58, which is well over the critical value of 1.96. The likelihood ratio test can be carried out using the initial results for the full model. The restricted value in

```
Log likelihood function    -13607.57507
Restricted log likelihood  -13609.65952
```

is based on the separate probit and ordered probit equations, which corresponds to the model with $\rho = 0$. The LR statistic would be 2(-13607.57507 - (-13609.65952) = 4.169. The critical chi squared with one degree of freedom would be 3.84, so the null hypothesis is rejected again.

A table of partial effects for the conditional model is produced for each outcome. Only the last one is shown here.

E35.4.4 Technical Details for the Selection Model

In the sample selection model, $[\varepsilon,u]$ are assumed to have a bivariate standard normal distribution with correlation ρ. Then, the probabilities in the log likelihood are:

For observations with $d_i = 0$, Prob = Prob$[d = 0]$ = univariate normal CDF.

For observations with $d_i = 1$, Prob = Prob$[y_i^*$ in particular range and $d = 1 \mid \rho]$

= bivariate normal probability.

The log likelihood for the model with sample selection is

$$\log L = \Sigma_{d=0} \log \Phi(-\boldsymbol{\alpha}'\mathbf{x}_2) + \Sigma_{d=1} \log \{\Phi_2[a_j,\boldsymbol{\alpha}'\mathbf{z},\rho] - \Phi_2[a_{j-1},\boldsymbol{\alpha}'\mathbf{z},\rho]\}$$

where $\Phi(\bullet)$ = standard normal CDF,

$\Phi_2(\bullet,\bullet,\bullet)$ = bivariate standard normal CDF,

$a_j = \mu_j - \boldsymbol{\beta}'\mathbf{x}$,

$a_{j-1} = \mu_{j-1} - \boldsymbol{\beta}'\mathbf{x}$,

and j = the value taken by y_i for that observation.

The same convention used above is maintained for the μs. The first derivatives are tedious but straightforward. They can be derived by applying the formulas given in Chapter E33 for the bivariate probit model. The derivation is a bit simpler here because for the differentiation of the bivariate CDF, q_1 and q_2 are both +1.

The second step reestimates $\boldsymbol{\alpha}$ from the probit model along with $\boldsymbol{\beta}$ and $\boldsymbol{\mu}$, obtaining a FIML set of estimates for all parameters including ρ. The ordered probit command results in two full rounds of estimation. In the first round, the model is estimated as if there were no selection. This provides the remaining starting values. The starting value for ρ is zero. Then, in the second round, the FIML estimates are computed. This model is rather difficult to estimate, and it is best to allow *LIMDEP* to use its own starting values. (In spite of this, nonconvergence can be a problem. When problems arise, be sure first to check the scaling of the independent variables.)

NOTE: This model is *not* fit by computing a 'lambda' variable, $\lambda_i = \phi(\boldsymbol{\alpha}'\mathbf{z}_i)/\ \Phi(\boldsymbol{\alpha}'\mathbf{z}_i)$ from the results of the first step probit and including it in the ordered probit at the second. It is estimated by maximizing the likelihood function above with respect to $\boldsymbol{\beta}$, $\boldsymbol{\alpha}$, and ρ. There will be no coefficient shown for such a variable in the estimation results, though the estimated ρ is shown.

NOTE: (This is another frequently asked question.) All observations in the sample are used in fitting this model, not just the ones for which $d = 1$. The observations for which $d = 0$ contribute to the probit part of the log likelihood. The remainder contribute both to the probit and the ordered probit.

The treatment effects model is developed in exactly the same steps as the recursive bivariate probit model in Section E33.6. The relevant probabilities that enter the log likelihood are

$$\log L_i \quad = \log [\text{Prob}(d_i = 1 \text{ or } 0) \times \text{Prob}(y_i = j \mid d_i = 1 \text{ or } 0)$$

which, once again, is simply the joint probability. Thus, the log likelihood function has terms

$$\Sigma_{\textit{all observations}} \log \{\Phi_2[(a_j - \gamma d_i), q_i\boldsymbol{\alpha}'\mathbf{z}, q_i\rho] - \Phi_2[a_{j-1} - \gamma d_{i,}\ q_i\boldsymbol{\alpha}'\mathbf{z}, q_i\rho]\}$$

where $q_i = 2d_i - 1 = -1\ (+1)$ when $d_i = 0\ (1)$.

E35.5 Generalized Ordered Choice and Parallel Regressions

Two specification questions that bear directly on the model discussed to this point are the 'proportional odds' assumption and the 'parallel regressions' assumption. We consider them in turn.

E35.5.1 The Proportional Odds Assumption

The proportional odds assumption is imposed (only) by the ordered logit model. If

$$\text{Prob}[y_i = j] = \Lambda(\mu_j - \boldsymbol{\beta}'\mathbf{x}) - \Lambda(\mu_{j-1} - \boldsymbol{\beta}'\mathbf{x})$$

Then,

$$\text{Prob}[y_i \le j] = \Lambda(\mu_j - \boldsymbol{\beta}'\mathbf{x})$$

Using the simple algebra of the logit model, it follows that

$$\log\{\text{Prob}[y_i \le j] / \text{Prob}[y_i > j]) = \mu_j - \boldsymbol{\beta}'\mathbf{x}_i.$$

This is known as the proportional odds assumption, and it is viewed as a restrictive assumption of the model. The implication is that the log-odds for any outcome, μ_j, differs from that for any other only by a constant, j. A number of alternative tests and assumptions have been proposed to relax the 'restriction.' In point of fact, the researcher bound by this restriction is a prisoner of the logistic assumption to begin with. It does not apply to any other model that we have considered, so the simple expedient to pursue if this assumption is viewed as problematic is to switch to an ordered probit model. But, this is merely a question of functional form, and the probit model may be no less 'restrictive' in this regard than the logit model. There is, however, a more substantive issue to consider. Whether the proportional odds assumption imposes a restriction on behavior is at least conceivable. The question is not unrelated to that of the 'independence from irrelevant alternatives' implication of the logit model in the discrete choice framework. That question seems at least ambiguous here – whether an assumption about the log odds translates backwards into an assumption about behavior seems at least uncertain.

We note, some authors have advocated abandoning the latent regression model altogether, in some cases, in favor of a multinomial logit model for the J+1 outcomes. By this prescription, one loses the ordered nature of the data, which could be argued to be at higher cost than the initial assumption that the same parameter vector, $\boldsymbol{\beta}$, appears in the probabilities of all J+1 outcomes to begin with. This issue is not settled in the literature, and can't be resolved here. We conclude at this point only that the alternatives that have been suggested can all be fit with *LIMDEP*, using other modeling frameworks.

E35.5.2 Brant Test of the Parallel Regressions Assumption

The 'parallel regressions' assumption, such as it is, also characterizes the ordered logit model, but no other functional form. The assumption, itself, is a curious one. The term appears to have gotten some impetus from a frequently cited 'result' for the ordered probit model in Long (1997) which states, for, say, a five outcome model, that

$$\frac{\partial \Pr[y \le 1 | x]}{\partial x} = \frac{\partial \Pr[y \le 2 | x]}{\partial x} = \frac{\partial \Pr[y \le 3 | x]}{\partial x}$$

at any trio of points, x_1, x_2 and x_3, at which all three probabilities are equal. 'It is this sense that the regression curves are parallel.' (Long (1997), page 141) The implication that the 'regression curves' implied by the model are parallel is cited as a significant restriction of the ordered choice model. In fact, these are not 'regressions' in any sense – they are not conditional mean functions. But, that is merely terminology. In this model, *some things* are parallel. The so called parallel regressions restriction has attracted some attention. A familiar 'test' for the assumption is the Brant test. Arguably, the Brant test is a test of preference homogeneity. It does provide an interesting specification test for the model – the preference heterogeneity implication of the model is testable. What rejection of the hypothesis then suggests is less than obvious, however.

The Brant test of homogeneity is constructed as follows: According to the ordered logit model,

$$\text{Prob}(y_i > j \mid \mathbf{x}_i) = \Lambda[\boldsymbol{\beta}'\mathbf{x}_i - \mu_j],\ j = 0, 1, ..., J\text{-}1.$$

If we define $z_{ij} = 1[y_i > j]$, then this defines a simple binary logit model for the J-1 binary outcomes, z_{ij}. The force of the restrictions of the model is that each such probability 'model' has the same coefficient vector, $\boldsymbol{\beta}$, though each has its own constant term. Define these as $\boldsymbol{\beta}_0$, $\boldsymbol{\beta}_1$,... The test is carried out by constructing a Wald test of the null hypothesis that $\boldsymbol{\beta}_0 - \boldsymbol{\beta}_1 = \mathbf{0}$, $\boldsymbol{\beta}_0 - \boldsymbol{\beta}_2 = \mathbf{0}$, etc. Note that the model does not imply that the constant terms are the same. We will return to this detail later. To carry out the test, we compute the J-1 binary logit models, and obtain $\mathbf{b}_0,...,\mathbf{b}_{J\text{-}1}$. With each coefficient vector, we compute the predicted probabilities, $p_{ij} = \exp(\mathbf{b}_j'\mathbf{x}_i)/[1+\exp(\mathbf{b}_j'\mathbf{x}_i)]$ for the sample and the quantities $w_{imj} = p_{ij} = p_{im}p_{ij}$. The moment matrix $\mathbf{V}_{mj} = \Sigma_i\, w_{imj}\mathbf{x}_i\mathbf{x}_i'$ is computed, where $\mathbf{x}_i$ includes the constant term. The matrix,

$$\mathbf{A}_{mj} = \mathbf{V}_{mm}^{-1}\, \mathbf{V}_{mj}\, \mathbf{V}_{jj}^{-1},$$

estimates the asymptotic covariance of $\mathbf{b}_m$ and $\mathbf{b}_j$. The row and column corresponding to the constant term are removed. Then, the covariance matrix, $\mathbf{V}$, for the set of estimates $\mathbf{b} = [\mathbf{b}_0',\mathbf{b}_1',...,\mathbf{b}_{J\text{-}1}']'$ is assembled in partitioned form using the blocks defined above (and their transposes). The Wald test of the homogeneity restriction is carried out using the chi squared statistic,

$$Wald = (\mathbf{Db})'\,[\mathbf{DVD}']^{-1}(\mathbf{Db}),$$

where

$$\mathbf{D} = \begin{bmatrix} \mathbf{I} & \mathbf{-I} & \mathbf{...} & \mathbf{0} \\ \mathbf{I} & \mathbf{0} & \mathbf{-I} & \mathbf{...} \\ \mathbf{...} & \mathbf{...} & \mathbf{...} & \mathbf{...} \\ \mathbf{I} & \mathbf{0} & \mathbf{...} & \mathbf{-I} \end{bmatrix}.$$

The statistic has a limiting chi squared distribution with degrees of freedom equal to $(J\text{-}1)K_1$ where K_1 is the number of independent variables in the model, not including the constant term. (E.g., if the original problem has y taking values 0,1,2,3,4, then we will compute $J = 4$ logit coefficient vectors, $\mathbf{b}_0$, $\mathbf{b}_1$, $\mathbf{b}_2$, $\mathbf{b}_3$, and (**J** - 1) contrasts, $\mathbf{b}_0 - \mathbf{b}_1$, $\mathbf{b}_0 - \mathbf{b}_2$ and $\mathbf{b}_0 - \mathbf{b}_3$.).

The Wald statistic is an omnibus test for homogeneity of the entire coefficient vector. It is possible that some of the coefficients are (or appear to be) homogeneous while others are not. The test can be carried out coefficient by coefficient by isolating just one of the contrasts in the set of K_1. Define the matrix **C** with J-1 rows and $(J\text{-}1)K_1$ columns. The row is a set of J-1 row vectors. There is a single one in the kth position of the jth row vector in the jth row of **C**, and zeros elsewhere Then, the chi squared for the kth coefficient is

$$Wald_k = [\mathbf{C}(\mathbf{Db})]'[\mathbf{C}(\mathbf{DVD}')\mathbf{C}]^{-1}[\mathbf{C}(\mathbf{Db})].$$

This statistic has a limiting chi squared distribution with J-1 degrees of freedom.

Application of the Brant Test

The Brant test is automated in *LIMDEP*. You need only add

; Brant test

to your **ORDERED ; Logit** command. The full set of results is computed and reported.

We have applied this test to the treatment effects model fit earlier, while treating *public* as exogenous. The following results are obtained.

```
+------------------------------------------------+
| Brant specification test for equal coefficient |
| vectors in the ordered prob. model. The model  |
| implies that logit[Prob(y>j|x)]=beta(j)*x - mj |
| for all j = 0,..., 9. The chi squared test is  |
| H0:beta(0) = beta(1) = ... beta( 9)            |
| Chi squared test statistic =    236.72126      |
| Degrees of freedom         =     45            |
| P value                    =       .00000      |
+------------------------------------------------+

===========================================================================
Specification Tests for Individual Coefficients in Ordered Logit Model

```

Based on these results, the null hypothesis is rejected. The results for the individual coefficients suggest that the hypothesis is rejected for all the individual coefficients as well.

The Brant test can be adapted to the normal distribution (ordered probit model). Two changes are required. First, in the procedure, itself, we would fit probit models rather than logit models. Second, we must change the computation of the parts of the asymptotic covariance matrix to conform to the probit model. To do this, we will use the BHHH estimator. The MLE of the parameter vector in each regression is written $(\mathbf{b}_j - \boldsymbol{\beta}) = \mathbf{H}_j^{-1}\mathbf{g}_j$ where $\mathbf{H}_j$ is the Hessian and $\mathbf{g}_j$ is the first derivatives vector. We then use the information matrix equality to invoke the BHHH estimator for the asymptotic variance of $\mathbf{b}_j$ which we write $(\mathbf{G}_j'\mathbf{G}_j)^{-1}$. For the asymptotic covariances, we once again invoke the information matrix equality, and the estimator of $\mathbf{H}_j$, which produces a sandwich style estimator,

$$\text{Est.Asy.Cov}[\mathbf{b}_j,\mathbf{b}_m] = (\mathbf{G}_j'\mathbf{G}_j)^{-1} (\mathbf{G}_j'\mathbf{G}_m) (\mathbf{G}_m'\mathbf{G}_m)^{-1}.$$

The remaining detail is how to compute the rows of $\mathbf{G}_j$. For the probit model, the relevant derivative is

$$\partial \log P_{ji} / \partial \boldsymbol{\beta}_j = (2z_{ji}-1)\, \phi[\boldsymbol{\beta}_j'\mathrm{x}_i] / \Phi[(2z_{ji}-1)\, \boldsymbol{\beta}_j'\mathbf{x}_i]\, \mathbf{x}_i.$$

LIMDEP detects this internally and adjusts the computations. For the earlier example, the automatically generated results are as follows:

```
+------------------------------------------------+
| Brant specification test for equal coefficient |
| vectors in the ordered probit model. The model |
| implies that normit[Prb(y>j|x)]=beta(j)*x - mj |
| for all j = 0,..., 9. The chi squared test is  |
| H0:beta(0) = beta(1) = ... beta( 9)            |
| Chi squared test statistic =    200.97546      |
| Degrees of freedom         =     45            |
| P value                    =      .00000       |
+------------------------------------------------+

The results are consistent with those for the ordered logit model, which might be expected.

E35.6 Generalized Ordered Choice Models

The preceding notwithstanding, researchers have devoted considerable attention to restructuring the ordered choice model to redeem it from the objectionable result noted above. We note, first, the latent regressions, ordered logit model already analyzed here implies the preference structure,

$$\text{Prob}[y_i \leq j \mid \mathbf{x}_i] = \Lambda[\mu_j - \boldsymbol{\beta}' \mathbf{x}_i].$$

The parallel regressions assumption is that the same $\boldsymbol{\beta}$ appears in every equation. The generalized ordered logit model suggested, e.g., by Williams (2006) is (using our normalizations)

$$\text{Prob}[\, y_i \leq j \mid \mathbf{x}_i \,] = \Lambda[\, \mu_j - \boldsymbol{\beta}_j' \mathbf{x}_i], j = 1,2,...,J.$$

Versions of this model appear in a number of publications. This specification has two major flaws. First, there is no parametric restriction, other than the one we seek to avoid to begin with ($\boldsymbol{\beta}_j = \boldsymbol{\beta}$ for all j) that can be used to make the probabilities of the $J + 1$ outcomes sum to one. The model is internally inconsistent unless each outcome is viewed as a model in its own right – a peculiar assumption about the distribution of preferences across individuals. Worse, for the interior outcomes of the dependent variable (i.e., not zero and not J), the probability is

$$\text{Prob}[y_i = j \mid \mathbf{x}_i] = \Lambda[\, \mu_j - \boldsymbol{\beta}_j'\mathbf{x}_i] - \Lambda[\, \mu_{j-1} - \boldsymbol{\beta}_{j-1}' \mathbf{x}_i]$$

a difference which cannot be forced even to be positive. For any $\boldsymbol{\beta}_j$ and $\boldsymbol{\beta}_{j-1}$, whether or not this difference is positive will be data dependent, and if there is more than one variable in $\mathbf{x}_i$, would be pure luck as much as anything else. The model is not an internally consistent probability model defined over an outcome space.

The difficulty being dealt with here ultimately arises from an assumption that the coding of the dependent variable in the model is structural. Why the observed respondent should have preferences that are structurally defined in terms of the coding of the survey is difficult to fathom. For example, in the simplest imaginable cases, it is difficult to see why the preference orderings of respondents should be functions of whether the surveyor presents them with a three point or a five point scale. In more general terms, in the generalized ordered logit model, the parameter vector seems to be a function of the dependent variable. This is unlike the multinomial logit model, in which the multiplicity of parameter vectors is merely the parameterization of J distinct utility functions defined across J alternatives. Here, each parameter vector is identified with a different response to the same question. It is unclear how one should interpret such a structure.

There is another aspect of this construction that suggests the ambiguity of the model. It is not possible to simulate data that correspond to the assumptions of the model. In the ordered probit model, with $\mathbf{x}$, $\boldsymbol{\beta}$ and $\boldsymbol{\mu}$ known, in order to simulate a draw on y, we would compute $\boldsymbol{\beta}'\mathbf{x}$, draw a random normal value ε, compute $y^* = \boldsymbol{\beta}'\mathbf{x} + \varepsilon$, then see which interval, $(-\infty,0)$, $(0,\mu_1)$, (μ_1,μ_2) etc. contains y^* to produce $y = 0$ or 1 or 2, etc. This is not possible for the 'generalized model' suggested here, because one needs to know y in order to compute $\boldsymbol{\beta}_j'\mathbf{x}$ (you need to know which $\boldsymbol{\beta}$ to use) so the outcome has to be known before ε is even drawn. This is the implication of the internal incoherency of the model.

E35.7 Hierarchical Ordered Probit Models

The hierarchical ordered probit model (or generalized ordered probit model) is a univariate ordered probit model in which the threshold parameters depend on variables. (We opt for the acronym HOPIT model as slightly more melodious than GOPIT. In the original proposal of this model (Pudney and Shields (2000)), the thresholds were modeled as linear functions of the data, producing the model

$$\begin{aligned} y^* &= \boldsymbol{\beta}'\mathbf{x} + \varepsilon \\ y &= 0 \text{ if } y^* \leq 0, \\ &= 1 \text{ if } 0 < y^* \leq \mu_1, \\ &= 2 \text{ if } \mu_1 < y^* \leq \mu_2, \\ &\ldots \\ \mu_j &= \boldsymbol{\delta}_j'\mathbf{z}. \end{aligned}$$

(There is no disturbance on the equation for the threshold variables.) The model has an inherent identification problem, because in

$$\text{Prob}[y = j] = \Phi(\mu_j - \boldsymbol{\beta}'\mathbf{x}) - \Phi(\mu_{j-1} - \boldsymbol{\beta}'\mathbf{x}),$$

if **x** and **z** have variables in common, then (with a sign change) the same model is produced whether the common variable appears in μ_j or $\boldsymbol{\beta}'\mathbf{x}$. (Pudney and Shields note and discuss this.) The *LIMDEP* implementation avoids this indeterminacy by using a different functional form. (That does imply that we achieve identification through functional form.)

Two forms of the model are provided.

$$\text{Form 1:}\ \mu_j = \exp(\theta_j + \boldsymbol{\delta}'\mathbf{z})$$

$$\text{Form 2:}\ \mu_j = \exp(\theta_j + \boldsymbol{\delta}_\mathbf{j}'\mathbf{z})$$

Note that in form 1, each μ_j has a different constant term, but the same coefficient vector, while in form 2, each threshold parameter has its own parameter vector. (We note, for purposes of estimation, it is always necessary for μ_j to be greater than μ_{j-1}. We are able to impose that on form 1 fairly easily by parameterizing θ_j in a way that does so. However, for form 2, this is much more difficult to obtain, and users should expect to see diagnostics about unordered thresholds when they use form 2.) The threshold coefficients will be difficult to compare between the original ordered probit model and form 2 of the HOPIT model. For form 1, the model reverts to the unmodified ordered probit model if the single vector $\boldsymbol{\delta}$ equals **0**.

The command for this model augments the usual ordered probit command with the specification for the thresholds,

```
ORDERED     ; Lhs = ... ; Rhs = ...
            ; HO1 = list of variables or ; HO2 = list of variables $
```

The list of variables in the HO1 or HO2 part must not contain a constant term (*one*). All other options for the ordered probit model are exactly as described previously, including fitted values, restrictions, marginal effects, and so on, unchanged. *This form of the ordered probit model can also be combined with the sample selection corrected ordered probit model described in Section E35.4.*

In the example below, the model is first fit to the health satisfaction variable with no modification to the thresholds. In the HOPIT model fit next, the thresholds vary with whether or not the family has kids in the household and with the number of types of insurance they have. For purpose of a limited example, we use a subset of the sample.

```
SAMPLE      ; All $
CREATE      ; insuranc = public + addon $
ORDERED     ; Lhs = hsat ; Rhs = one,age,educ,female,hhninc
            ; Partial Effects $
ORDERED     ; Lhs = hsat ; Rhs = one,age,educ,female,hhninc
            ; HO1 = hhkids,insuranc
            ; Partial Effects $
```

These are the estimates for the base case. (We have omitted the partial effects.)

E35.8 Zero Inflated Ordered Probit (ZIOP, ZIHOP) Models

Harris and Zhao (2007) have developed a zero inflated ordered probit (ZIOP) counterpart to the zero inflated Poisson model. The ZIOP formulation would appear

$$
\begin{aligned}
d^* &= \boldsymbol{\alpha}'\mathbf{w} + u, & d &= 1\,(d^* > 0)\\
y^* &= \boldsymbol{\beta}'\mathbf{x} + \varepsilon, & y &= 0 \text{ if } y^* \le 0 \text{ or } d = 0 \leftarrow\\
& & &\ 1 \text{ if } 0 < y^* \le \mu_1 \text{ and } d = 1,\\
& & &\ 2 \text{ if } \mu_1 < y^* \le \mu_2 \text{ and } d = 1,\\
& & &\ \text{and so on.}
\end{aligned}
$$

The first equation is assumed to be a probit model (based on the normal distribution) – this estimator does not support a logit formulation. The correlation between u and ε is ρ, which by default equals zero, but may be estimated instead. The latent class nature of the formulation has the effect of inflating the number of observed zeros, even if u and ε are uncorrelated. The model with correlation between u and ε is an optional specification that analysts might want to test. The zero inflation model may also be combined with the hierarchical (generalized) model discussed in the previous section. Thus, it might also be specified as part of the model that

$$
\begin{aligned}
\text{Form 1:}\ \mu_j &= \exp(\theta_j + \boldsymbol{\delta}'\mathbf{z})\\
\text{Form 2:}\ \mu_j &= \exp(\theta_j + \boldsymbol{\delta}_j'\mathbf{z})
\end{aligned}
$$

The command structure for ZIOP and ZIHOP models are

```
PROBIT      ; Lhs = d ; Rhs = variables in w ; Hold $
ORDERED     ; Lhs = y ; Rhs = variables in x
            ; ZIOP $
```

This form of the model imposes $\rho = 0$. To allow the correlation to be a free parameter, add

```
            ; Correlation
```

to the command.

NOTE: The **; HO1** and **; HO2** specifications discussed in the preceding section may also be used with this model.

In the example below, we continue the analysis of the health care data. The (artificial) model has the zero inflation probability based on the presence of ‘public’ insurance while the ordered outcome continues to be the self reported health satisfaction. Here, we have used the entire sample of 27,236 observations.

The commands are:

```
SAMPLE      ; All $
PROBIT      ; Lhs = public
            ; Rhs = one,age,hhninc,hhkids,married ; Hold $
ORDERED     ; Lhs = hsat
            ; Rhs = one,age,educ,female

E35.9 Bivariate Ordered Probit and Polychoric Correlation

The bivariate ordered probit model is analogous to the SUR model for the ordered probit case:

$$
\begin{aligned}
y_{ji}^* &= \boldsymbol{\beta}_j'\mathbf{x}_{ji} + \varepsilon_{ji}\\
y_{ji} &= 0 \text{ if } y_{ji}^* \le 0,\\
&\quad 1 \text{ if } 0 < y_{ji}^* < \mu_1,\\
&\quad 2, \ldots \text{ and so on, } j = 1,2,
\end{aligned}
$$

for a pair of ordered probit models that are linked by Cor(ε_{1i},ε_{2i}) = ρ. The model can be estimated one equation at a time using the results described earlier. Full efficiency in estimation and an estimate of ρ are achieved by full information maximum likelihood estimation. *LIMDEP*'s implementation of the model uses FIML, rather than GMM. Either variable (but not both) may be binary. If both are binary, the bivariate probit model should be used. (The development here draws on Butler and Chatterjee (1997) who analyzed maximum likelihood and GMM estimators for the bivariate extension of the ordered probit model.)

The command structure requires prior estimation of the two univariate models to provide starting values for the iterations. The third command then fits the bivariate model. We assume that the first variable is multinomial.

```
ORDERED      ; Lhs = y1 ; Rhs = ... $
MATRIX       ; b1 = b ; mu1 = mu $
```

Use one of the following. If the second variable has more than two outcomes, use

```
ORDERED      ; Lhs = y2 ; Rhs = ... $
MATRIX       ; b2 = b ; mu2 = mu $
```

If the second variable is binary, use

```
PROBIT       ; Lhs = y2 ; Rhs = ... $
MATRIX       ; b2 = b $
```

Then, estimate the bivariate model with

```
ORDERED      ; Lhs = y1,y2 ; Rh1 = ... ; Rh2 = ...
             ; Start = b1,mu1,b2,mu2, 0 $
```

The variable *mu*2 is omitted if *y*2 is binary. The final zero in the list of starting values is for ρ. You may use some other value if you have one.

The standard options for estimation are available (iteration controls, technical output, cluster corrections, etc.). You may also retain fitted values with **; Keep = yf1,yf2** (note that both names are provided). Probabilities for the joint observed outcome are retained with **; Prob = name**. Listings of probabilities for outcomes are obtained with **; List** as usual.

To illustrate the estimator, we use the health care utilization data analyzed earlier. The two outcomes are *y*1 = health care satisfaction, taking values 0 to 5 (we reduced the sample) and *y*2 = the number of types of health care insurance. Results for a bivariate ordered probit model appear below. The initial univariate models are omitted.

```
SAMPLE       ; All $
REJECT       ; newhsat > 5  | _groupti < 7  $
ORDERED      ; Lhs = newhsat ; Rhs = one,age,educ,female,hhninc $
MATRIX       ; b1 = b ; mu1 = mu $
CREATE       ; insuranc = public + addon $
CROSSTAB     ; Lhs = newhsat  ; Rhs = insuranc $
ORDERED      ; Lhs = insuranc ; Rhs = one,age,educ,hhninc,hhkids $
MATRIX       ; b2 = b ; mu2 = mu $
ORDERED      ; Lhs = newhsat,insuranc
             ; Rh1 = one,age,educ,female,hhninc
             ; Rh2 = one,age,educ,hhninc,hhkids
             ; Start = b1,mu1,b2,mu2,0 $
```

Polychoric Correlation

The polychoric correlation coefficient is used to quantify the correlation between discrete variables that are qualitative measures. The standard interpretation is that the discrete variables are discretized counterparts to underlying quantitative measures. We typically use ordered probit models to analyze such data. The polychoric correlation measures the correlation between $y_1 = 0,1,...,J_1$ and $y_2 = 0,1,...,J_2$. (Note, J_1 need not equal J_2.) One of the two variables may be binary as well. (If both variables are binary, we use the tetrachoric correlation coefficient described in Section E33.3.)

By this description, the polychoric correlation is simply the correlation coefficient in the bivariate ordered probit model when the two equations contain only constant terms. Thus, to compute the polychoric correlation for a pair of qualitative variables, you can use *LIMDEP*'s bivariate ordered probit model. The commands are as follows: The first two model commands compute the starting values, and the final one computes the correlation.

```
      ORDERED   ; Lhs = y1 ; Rhs = one $
      MATRIX    ; b1 = b ; mu1 = mu $
      ORDERED   ; Lhs = y2 ; Rhs = one $
      MATRIX    ; b2 = b ; mu2 = mu $

or    PROBIT    ; Lhs = y2 ; Rhs = one $
      MATRIX    ; b2 = b $

Then, ORDERED   ; Lhs = y1,y2 ; Rh1 = one ; Rh2 = one
                ; Start = b1,mu1,b2,mu2,0 $
```

For a simple example, we compute the polychoric correlation between self reported health status and sex in the health care usage data examined earlier. Results appear below. Note that the 'model' for sex is simply a computational device.

```
ORDERED   ; Lhs = newhsat ; Rhs = one $
MATRIX    ; b1 = b ; mu1 = mu $
PROBIT    ; Lhs = female ; Rhs = one $
MATRIX    ; b2 = b $
ORDERED   ; Lhs = newhsat,female
          ; Rh1 = one ; Rh2 = one ; Start = b1,mu1,b2,0 $
```

```

E36: Panel Data Models for Ordered Choice

E36.1 Introduction

The basic ordered choice model is based on the following specification: There is a latent regression,

$$y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ \ \varepsilon_i \sim F(\varepsilon_i\,|\boldsymbol{\theta}),\ \mathrm{E}[\varepsilon_i|\mathbf{x}_i] = 0,\ \mathrm{Var}[\varepsilon_i|\mathbf{x}_i] = 1,$$

The observation mechanism results from a complete censoring of the latent dependent variable as follows:

$$\begin{aligned} y_i &= 0 \text{ if } y_i \le \mu_0, \\ &= 1 \text{ if } \mu_0 < y_i \le \mu_1, \\ &= 2 \text{ if } \mu_1 < y_i \le \mu_2, \\ &\ldots \\ &= J \text{ if } \ y_i > \mu_{J\text{-}1}. \end{aligned}$$

The latent 'preference' variable, y_i^* is not observed. The observed counterpart to y_i^* is y_i. Four stochastic specifications are provided for the basic model shown above. The *ordered probit* model based on the normal distribution was developed by Zavoina and McElvey (1975). It applies in applications such as surveys, in which the respondent expresses a preference with the above sort of ordinal ranking. The variance of ε_i is assumed to be one, since as long as y_i^*, $\boldsymbol{\beta}$, and ε_i are unobserved, no scaling of the underlying model can be deduced from the observed data. Estimates are obtained by maximum likelihood. The probabilities which enter the log likelihood function are

$$\mathrm{Prob}[y_i = j] = \mathrm{Prob}[y_i^* \text{ is in the } j\text{th range}].$$

The model may be estimated either with individual data, with $y_i = 0, 1, 2, \ldots$ or with grouped data, in which case each observation consists of a full set of J+1 proportions, $p_{0i},\ldots,p_{Ji}$. This chapter gives the panel data extensions of the ordered choice model.

NOTE: The panel data versions of the ordered choice models require individual data.

There are four classes of panel data models in *LIMDEP*, fixed effects, random effects, random parameters, and latent class. All four are supported for all five of the functional forms presented in Chapter E34.

E36.2 Fixed Effects Ordered Choice Models

The fixed effects models are estimated by maximum likelihood. The command for requesting the model is in two parts. You must fit the model without fixed effects first, to provide the starting values, then the command for the fixed effects estimator follows. The first command and the second must be identical, save for the panel specification in the second command and the constant term in the first, as noted below.

```
ORDERED   ; Lhs = dependent variable
          ; Rhs = independent variables
          [ ; Model = Weibull, Logit , Arctangent or Gompertz ] $
ORDERED   ; Lhs = dependent variable
          ; Rhs = independent variables
          ; Pds = fixed number of periods or count variable
          ; Fixed Effects
          [ ; Model = Weibull, Logit, Arctangent or Gompertz ] $
```

NOTE: The Rhs in your first command must contain a constant term, *one* as the first variable. Your Rhs list for a fixed effects model generally should not include a constant term as the fixed effects model fits a complete set of constants for the set of groups. But, for the ordered probit model, you must provide the identical Rhs list as in the first command, so for this model, do include *one*. It will be removed prior to beginning estimation. When you set up your commands, leaving *one* in the Rhs list will help insure that your model specification is correct. It will look correct. Note, it is crucial that you fit the pooled model first so that *LIMDEP* can find the right starting values for the second estimation step.

The fixed effects model assumes a group specific effect:

$$\text{Prob}[y_{it} = j] = F(j, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i)$$

where α_i is the parameter to be estimated. You may also fit a two way fixed effects model

$$\text{Prob}[y_{it} = j] = F(j, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i + \gamma_t)$$

where γ_t is an additional, time (period) specific effect. The time specific effect is requested by adding

; Time

to the command if the panel is balanced, and

; Time = variable name

if the panel is unbalanced. For the unbalanced panel, we assume that overall, the sample observation period is $t = 1,2,..., T$ and that the '*Time*' variable gives for the specific group, the particular values of t that apply to the observations. Thus, suppose your overall sample is five periods. The first group is three observations, periods 1, 2, 4, while the second group is four observations, 2, 3, 4, 5. Then, your panel specification would be

	; Pds = Ti	for example, where *Ti* = 3, 3, 3, 4, 4, 4, 4
and	**; Time = Pd**	for example, where *Pd* = 1, 2, 4, 2, 3, 4, 5.

NOTE: See the discussion below on how this model is estimated. It places an important restriction on the two way fixed effects model.

You must provide the starting values for the iterations by fitting the basic model without fixed effects. You will have a constant term in these results even though it is dropped from the fixed effects model. This is used to get the starting value for the fixed effects. Iterations begin with the restricted model that forces all the fixed effects to equal the constant term in the restricted model.

Results that are kept for this model are

Matrices: *b* = estimate of $\boldsymbol{\beta}$
varb = asymptotic covariance matrix for estimate of $\boldsymbol{\beta}$.
alphafe = estimated fixed effects

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variables*

Last Function: None

The upper limit on the number of groups is 100,000. Technical details on the method of estimation for this model are given below and in Chapter R23. Full estimation of the fixed effects model in this fashion encounters the 'incidental parameters' problem.

NOTE: In the ordered probit model with fixed effects α_i, the individual effect coefficient cannot be estimated if the dependent variable within the group takes the same value in every period. The results will indicate how many such groups had to be removed from the sample.

E36.2.1 Standard Model Specifications for Panel Data Ordered Choice Models

This is the full list of general specifications that are applicable to this model estimator. See Chapter E1 and references noted there for further details on these specifications.

Controlling Output from Model Commands

; Par keeps ancillary parameters μ_j with main parameter β vector in *b*.
; Partial Effects displays marginal effects, same as **; Marginal Effects**.
; Table = name saves model results to be combined later in output tables.

Asymptotic Covariance Matrices

Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Hpt = n sets the number of points to use for Hermite quadrature
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Prob = name saves probabilities as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E36.2.2 Application

We have fit a fixed effects ordered probit model with the German health care data used in the previous examples. This is an unbalanced panel with 7,293 individuals. The health status variable is coded 0 to 10. The model is fit using the commands below. We first fit the pooled model, then the fixed effects model.

```
SAMPLE      ; All $

```

The results below compare the estimated partial effects for the outcome y = 10 for the fixed effects model followed by the pooled model. The differences are large. Note that the *educ* coefficient is significantly negative in the fixed effects model and significantly positive in the pooled model. The log likelihood for the pooled model is -57420.08880, so the LR test statistic is about 30,000 with 7,293 degrees freedom. The critical chi squared for 7,292 degrees of freedom, given with the command

CALC ; List ; Ctb(.95,7292) $

is 7,491, which suggests that the fixed effects estimator, at least at this point is preferred. The remains some question, however, because of the incidental parameters problem. Based on received results, in the OP setting, the coefficient is biased away from zero, but not in sign, which still weighs in favor of the FEM result.

Technical Notes

The fixed effects model is fit essentially by 'brute force.' *LIMDEP* actually estimates the full $K + N$ up to 100,150 coefficients by Newton's method. It is possible to fit the huge number of coefficients because we take advantage of the properties of the sparse second derivatives matrix. One of the implications, however, is that there is no covariance matrix computed for the fixed effects. It is possible to test for the fixed effects model with a likelihood ratio test or a Lagrange multiplier test, but since the covariance matrix is not computed, it is not possible to do any kind of inference for individual fixed effects.

The two way fixed effects estimator is computed by actually creating the time specific dummy variables and adding them to the model. This means that the usual 150 parameter limit on model size applies to the number of variables in the model plus the number of periods (minus one).

Marginal effects in the fixed effects model are computed at the means of the data and with the sample average of the fixed effects estimates as the constant term.

The unconditional log likelihood is maximized by using Newton's method. A full discussion of the method is given in Chapter R23.

E36.3 Random Effects Ordered Choice Models

The random effects model is

$$y_{it}^* = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i$$

where $i = 1,...,N$ indexes groups and $t = 1,...,T_i$ indexes periods. (As always, the number of periods may vary by individual.) The unique term, ε_{it}, is distributed as $N[0,1]$, standard logistic, extreme value, or Gompertz as specified in the general model discussed earlier. The group specific term, u_i is distributed as $N[0,\sigma^2]$ for all cases. Note that the unobserved heterogeneity, u_i is the same in every period. The parameters of the model are fit by maximum likelihood. As in the binary choice models, the underlying variance, $\sigma^2 = \sigma_u^2 + \sigma_\varepsilon^2$ is not identified. The reduced form parameter, $\rho = \sigma_u^2/\left(\sigma_\varepsilon^2 + \sigma_u^2\right)$, is estimated directly. With the normalization that we used earlier, $\sigma_\varepsilon^2 = 1$, we can determine $\sigma_u = \sqrt{\rho/(1-\rho)}$. Further discussion of the estimation of the structural parameters appears in Chapter R24. The ordered probability model with random effects is estimated in the same fashion as the binary probability models with random effects. The heterogeneity is handled by using Hermite quadrature to integrate the effect out of the joint density of the T_i observations for the ith group. Technical details appear at the end of this section.

E36.3.1 Commands

The specification is for the ordered probability model. Use

```
ORDERED     ; Lhs = ... ; Rhs = ...
            ; Panel spec.
            [ ; Model = Logit, Comploglog, Arctangent or Gompertz] $
```

where the **; Pds** specification follows the standard convention, fixed T or variable name for variable T. The default is the ordered probit. Request the ordered logit just by adding **; Model = Logit** etc. to the command. The random effects model is the default panel data model for the ordered probability models, so you need only include the **; Pds** specification in the command.

NOTE: The random effect, u_i is assumed to be normally distributed in all models. Thus, the logit, arctangent, and other models contain a hybrid of distributions.

All other options are the same as were listed earlier for the pooled ordered probability models.

Marginal effects are computed by setting the heterogeneity term, u_i to its expected value of zero. In order to do the computations of the marginal effects, it is also necessary to scale the coefficients. The ordered probability model with the random effect in the equation is based on the index function $(\mu_j - \boldsymbol{\beta}'\mathbf{x}_i) / (1 + \sigma_u^2)$.

This estimator can accommodate restrictions, so

; Rst = list

and **; CML: specification**

are both available. Restrictions may be tested and imposed exactly as in the model with no heterogeneity. Since restrictions can be imposed on all parameters, including ρ, you can fix the value of ρ at any desired value. Do note that forcing the ancillary parameter, in this case, ρ, to equal a slope parameter will almost surely produce unsatisfactory results, and may impede or even prevent convergence of the iterations.

Starting values for the iterations are obtained by fitting the basic model without random effects. Thus, the initial results in the output for these models will be the ordered choice models discussed earlier. You may provide your own starting values for the parameters with

; Start = ... the list of values for β, values for μ, value for ρ

There is no natural moment based estimator for ρ, so a relatively low guess is used as the starting value instead. The starting value for ρ is approximately .2 ($\theta = [2\rho/(1-\rho)]^{1/2} \approx .29$ – see the technical details below. Maximum likelihood estimates are then computed and reported, along with the usual diagnostic statistics. (An example appears below.)

E36.3.2 Output and Results

Your data may not be consistent with the random effects model. That is, there may be no discernible evidence of random effects in your data. In this case, the estimate of ρ will turn out to be negligible. If so, the estimation program issues a diagnostic and reverts back to the original, uncorrelated formulation and reports (again) the results for the basic model.

Results that are kept for this model are

Matrices: *b* = estimate of **β**
varb = asymptotic covariance matrix for estimate of **β**.

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function
rho = estimated value of ρ
varrho = estimated asymptotic variance of estimator of ρ.

Last Model: *b_variables*

Last Function: Prob(y = outcome | **x**)

The additional specification

; Par

in the command requests that μ and σ_u be included in *b* and the additional rows and columns be included in *varb*. The **PARTIAL EFFECTS** and **SIMULATE** commands use the same probability function as the pooled model. The default outcome is the highest one, but you may use **; Outcome = j** to specify a specific one, or **; Outcome = *** for all.

NOTE: The hypothesis of no group effects can be tested with a Wald test (simple t test) or with a likelihood ratio test. The LM approach, using **; Maxit = 0** with a zero starting value for ρ does not work in this setting because with ρ = 0, the last row of the covariance matrix turns out to contain zeros.

NOTE: This model is fit by approximating the necessary integrals in the log likelihood function by Hermite quadrature. An alternative approach to estimating the same model is by Monte Carlo simulation. You can do exactly this by fitting the model as a random parameters model with only a random constant term. This model is described in Section E36.4.

E36.3.3 Application

In the following example, we fit random effects ordered probit models for the health status data. The pooled estimator is fit with and without the clustered data correction. Then, the random effects model is fit, first using the Butler and Moffitt method, then as a random parameters model with a random constant term.

```
SAMPLE      ; All $
SETPANEL    ; Group = id ; Pds = ti $
ORDERED     ; Lhs = newhsat ; Rhs = one,hhninc,hhkids,educ $
ORDERED     ; Lhs = newhsat ; Rhs = one,hhninc,hhkids,educ
            ; Cluster = id $
ORDERED     ; Lhs = newhsat ; Rhs = one,hhninc,hhkids,educ
            ; Panel  $
ORDERED     ; Lhs = newhsat ; Rhs = one,hhninc,hhkids,educ $
ORDERED     ; Lhs = newhsat ; Rhs = one,hhninc,hhkids,educ
            ; Panel ; RPM ; Fcn = one(n) ; Halton ; Pts = 25 $
```

The first pair of estimation results shown below compares the cluster estimator of the covariance matrix to the pooled estimator which ignores the panel data structure. As can be seen in the results, the robust standard errors are somewhat higher. The second set of results compares two estimators of the random effects model. The first results are based on the quadrature estimator. The second uses maximum simulated likelihood. These two estimators give almost the same results. They would be closer still had we used a larger number of Halton draws. We set this to 25 to speed up the computation. With, say, 250, the results of the two estimators would be extremely close.

E36.3.4 Technical Details for the Random Effects Models

The structure of the random effects model is

$$z_{it} \mid u_i \;=\; \boldsymbol{\beta}'\mathbf{x}_{it} \;+\; \varepsilon_{it} \;+\; \sigma_u u_i$$

where u_i ~ N[0,1], and ε_{it} is the stochastic term in the model that provides the *conditional* distribution,

$$\text{Prob}[y_{it} = j \mid \mathbf{x}_{it}, u_i] \;=\; F[j, \boldsymbol{\mu},(\boldsymbol{\beta}'\mathbf{x}_{it} \;+\; \sigma_u u_i)]\; i = 1,...,N,\; t = 1,...,T_i.$$

where $F(.)$ is based on the distribution discussed earlier (normal, logistic, extreme value, arctangent, Gompertz). The parameter vector for the random effects model is

$$\boldsymbol{\theta} \;=\; [\beta_1,...,\beta_K,\, \mu_1,\ldots,\mu_{J\text{-}1},\, \rho]'.$$

With the usual normalization, $\sigma_\varepsilon = 1$,

$$\sigma_u \;=\; \sqrt{\frac{\rho}{1-\rho}}\,.$$

The log likelihood function is

$$\log L \;=\; \Sigma_i \;\log L_i$$

where $\log L_i$ is the contribution of the ith individual (group) to the total. Conditioned on u_i, the joint probability for the ith group is

$$\text{Prob}[Y_{i1} = y_{i1},...,Y_{iTi} = y_{iTi} \mid \mathbf{x}_{i1,...,}u_i] \;=\; \prod_{t=1}^{T_i} F\left[y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_u u_i\right]$$

where now, u_i is normalized to unit variance. Since u_i is unobserved, it is necessary to obtain the unconditional log likelihood by taking the expectation of this over the distribution of u_i. For convenience, write the tth term in the probability above as $G(y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \gamma u_i)$, where $\gamma = \sigma_u$, so that

$$L_i \mid u_i \;=\; \prod_{t=1}^{T_i} G(\,y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\gamma} u_i\,)\,.$$

Then,

$$L_i \;=\; E_{ui}\,[L_i \mid u_i]$$

$$= \int_{-\infty}^{\infty} \frac{\exp(-u_i^2/2)}{\sqrt{2\boldsymbol{\pi}}} \prod_{t=1}^{T_i} F(y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\gamma} u_i)\; d\;\mu_i$$

NOTE: It can be seen in the likelihood function that it is necessary actually to compute the product of the probabilities for the group, not the sum of the logs. For this reason, the number of observations in a group cannot be extremely large. Since the probability is likely to be on the order of .25 or so, the product of 100 probabilities is on the order of 10^{-100}. This means that the end result is more rounding error than result. In worse cases, the computation will 'overflow' – that is, exceed the computer's capacity to compute the value. For example, the correct result for the product of 100 probabilities on the order of .01 cannot be computed in the accuracy of the computer, which is about $10^{+/-380}$. The diagnostic that this estimator produces mentions a 'Bad counter...' When the counter for group size exceeds 100, the estimator assumes that you have made some kind of error.

Then, finally,

$$\log L \quad = \sum\nolimits_{i=1}^{N} \log L_i$$

The function is maximized by solving the likelihood equations:

$$\frac{\partial \log L}{\partial \begin{pmatrix} \boldsymbol{\beta} \\ \gamma \end{pmatrix}} = \sum\nolimits_{i=1}^{N} \frac{\partial \log L_i}{\partial \begin{pmatrix} \boldsymbol{\beta} \\ \gamma \end{pmatrix}} = \mathbf{0}.$$

For convenience below, let $\boldsymbol{\theta}$ denote the full parameter vector, $[\boldsymbol{\beta},\gamma]'$.

The integration is done with Hermite quadrature. Make the change of variable to $v_i = u_i/\sqrt{2}$. Then,

$$\log L_i = \ log \frac{1}{\sqrt{\pi}} \int_{-\infty}^{\infty} \exp(-v_i^2) \prod_{t=1}^{T_i} F(\, y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta v_i \,)\, dv_i$$

where $\delta = \gamma \times \sqrt{2}$ [so $\rho = \delta^2/(2 + \delta^2)$] and $\sigma_u = [\rho/(1-\rho)]^{1/2}$]. The integral of the form

$$\int_{-\infty}^{\infty} \exp(-v^2) g(v) dv$$

is approximated by the Hermite quadrature,

$$\int_{-\infty}^{\infty} \exp(-v^2) g(v) dv \approx \sum\nolimits_{h=1}^{H} w_h g(z_h)$$

where w_h are the weights and z_h are the abscissas for the approximation. (See Section R23.3.1, Butler and Moffitt (1982) and Abramovitz and Stegun (1972) for further details.) Collecting terms, then, the log likelihood is computed with

$$\text{logL} \ \approx \sum\nolimits_{i=1}^{N} \ log \left\{ \frac{1}{\sqrt{\pi}} \sum\nolimits_{h=1}^{H} w_h \left[\prod_{t=1}^{T_i} F(\, y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta z_h \,) \right] \right\}$$

The derivatives of the log likelihood function are approximated as well (the derivation appears in Chapter R23),

$$\frac{\partial \log L}{\partial \boldsymbol{\theta}} \approx \sum_{i=1}^{N} \frac{\left\{\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H} w_h \left[\prod_{t=1}^{T_i} F(y_{it},\boldsymbol{\mu},\boldsymbol{\beta}'\mathbf{x}_{it}+\delta z_h)\right]\left[\sum_{t=1}^{T_i}\frac{\partial \log F(y_{it},\boldsymbol{\mu},\boldsymbol{\beta}'\mathbf{x}_{it}+\delta z_h)}{\partial \boldsymbol{\theta}}\right]\right\}}{\left\{\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H} w_h \left[\prod_{t=1}^{T_i} F(y_{it},\boldsymbol{\mu},\boldsymbol{\beta}'\mathbf{x}_{it}+\delta z_h)\right]\right\}}$$

Note that L_i and its derivatives are approximated separately. The summation involves two separate integrals. We use a 20 point quadrature by default, but you can change the number of quadrature points by including **; Hpt = p** in the command, where 'p' is the desired number of points, from 4 to 96 (even). In some cases, the accuracy of the computations will improve with the number of quadrature points. However, the amount of computation will increase as well at the same rate.

The variance, δ, appears linearly in the function along with $\boldsymbol{\beta}$, so no complication is added by this additional parameter as the summation is done over the nodes. In each case, the term is

$$F(y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \gamma z_h) = F\left[\mu_y - (\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma z_h)\right] - F\left[\mu_{y-1} - (\boldsymbol{\beta}'\mathbf{x}_{it} + \gamma z_h)\right]$$

The forms of the particular distribution functions, $F_{it}(.)$, differ among the five models. The functional forms appear in Section E34.1. The asymptotic covariance matrix is estimated by the BHHH estimator,

$$\mathbf{H} = \left[\sum_{i=1}^{N}\left(\frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}\right)\left(\frac{1}{L_i}\frac{\partial L_i}{\partial \boldsymbol{\theta}}\right)'\right]^{-1}$$

It is necessary to account for the presence of the random effect when computing probabilities or marginal effects from this model. The CDF is computed from

$$y_{it}^* = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i.$$

Thus,

$$\text{Prob}[y_{it}^* \le \mu] = \text{Prob}[\boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i \le \mu]$$

or

$$= \text{Prob}[\varepsilon_{it} + u_i \le \mu - \boldsymbol{\beta}'\mathbf{x}_{it}]$$

$$= \text{Prob}\left[\frac{\varepsilon_{it}+u_i}{\sqrt{1+\sigma_u^2}} \le \frac{\mu-\boldsymbol{\beta}'\mathbf{x}_{it}}{\sqrt{1+\sigma_u^2}}\right]$$

$$= \text{Prob}\,[v_{it} \le \mu^* - \boldsymbol{\beta}^{*\prime}\mathbf{x}_{it}]$$

where $v_{it} \sim N[0,1]$. These are the probabilities that enter the calculation of marginal effects and fitted values.

E36.4 Random Parameters and Random Thresholds Ordered Choice Models

The structure of the random parameters model is based on the conditional probability

$$\text{Prob}[y_{it} = j |\, \mathbf{x}_{it}, \boldsymbol{\beta}_i] = F(\,j,\boldsymbol{\mu}, \boldsymbol{\beta}_i'\mathbf{x}_{it} + \alpha_i),\ i = 1,...,N,\ t = 1,...,T_i.$$

where $F(.)$ is the distribution discussed earlier (normal, logistic, extreme value, Gompertz). The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals) parameters generated by

$$\text{E}[\boldsymbol{\beta}_i |\, \mathbf{z}_i] = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i,$$

(the second term is optional – the mean may be constant),

$$\text{Var}[\boldsymbol{\beta}_i |\, \mathbf{z}_i] = \boldsymbol{\Sigma}.$$

The model is operationalized by writing

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i.$$

As noted earlier, the heterogeneity term is optional. In addition, it may be assumed that some of the parameters are nonrandom. It is convenient to analyze the model in this fully general form here. We accommodate nonrandom parameters just by placing rows of zeros in the appropriate places in $\boldsymbol{\Delta}$ and $\boldsymbol{\Gamma}$.

NOTE: If there is no heterogeneity in the mean, and only the constant term is considered random – the model may specify that some parameters are nonrandom – then this model is functionally equivalent to the random effects model of the preceding section. The estimation technique is different, however. An application appears in the previous section.

Two major extensions of the RP-OC model are provided. The threshold parameters, μ_{ij} and disturbance variance of ε_i may also be random, in the form

$$\mu_{ij} = \mu_{i,j\text{-}1} + \exp(\alpha_j + \boldsymbol{\delta}'\mathbf{w}_i + \theta u_{ij}),\ \mu_0 = 0,\ u_{ij} \sim \text{N}[0,1]$$

$$\varepsilon_{it} \sim \text{N}[0,\sigma_i^2],\ \sigma_i = \exp(\boldsymbol{\gamma}'\mathbf{f}_i + \tau h_i),\ h_i \sim \text{N}[0,1]$$

This model is developed in Section E36.4.4.

E36.4.1 Model Commands

The basic model command for this form of the model is, as is the fixed effects estimator, given in two parts. The model is fit conventionally first to provide the starting values, then fully specified.

```
ORDERED     ; Lhs = dependent variable
            ; Rhs = independent variables
            [ ; Model = Gompertz, Logit or Weibull ] $
ORDERED     ; Lhs = dependent variable
            ; Rhs = independent variables
            ; Pds = fixed periods or count variable
            ; RPM
            ; Fcn = random parameters specification
            [ ; Model = Gompertz, Logit or Weibull ] $
```

NOTE: For this model, your Rhs list should include a constant term.

Starting values for the iterations are provided by the user by fitting the basic model without random parameters first. Note in the applications below that the two random parameters ordered probit estimators are each preceded by an otherwise identical fixed parameters version.

NOTE: The command cannot reuse an earlier set of results. You must refit the basic model without random parameters each time. Thus,

```
ORDERED     ; ... $
ORDERED     ; RPM ; ... $
ORDERED     ; RPM ; ... $
```

will not work properly. Each random parameters model must be preceded by a set of starting values.

Correlated Random Parameters

The preceding defines an estimator for a model in which the covariance matrix of the random parameters is diagonal. To extend it to a model in which the parameters are freely correlated, add

; Correlation (or just ; Cor)

to the command. Note that this formulation of the model has an ambiguous interpretation if your parameters are not jointly normally distributed. A correlated mixture of several distributions is difficult to interpret.

Heterogeneity in the Means

The preceding examples have specified that the mean of the random variable is fixed over individuals. If there is measured heterogeneity in the means, in the form of

$$E[\beta_{ki}] = \beta_k + \Sigma_m \delta_{km} z_{mi}$$

where z_m is a variable that is measured for each individual, then the command may be modified to

; RPM = list of variables in z.

In the data set, these variables must be repeated for each observation in the group.

Autocorrelation

You may change the character of the heterogeneity from a time invariant effect to an AR(1) process, $v_{kit} = \rho_k v_{ki,t-1} + w_{kit}$. (See Section R24.7 for details.)

Controlling the Simulation

There are two parameters of the simulations that you can change. *R* is the number of points in the simulation. Authors differ in the appropriate value. Train (2009) recommends several hundred. Bhat suggests 1,000 is an appropriate value. The program default is 100. You can choose the value with

; Pts = number of draws, R

The value of 50 that we set in our experiments above was chosen purely to produce an example that you could replicate without spending an inordinate amount of waiting for the results.

The standard approach to simulation estimation is to use random draws from the specified distribution. As suggested immediately above, good performance in this connection requires very large numbers of draws. The drawback to this approach is that with large samples and large models, this entails a huge amount of computation and can be very time consuming. Some authors have documented dramatic speed gains with no degradation in simulation performance through the use of a small number of Halton draws instead of a large number of random draws. Halton sequences are discussed in Section R24.7. Some authors (e.g., Bhat (1999)) have found that a Halton sequence of draws with only one tenth the number of draws as a random sequence is equally effective. To use this approach, add

; Halton

to your model command.

In order to replicate an estimation, you must use the same random draws. One implication of this is that if you give the identical model command twice in sequence, you will not get the identical set of results because the random draws in the sequences will be different. To obtain the same results, you must reset the seed of the random number generator with a command such as

CALC ; Ran (seed value) $

(Note that we have used **Ran(12345)** before each of our examples above, precisely for this reason. The specific value you use for the seed is not of consequence; any odd number will do.

In this connection, we note a consideration which is crucial in this sort of estimation. The random sequence used for the model estimation must be the same in order to obtain replicability. In addition, during estimation of a particular model, the same set of random draws must be used for each person every time. That is, the sequence $\mathbf{v}_{i1}$, $\mathbf{v}_{i2}$, ..., $\mathbf{v}_{iR}$ used for each individual must be the same every time it is used to calculate a probability, derivative, or likelihood function. (If this is not the case, the likelihood function will be discontinuous in the parameters, and successful estimation becomes unlikely. This has been called simulation 'noise' or 'buzz' in the literature.) One way to achieve this which has been suggested in the literature is to store the random numbers in advance, and simply draw from this reservoir of values as needed. Because *LIMDEP* is able to use very large samples, this is not a practical solution, especially if the number of draws is large as well. We achieve the same result by assigning to each individual, i, in the sample, their own random generator seed which is a unique function of the global random number seed, S, and their group number, i;

$$\text{Seed}(S,i) = S + 123.0 \times i, \text{ then minus 1.0 if the result is even.}$$

Since the global seed, S, is a positive odd number, this seed value is unique, at least within the several million observation range of *LIMDEP*.

Specifying Random Parameters

The **; Fcn = specification** is used to define the random parameters. It is constructed from the list of Rhs names as follows: Suppose your model is specified by

; Rhs = one, x1, x2, x3, x4

This involves five coefficients. Any or all of them may be random; any not specified as random are assumed to be constant. For those that you wish to specify as random, use

; Fcn = variable name (distribution), variable name (distribution), ...

Numerous distributions may be specified. All random variables, v_{ik}, have mean zero. See Section R24.3 for details.

c for constant (zero variance), $v_i = 0$
n for normally distributed, v_i = a standard normally distributed variable
u for uniform, v_i= a standard uniform distributed variable in (-1,+1)
t for triangular (the 'tent' distribution)
h for negative half normal, $v = (2\pi)^{-1/2} - |u|$
e for centered lognormal, $v = \text{Exp}(u) - \text{Sqr(e)}$
s for Johnson S_b, $v = \text{Exp}(u) / [1 + \text{Exp}(u)]$
l for lognormal

Each of these is scaled as it enters the distribution, so the variance is only that of the random draw before multiplication. The latter two distributions are provided as one may wish to reduce the amount of variation in the tails of the distribution of the parameters across individuals and to limit the range of variation. (See Train (2009) for discussion.) To specify that the constant term and the coefficient on $x1$ are normally distributed with fixed mean and variance, use

; Fcn = one(n), x1(n)

This specifies that the first and second coefficients are random while the remainder are not. The parameters estimated will be the mean and standard deviations of the distributions of these two parameters and the fixed values of the other three.

Standard Model Specifications for the Random Parameters Ordered Choice Models

This is the full list of general that are applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps individual specific parameter estimates.
; Partial Effects	displays marginal effects, same as **; Marginal Effects**.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E36.4.2 Results

Results saved by this estimator are:

Matrices:	*b*	= estimate of θ
	varb	= asymptotic covariance matrix for estimate of θ.
	beta_i	= individual specific parameters, if **; Par** is requested.
Scalars:	*kreg*	= number of variables in Rhs
	nreg	= number of observations
	logl	= log likelihood function
Last Model:	*b_variables*	

Last Function: Prob($y_{it} = J|\mathbf{x}_{it}$) = Probability of the highest cell.
May be changed with **; Outcome = j** or **; Outcome = ***.

E36.4.3 Application

The following example illustrates the random parameters ordered probit model. The data are recoded to make a more compact example, and the sample is restricted to those groups that have seven observations, to speed up the simulations. The first two ordered probit models are the fixed parameters, pooled estimator followed by the random parameters case in which two of the five coefficients are random. After the random parameters model is estimated, the individual specific estimates of $E[\beta_{educ}|hs,x]$ are collected in a variable then a kernel estimator describes the distribution of the conditional means across the sample. The results are rearranged to compare the coefficient estimates then the partial effects across the specifications.

The results include estimates of the means and standard deviations of the distributions of the random parameters and the estimates of the nonrandom parameters. The log likelihood shown is conditioned on the random draws, so one might be cautious about using it to test hypotheses, for example, that the parameters are random at all by comparing it to the log likelihood from the basic model with all nonrandom coefficients.

The commands are:

```

E36.4.4 Random Parameters HOPIT Model

This model extends the hierarchical ordered probit model in several directions. The core model is an ordered probit specification:

$$
\begin{aligned}
y_{it}^* &= \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it},\\
y_{it} &= 0 \text{ if } y_{it}^* \le 0,\\
&= 1 \text{ if } 0 < y_{it}^* \le \mu_1,\\
&= 2 \text{ if } \mu_1 < y_{it}^* \le \mu_2,\\
&\ldots\\
&= J \text{ if } y_{it}^* > \mu_J
\end{aligned}
$$

as usual. The model is constructed to include random coefficients, $\boldsymbol{\beta}_i$, random variance heterogeneity, σ_i, and random thresholds, μ_{ij}. The random parameters form of the general model is

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{h}_i + \boldsymbol{\Gamma}\mathbf{w}_i$$

where $\boldsymbol{\Gamma}$ is a diagonal matrix of standard deviations and $w_{ik} \sim N[0,1]$, $k = 1,\ldots,K$. The mean of the random parameter vector is $\boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{h}_i$ where $\mathbf{h}_i$ may be a set of variables specified in the model. The disturbance in the model may be heteroscedastic and distributed with random standard deviation as well, with

$$\varepsilon_{it} \sim N[0,\sigma_i^2],\ \ \sigma_i = \exp[\boldsymbol{\gamma}'\mathbf{z}_i + \tau v_i] \text{ where } v_i \sim N[0,1].$$

Finally, the thresholds are formed as shown for the cross section variant of this model in Section E35.6;

$$
\begin{aligned}
\mu_{ij} &= \mu_{i,j-1} + \exp(\alpha_j + \boldsymbol{\delta}'\mathbf{w}_i + \theta_j u_{ij}], \text{ where } u_{ij} \sim N[0,1]\\
\mu_0 &= 0 \text{ and } \mathbf{x}_{it} \text{ contains a constant term.}
\end{aligned}
$$

The various parts are optional. In addition, the model may be fit with cross section or panel data. As usual, panel data are likely to be more effective. The command for this model is

ORDERED ; Lhs = … ; Rhs = …

; RPM for the random coefficients, β

or **; RPM = list of variables in $\mathbf{h_i}$**

; RTM for the random thresholds model
; Limits = list of variables for the $\mathbf{w_i}$ in the thresholds
; Random Effects to use a common $\mathbf{u_i}$ in the thresholds

; RVM for the random term i, $\mathbf{v_i}$ in $\boldsymbol{\sigma_i}$
; Het ; Hfn = list of variables in $\mathbf{z_i}$ for the heteroscedastic model $

When the model includes any of the three random components, the maximum simulated likelihood estimator is used. The default model is an ordered probit specification. You may specify an ordered logit model instead by adding

; Logit

to the command.

The simulation can be modified with

; Pts = the number of points or draws

and **; Halton**

to indicate that Halton sequences rather than random draws be used for the simulations. Halton sequences are recommended. The simulation is over the J elements in μ_{ij} plus the element v_i in σ_i plus the K variables in the Rhs specification. If you specify a 'random effects' model, then the same single random term appears in all of the threshold equations.

If you are using a panel data set, use either

SETPANEL ; Group = variable name
; Pds = variable name $

with **; Panel**

in the **ORDERED** command, or, if the Pds variable is already prepared, use

; Pds = the group count variable.

Partial effects for this model are computed internally and requested with

; Partial Effects.

This general form of the random parameters ordered probit model does not use the template random parameters form described in Chapter R24. (Note that there is no **; Fcn** = specification component in the command.) As formulated, all parameters on the variables in the Rhs list are assumed to be random. You can modify this by imposing a constraint that the corresponding diagonal element of $\mathbf{\Gamma}$, which is the standard deviation of the random part of that element of $\boldsymbol{\beta}_i$, be equal to zero. To do this, include in the command

; Rh2 = list of variables with nonrandom parameters.

Thus, the full list of variables in the model is those in the Rhs list plus those in the Rh2 list. There is no overlap – variables must appear in only one of these two lists.

Results saved by this estimator are:

Matrices:	*b*	= estimate of β
	varb	= asymptotic covariance matrix for estimate of θ.
	betartop	= full set of parameter estimates , if **; Par** is requested.
Scalars:	*kreg*	= number of variables in Rhs
	nreg	= number of observations
	logl	= log likelihood function
Last Model:	*b_variables*	
Last Function:	None	

Standard Model Specifications for the Random Parameters Ordered Choice Models

This is the full list of general that are applicable to this model estimator.

Controlling Output from Model Commands

; Par keeps individual specific parameter estimates.
; Partial Effects displays partial effects, same as **; Marginal Effects**.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

The following application uses the subset of the GSOEP sample that have five observations in each group. The application is further speeded up by using only 10 Halton draws in the simulations. This is sufficient for a numerical example, but would be far too small for an actual application. The estimated model allows for unobserved heterogeneity in all three places, the parameters, thresholds and disturbance variance.
