E36.5 Latent Class Ordered Choice Models

The ordered choice model for a panel of data, $i = 1,...,N$, $t = 1,...,T_i$ is

$$\text{Prob}[Y_{it} = y_{it}|\ \mathbf{x}_{it}] = F(y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it}) = P(i,t), y_{it} = 0, 1,...,.$$

Henceforth, we use the term 'group' to indicate the T_i observations on respondent i in periods $t = 1,...,T_i$. Unobserved heterogeneity in the distribution of Y_{it} is assumed to impact the density in the form of a random effect. The continuous distribution of the heterogeneity is approximated by using a finite number of 'points of support.' The distribution is approximated by estimating the location of the support points and the mass (probability) in each interval. In implementation, it is convenient and useful to interpret this discrete approximation as producing a sorting of individuals (by heterogeneity) into J classes, $j = 1,...,J$. (Since this is an approximation, J is chosen by the analyst.)

Thus, we modify the model for a latent sorting of y_{it} into J 'classes' with a model which allows for heterogeneity as follows: The probability of observing y_{it} given that regime j applies is

$$P(i,t|j) = \text{Prob}[Y_{it} = y_{it}|\ \mathbf{x}_{it}, j]$$

where the density is now specific to the group. The analyst does not observe directly which class, $j = 1,...,J$ generated observation $y_{it}|j$, and class membership must be estimated. Heckman and Singer (1984) suggest a simple form of the class variation in which only the constant term varies across the classes. This would produce the model

$$P(i,t|j) = F[y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \delta_j], \text{Prob}[\text{class} = j] = F_j.$$

We formulate this approximation more generally as,

$$P(i,t|j) = F[y_{it}, \boldsymbol{\mu}, \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}_j'\mathbf{x}_{it}], F_j = \exp(\theta_j) / \Sigma_{\text{j}} \exp(\theta_j), \text{ with } \theta_J = 0.$$

In this formulation, each group has its own parameter vector, $\boldsymbol{\beta}_j' = \boldsymbol{\beta} + \boldsymbol{\delta}_j$, though the variables that enter the mean are assumed to be the same. (This can be changed by imposing restrictions on the full parameter vector, as described below.) This allows the Heckman and Singer formulation as a special case by imposing restrictions on the parameters – each $\boldsymbol{\delta}_j$ has only one nonzero element in the location of the constant term. You may also specify that the latent class probabilities depend on person specific characteristics, so that

$$\theta_{ij} = \boldsymbol{\theta}_j'\mathbf{z}_i, \boldsymbol{\theta}_J = \mathbf{0}.$$

Technical details for estimation of latent class models are given in Section R25.9.

E36.5.1 Command

The estimation command for this model is

ORDERED **; Lhs = ...**
; Rhs = independent variables
[; Model = Weibull, Logit or Gompertz]
; LCM (for latent class model)
[; LCM = list of variables in z_i for multinomial logit class probabilities]
; Pds = panel data specification $

The default number of support points is five. You may set *J* to 2, 3, ..., 10 with

; Pts = the value you wish.

Some particular values computed for the latent class model are

; Group = the index of the most likely latent class
; Cprob = estimated posterior probability for the most likely latent class

You can obtain a listing of these two results by using

; List.

Standard Model Specifications for the Latent Class Ordered Choice Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par keeps individual specific parameter estimates.
; Partial Effects displays marginal effects, same as **; Marginal Effects**.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

You can use the **; Rst = list** option to structure the latent class model so that different variables appear in different classes. Alternatively, you can use this to force the Heckman and Singer form of the model as follows, where we use a three class model as an example:

```
NAMELIST   ; x = ... one, list of variables $
CALC       ; k1 = Col(x) - 1 ; kmu = Max(y) - 1 $
ORDERED    ; Lhs = ... ; Rhs = x ; LCM ; Pts = 3
           ; Rst = d1, k1_b, kmu_mu,
                   d2, k1_b, kmu_mu,
                   d3, k1_b, kmu_mu,  t1,t2,t3 $
```

E36.5.2 Results

Results saved by this estimator are

Matrices: *b* = full parameter vector, $[\boldsymbol{\beta}_1', \boldsymbol{\beta}_2',\ldots F_1,\ldots,F_J]$
varb = full covariance matrix

(Note that *b* and *varb* involve $J\times(K$+#outcomes - 1) estimates.)

*beta_* = individual specific parameters, if **; Par** is requested
b_class = a $J\times K$ matrix with each row equal to the corresponding $\boldsymbol{\beta}_j$
class_pr = a $J\times 1$ vector containing the estimated class probabilities

Scalars: *kreg* = number of variables in Rhs list
nreg = total number of observations used for estimation
logl = maximized value of the log likelihood function
exitcode = exit status of the estimation procedure

Last Function: None

Application

To illustrate the model, we will fit an ordered probit model with three latent classes. We have modified the health care data set to set up a compact example. (The latent class estimator is actually unable to resolve more than one class with nine threshold parameters.) We have censored the health satisfaction measure to three classes for purpose of this exercise. The ordered probit model is the same one specified earlier. Some of the numerical results are omitted to simplify comparison of the estimated models. The first set of commands creates the data set.

```
SAMPLE      ; All $
SETPANEL    ; Group = id ; Pds = ti $
CREATE      ; health = newhsat $
RECODE      ; health ; 0/4 = 0 ; 5/8 = 1 ; 9/10 = 2 $
NAMELIST    ; x = one,hhninc,hhkids,educ $
```

We now fit the base case pooled model.

```
ORDERED     ; Lhs = health ; Rhs = x ; Partial Effects $
```

This is a three class latent class model.

```
ORDERED     ; Lhs = health ; Rhs = x ; Partial Effects
            ; LCM ; Pts = 3 ; Panel $
```

This fits two random effects models, the continuous, normally distributed effects model and Heckman and Singer’s discrete approximation.

```
ORDERED     ; Lhs = health ; Rhs = x ; Partial Effects ; Panel $
ORDERED     ; Quietly ; Lhs = health ; Rhs = x $
ORDERED     ; Lhs = health ; Rhs = x ; Partial Effects
            ; LCM  ; Pts = 3 ; Panel
            ; Rst =  alpha0,3_b,cmu,alpha1,3_b,cmu,
                     alpha2,3_b,cmu,theta0,theta1,theta2 $
```

This model specifies that the class probabilities depend on age and sex.

```
SAMPLE      ; All $
ORDERED     ; Quietly ; Lhs = health ; Rhs = x $
ORDERED     ; Lhs = health ; Rhs = x ; Partial Effects
            ; LCM = one,age,female ; Pts = 3 ; Panel $
```

Finally, we use a small subsample to show the listing of the posterior class probabilities.

```
REJECT      ; ti # 3 $
ORDERED     ; Quietly ; Lhs = health ; Rhs = x $
ORDERED     ; Lhs = health ; Rhs = x ; Partial Effects
            ; LCM = one,age,female ; Pts = 3 ; Panel ; List $
```

This is the base case, pooled ordered probit model, with no group effects followed by the estimates of the parameters of the three class latent class model.

This is the random effects model. It is comparable to the Heckman and Singer form that follows. The first model with continuously distributed effects suggests a random constant term with mean 2.33642 and standard deviation 0.99095. From the Heckman and Singer model, using the three estimated constants and the three estimated prior probabilities, we find a mean of 2.19016 and standard deviation 0.90994. Since the remaining coefficients in the latent class model do not differ across classes, they are directly comparable to the random effects model. The overall similarity is to be expected, but there are some substantive differences. For example, the latent class model predicts a much smaller influence of marital status than does the random effects model.

The following takes a closer look at the distributions of heterogeneity implied by the continuous random effects model and the discrete distribution implied by the Heckman and Singer model. The program below plots the two distributions. The densities are evaluated at 500 points ranging from the mean of the continuous distribution plus and minus three standard deviations. (The program could be made generic based on the model results. We have used the actual values in a few commands.)

```

```

In the model below, the class probabilities depend on age and sex. These are averaged over the data in the table at the end of the results. The constant probabilities from the model estimated earlier are shown with them. An important feature to note here is that there is no natural ordering of classes in the latent class model. The ordering of the second and third classes has changed from the earlier model to this one.

```

The model estimates include the estimates of the prior probabilities of group membership. As shown in Section R25.9, it is also possible to compute the posterior probabilities for the groups, conditioned on the data. The **; List** specification will request a listing of these. The following illustration shows this feature for a small subset of the data used above.

```
Predictions computed for the group with the largest posterior probability

```

E36.6 Stratification by Thresholds

A version of the ordered probability model for a particular type of stratified data may be estimated with

```
ORDERED     ; Lhs = your dependent variable
            ; Rhs = ...
            ; Str  = your stratification variable $
```

The Lhs and Rhs variables are as usual and *y* is still coded 0,1,2,... The model assumes that there are $S \leq 9$ strata, indicated for each observation with the value of the stratification variable. The model estimates the slope parameters as usual but allows each stratum to have its own set of cutoff values. These are the μs. They are marked accordingly in the output. For example, suppose that *y* takes values 0,1,2,3, and there are four strata. Variable *stratum* takes values 1,2,3,4. The commands which use an artificial set of data,

```
CALC        ; Ran (12345) $
SAMPLE      ; 1-500 $
CREATE      ; x1 = Rnn(1,4) ; x2 = Rnd(2) - 1 $
CREATE      ; y = 1 + .5*x1 + 1.2*x2 + Rnn(0,1) $
RECODE      ; y ; -10/2.5 = 0 ; 2.501/3 = 1 ; 3.001 /4 = 2 ; 4.001/10 = 3 $
CREATE      ; stratum = Rnd(4)
            ; s2 = (stratum = 2)
            ; s3 = (stratum = 3)
            ; s4 = (stratum = 4) $
ORDERED     ; Lhs = y
            ; Rhs = one, s2, s3, s4, x1, x2
            ; Str = stratum
            ; Partial Effects $
```

estimate parameters β_0, α_2, α_3, α_4, β_1, β_2, and μ_{11}, μ_{21}, μ_{12}, μ_{22}, μ_{13}, μ_{23}, μ_{14}, μ_{24}. The Lhs variable *y* takes four values, so each stratum has a μ_1 and a μ_2. There are four such pairs.

Because the first of the cutoff parameters for each stratum is a free parameter, and the intercept is adjusted as a normalization, you should have a constant term for each stratum. Instead of separate intercepts, you *must* have a basis constant term and then separate dummy variables for *S* - 1 other strata. Omit one of the dummy variables to avoid the dummy variable trap.

With stratification, the vector *mu* contains the *S* times (*J*-1) values, where *S* is the number of strata. Likewise, in the *Last Model* labels vector, the parameters are labeled as shown above, that is *mu*1_1,*mu*2_1, and so on. Aside from these changes, the model is otherwise unchanged. The results below are produced by the preceding set of commands.

```

E37: Multinomial Logit Models

E37.1 Introduction

Chapters E37 and E38 will describe two forms of the ‘multinomial logit’ model. These models are also known variously as ‘conditional logit,’ ‘discrete choice,’ and ‘universal logit’ models, among other names. All of them can be viewed as special cases of a general model of utility maximization: An individual is assumed to have preferences defined over a set of alternatives (travel modes, occupations, food groups, etc.)

$$U(\text{alternative } 0) = \boldsymbol{\beta}_0'\mathbf{x}_{i0} + \varepsilon_{i0}$$

$$U(\text{alternative } 1) = \boldsymbol{\beta}_1'\mathbf{x}_{i1} + \varepsilon_{i1}$$

...

$$U(\text{alternative } J) = \boldsymbol{\beta}_J'\mathbf{x}_{iJ} + \varepsilon_{iJ}$$

$$\text{Observed } Y_i = \text{choice } j \text{ if } U_i(\text{alternative } j) > U_i(\text{alternative } k)\ \forall\ k \neq j.$$

The ‘disturbances’ in this framework (individual heterogeneity terms) are assumed to be independently and identically distributed with identical extreme value distribution; the CDF is

$$F(\varepsilon_j) = \exp(-\exp(-\varepsilon_j)).$$

Based on this specification, the choice probabilities,

$$\text{Prob[choice } j \text{]} = \text{Prob}[U_j > U_k],\ \forall\ k \neq j$$

$$= \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_{ji})}{\sum_{m=0}^{J}\exp(\boldsymbol{\beta}_m'\mathbf{x}_{mi})},\ j = 0,...,J,$$

where ‘i’ indexes the observation, or individual, and ‘j’ and ‘m’ index the choices. We note at the outset, the IID assumptions made about ε_j are quite stringent, and lead to the ‘Independence from Irrelevant Alternatives’ or IIA implications that characterize the model. Much (perhaps all) of the research on forms of this model consists of development of alternative functional forms and stochastic specifications that avoid this feature. We return to that aspect in Chapter E38, and leave it unresolved for the present.

The observed data consist of the Rhs vectors, $\mathbf{x}_{jt}$, and the outcome, or choice, y_t. (We also consider a number of variants.) There are many forms of the multinomial logit, or multinomial choice model supported in *LIMDEP*. The *NLOGIT* program provides the major extensions. *LIMDEP* contains two basic forms of the model that are documented in this and the next chapter of this manual.

This chapter will examine what we call the *multinomial logit* model. In this setting, it is assumed that the Rhs variables consist of a set of individual specific characteristics, such as age, education, marital status, etc. These are the same for all choices, so the choice subscript on **x** in the formula above is dropped. The observation setting is the individual's choice among a set of alternatives, where it is assumed that the determinant of the choice is the *characteristics* of the individual. An example might be a model of choice of occupation. (This is the model originally devised by Nerlove and Press (1973).) For convenience at this point, we label this the multinomial logit model.

Chapter E38 will examine what we call (again, purely for convenience) the *discrete choice* model and, also, to differentiate the command, the *conditional logit* model. In this framework, we observe the *attributes* of the choices, as well as (or, possibly, instead of) the characteristics of the individual. A well known example is travel mode choice. Samples of observations often consist of the attributes of the different modes and the choice actually made. Sometimes, no characteristics of the individuals are observed beyond their actual choice. Models may also contain mixtures of the two types of choice determinants. These are considered in Chapter E38 as well. (We emphasize, these naming distinctions are meaningless in the modeling framework – we just use them here only to organize the applicable parts of *LIMDEP*. In practice, all of the models considered in this chapter and Chapter E38 are multinomial logit models.

E37.2 The Multinomial Logit Model – MLOGIT

The general form of the *multinomial logit* model is

$$\text{Prob[choice } j \text{]} = \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_t)}{\sum_{m=1}^{J}\exp(\boldsymbol{\beta}_m'\mathbf{x}_t)}, \; j = 0,...,J,$$

A possible J+1 *unordered* outcomes can occur. In order to identify the parameters of the model, we impose the normalization $\boldsymbol{\beta}_0 = \mathbf{0}$. This model is typically employed for individual or grouped data in which the '**x**' variables are characteristics of the observed individual(s), not the choices. For present purposes, that is the main distinction between this and the *discrete choice* model described in Chapter E38. The characteristics are the same across all outcomes. The study of occupational choice, by Schmidt and Strauss (1975) provides a well known application.

The data will appear as follows:

- Individual data: y_t coded 0, 1, ..., J,
- Grouped data: y_{0t}, y_{1t},...,y_{Jt} give proportions or shares.

In the grouped data case, a weighting variable, n_t, may also be provided if the observations happen to be frequencies. The proportions variables must range from zero to one and sum to one at each observation. The full set must be provided, even though one is redundant. The data are inspected to determine which specification is appropriate. The number of Lhs variables given and the coding of the data provide the full set of information necessary to estimate the model, so no additional information about the dependent variable is needed. There is a single line of data for each individual.

This model proliferates parameters. There are $J \times K$ nonzero parameters in all, since there is a vector $\boldsymbol{\beta}_j$ for each probability except the first. Consequently, even moderately sized models quickly become very large ones if your outcome variable, *y*, takes many values. The maximum number of parameters which can be estimated in a model is 150 as usual with the standard configuration. However, if you are able to forego certain other optional features, the number of parameters can increase to 300. The model size is detected internally. If your configuration contains more than 150 parameters, the following options and features become unavailable:

- marginal effects
- choice based sampling
- **; Rst** = list for imposing restrictions
- **; CML:** specification for imposing linear constraints
- **; Hold** for using the multinomial logit model as a sample selection equation

In addition, if your model size exceeds 150 parameters, the matrices *b* and *varb* cannot be retained. (But, see below for another way to retrieve large parameter matrices.)

The choice set should be restricted to no more than 25 choices. If you have more than 25 choices, the number of characteristics that may be used becomes very small. Nonetheless, it is possible to fit models with up to 100 choices by using **CLOGIT**, as discussed in Chapter E38. In addition, if you are able to make a few other compromises on the model specification, it is possible to fit models with up to 200 choices by using the panel data binary logit estimator – this is a 'trick'– as described below in Section E37.10.

E37.3 Model Command for the Multinomial Logit Model

The command for fitting this form of multinomial logit model is

MLOGIT ; Lhs = y or **y0,y1,...yJ**
; Rhs = regressors $

(The command may also be **LOGIT**, which is what has always been used in previous versions of *LIMDEP*.) All general options for controlling output and iterations are available except **; Keep = name**. (A program which can be used to obtain the fitted probabilities is listed below.) There are internally computed predictions for the multinomial logit model. The command builder for this model is found in Model:Discrete Choice/MLogit.

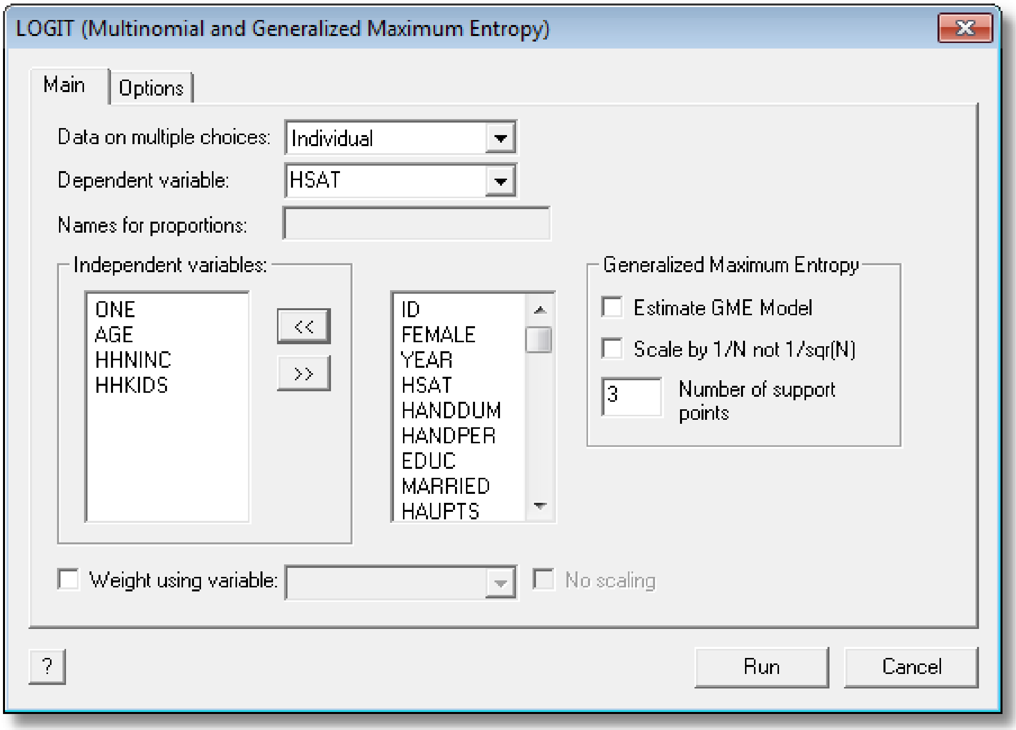

Figure E37.1 Command Builder for Multinomial Logit Models

Standard Model Specifications for the Multinomial Logit (MLOGIT) Model

This is the full list of general specifications that are applicable for this model:

Controlling Output from Model Commands

; Partial Effects displays marginal effects, same as **; Marginal Effects**.
; OLS displays least squares starting values when (and if) they are computed.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Choice uses choice based sampling (sandwich with weighting) estimated matrix.
; Cluster = name cluster form of corrected covariance estimator.
; Robust requests a ‘sandwich’ estimator or robust covariance matrix for TSCS and several discrete choice models.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Prob = name	saves probabilities as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

Imposing Constraints on Parameters

The **; Rst = list** form of restrictions is supported for imposing constraints on model parameters, either fixed value or equality. One possible application of the constrained model involves making the entire vector of coefficients in one probability equal that in another. You can do this as follows:

```
NAMELIST   ; x = the entire set of Rhs variables $
CALC       ; k = Col(x) $
LOGIT      ; Lhs  = y
           ; Rhs  = x
           ; Rst = k_b, k_b, ... , k_b $
```

This would force the corresponding coefficients in all probabilities to be equal. You could also apply this to some, but not all of the outcomes, as in

```
           ; Rst = k_b, k_b, k_b2, k_b3
```

> **HINT:** The coefficients in this model are not the marginal effects. But, forcing the coefficient on a characteristic in probability *j* to equal its counterpart in probability *m* also forces the two marginal effects to be equal.

Starting Values

The parameter vector for this model is a $J \times K$ column vector,

$$\Theta = [\beta_1' , \beta_2' , ..., \beta_J']'.$$

You may provide starting values with **; Start = list**.

E37.4 Choice Based Sampling and Robust Covariance Matrices

Choice Based Sampling

The choice based sampling methodology for individual data can be applied here. You must provide a weighting variable which gives the sampling ratios. The variable gives the ratio of the true, population proportion to the sample proportions. This presumes that you know the population proportions, $\phi_0,...,\phi_J$. If you know the sample proportions, $f_0,...,f_J$, as well, then you can calculate the necessary ratios, $w_0,...,w_J = \phi_j/f_j$ needed for the calculations to follow. With these in hand, you can create the weights using **RECODE** as follows:

```
CREATE    ; wts  = y (your dependent variable) $
RECODE    ; wts  ; 0 = weight for 0
                 ; 1 = weight for 1
          ; ... $
```

Perhaps a more convenient way to do the same computation is to create a vector with the weights,

MATRIX ; cbwt = [w_0, w_1,...,w_J] $

then you can use the following:

CREATE ; yplus1 = y + 1 ; wts = cbwt(yplus1) $ Zero is not a valid subscript.

Regardless, you must have the population proportions in hand. If you do not know the appropriate sample proportions, there is a special **MATRIX** function, Prpn(*variable*), for this purpose, which you can use as follows:

```
CREATE    ; yplus1 = y + 1 $
MATRIX    ; f = Prpn (yplus1) $
```

Since you have ϕ_j in hand, you can now proceed as follows:

MATRIX ; phi = [ϕ_0,...,ϕ_J] $ You provide the values.
MATRIX ; cbwt = diag(f) ; cbwt = phi * <cbwt> $
CREATE ; wts = cbwt(yplus1) $

(Note, the Prpn(*variable*) function is used specifically for this purpose. It creates a vector with one column and number of rows equal to the minimum of 100 and the maximum of *yplus*1. Values larger than 100 or less than one are discarded, and not counted in the proportions.)

Be sure to provide a sampling ratio for every outcome. With the weights in place, your **MLOGIT** command is

MLOGIT ; Lhs = y
; Rhs = regressors
; Wts = weights
; Choice Based Sampling $

This adjustment changes the estimator in two ways. First, the observations are weighted in computing the parameter estimates. Second, after estimation, the standard errors are adjusted. The estimator of the asymptotic covariance matrix for the choice based sampling case is

$$\text{Asy.Var}[\mathbf{b}_{CBWT}] = (\mathbf{-H})^{-1}\mathbf{BHHH}\,(\mathbf{-H})^{-1}$$

where the weighted matrices are constructed from the Hessian and first derivatives using

$$\partial^2 \log L/\partial\boldsymbol{\beta}_l\partial\boldsymbol{\beta}_m' = \Sigma_t\, w_t\{-[\mathbf{1}(l{=}m)P_l - P_lP_m\,]\}\mathbf{X'X}.$$

$$\partial \log L/\partial\boldsymbol{\beta}_{\text{j}} = \Sigma_t\, w_i(\text{d}_{tj} - t_{ij})\mathbf{x}_t \text{ where } d_{tj} = 1 \text{ if person } t \text{ makes choice } j;$$

$$\mathbf{BHHH}\text{(in blocks)} = \Sigma_t\, w_i(\text{d}_{tl} - P_{tl})(\text{d}_{tm} - P_{tm})\mathbf{x}_t\mathbf{x}_t'$$

and w_t = population frequency for choice made by individual t divided by sample proportion for choice made by individual t.

Generic Robust Covariance Matrix

It has become common in the literature to compute a ‘robust covariance matrix’ for the MLE. (The misspecification to which the matrix is robust is left unspecified in most cases.) The desired robust covariance matrix would result in the preceding computation if w_i equals one for all observations. This suggests a simple way to obtain it, just by specifying

; Choice Based ; Wts = one.

Alternatively, just use

; Robust

which is equivalent.

Cluster Correction

A related calculation is used when observations occur in groups which may be correlated. This is rather like a panel; one might use this approach in a random effects kind of setting in which observations have a common latent heterogeneity. The parameter estimator is unchanged in this case, but an adjustment is made to the estimated asymptotic covariance matrix. The calculation is done as follows: Suppose the n observations are assembled in C clusters of observations, in which the number of observations in the cth cluster is n_c. Thus,

$$\sum_{c=1}^{C} n_c = n.$$

Denote by $\boldsymbol{\beta}$ the full set of model parameters, $[\boldsymbol{\beta}_1', ..., \boldsymbol{\beta}_J']'$. Let the observation specific gradients and Hessians for individual i in cluster c be

$$\mathbf{g}_{ic} = \frac{\partial \log L_{ic}}{\partial \boldsymbol{\beta}}$$

$$\mathbf{H}_{ic} = \frac{\partial^2 \log L_{ic}}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'}.$$

The uncorrected estimator of the asymptotic covariance matrix based on the Hessian is

$$\mathbf{V}_H = -\mathbf{H}^{-1} = \left(-\sum_{c=1}^{C} \sum_{i=1}^{n_c} \mathbf{H}_{ic}\right)^{-1}$$

The corrected asymptotic covariance matrix is

$$\text{Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \mathbf{V}_H \frac{C}{C-1}\left[\sum_{c=1}^{C}\left(\sum_{i=1}^{n_c} \mathbf{g}_{ic}\right)\left(\sum_{i=1}^{n_c} \mathbf{g}_{ic}\right)'\right] \mathbf{V}_H$$

Note that if there is exactly one observation per cluster, then this is $C/(C\text{-}1)$ times the sandwich (robust) estimator discussed above. Also, if you have fewer clusters than parameters, then this matrix is singular – it has rank equal to the minimum of C and JK, the number of parameters. This estimator is requested with

; Cluster = specification

where the specification is either a fixed number of observations per cluster, or an identifier that distinguishes clusters, such as an identification number. This estimator can also be extended to stratified as well as clustered data, using

; Stratum = specification

The full description of using these procedures appears in Chapter R10.

E37.5 Output for the Logit Models

Initial ordinary least squares results are used for the starting values for this model. For individual data, J binary variables are implied by the model. These are used in a least squares regression. For the grouped data case, a minimum chi squared, generalized least squares estimate is obtained by the weighted regression of

$$q_{ij} = \log(P_{ij} / P_{i0})$$

on the regressors, with weights $w_{ij} = (n_i P_{ij} P_{i0})^{1/2}$ (n_i may be 1.0). The OLS estimates based on the individual data are inconsistent, but the grouped data estimates are consistent (and, in the binomial case, efficient). The least squares estimates are included in the displayed results by including

; OLS

in the model command. The iterations are followed by the maximum likelihood estimates with the usual diagnostic statistics. An example is shown below.

NOTE: Minimum chi squared (MCS) is an estimator, not a model. Moreover, the MCS estimator has the same properties as, but is different from the maximum likelihood estimator. Since the MCS estimator in *LIMDEP* is not iterated, it should not be used as the final results of estimation. Without iteration, the MCS estimator is not a fixed point – the weights are functions only of the sample proportions, not the parameters. For current purposes, these are only useful as starting values.

Standard output for the logit model will begin with a table such as the following which results from estimation of a model in which the dependent variable takes values 0,1,2,3,4,5:

```
SAMPLE   ; All $
REJECT   ; hsat > 5 $
LOGIT    ; Lhs = hsat ; Rhs = one,educ,hhninc,age,hhkids $
```

(This is based on the health satisfaction variable analyzed in the preceding chapter. We reduced the sample to those with *hsat* reported zero to five. We would note, though these make for a fine numerical example, the multinomial logit model would be inappropriate for these ordered data.) The restricted log likelihood is computed for a model in which *one* is the only Rhs variable. In this case,

$$\log L_0 = \Sigma_j n_j \log P_j$$

where n_j is the number of individuals who choose outcome j and $P_j = n_j/n$ = the jth sample proportion. The chi squared statistic is $2(\log L - \log L_0)$. If your model does not contain a constant term, this statistic need not be positive, in which case it is not reported. But, even if it is computable, the statistic is meaningless if your model does not contain a constant.

The diagnostic statistics are followed by the coefficient estimates: These are $\boldsymbol{\beta}_1,...,\boldsymbol{\beta}_J$. Recall $\boldsymbol{\beta}_0$ is normalized to zero, and not reported.

```

The prediction for any observation is the cell with the largest predicted probability for that observation.

NOTE: If you have more than three outcomes, it is very common, as occurred above, for the model to predict zero outcomes in one or more of the cells. Even in a model with very high t ratios and great statistical significance, it takes a very well developed model to make predictions in all cells.

The **; List** specification produces a listing such as the following:

```
Predicted Values          (* => observation was not in estimating sample.)
Observation         Observed Y    Predicted Y   Residual      MaxPr(i)  Prob[Y*=y]
       20           2.0000000    5.0000000      .000000      .6845695     .0631146
       24             .000000    4.0000000      .000000      .3196778     .0885942

```

In the listing, the MaxPr(i) is the probability attached to the outcome with the largest predicted probability; the outcome is shown as the Predicted Y. The last column shows the predicted probability for the observed outcome. Residuals are not computed – there is no significance to the reported zero. (The results above illustrate the format of the table. They were complete with a small handful of observations, not the 8,140 used to fit the model shown earlier.)

The results kept for further use are:

Matrices: *b* and *varb*.
b_logit = $(J+1)\times K$.
This additional matrix contains the parameters arranged so that $\boldsymbol{\beta}_j'$ is the jth row. The first row is zero. This matrix can be used to obtain fitted probabilities, as discussed below.

Scalars: *kreg*, *nreg*, *logl*, and *exitcode*.

Labels for **WALD** are constructed from the outcome and variable numbers. For example, if there are three outcomes and **; Rhs = one,x1,x2**, the labels will be

Last Model: [*b*1_1,*b*1_2,*b*1_3,*b*2_1,*b*2_2,*b*2_3].

Last Function: Prob($y = J|\mathbf{x}$).
You may specify other outcomes in the **PARTIALS** and **SIMULATE** commands.

E37.6 Partial Effects

The partial effects in this model are

$$\boldsymbol{\delta}_j = \partial P_j/\partial \mathbf{x},\ \ j = 0,1,...,J.$$

For the present, ignore the normalization $\boldsymbol{\beta}_0 = \mathbf{0}$. The notation P_j is used for Prob[y = j]. After some tedious algebra, we find

$$\boldsymbol{\delta}_j = P_j(\boldsymbol{\beta}_j - \bar{\boldsymbol{\beta}})$$

where
$$\bar{\boldsymbol{\beta}} = \sum_{j=0}^{J} P_j \boldsymbol{\beta}_j.$$

It follows that neither the sign nor the magnitude of $\boldsymbol{\delta}_j$ need bear any relationship to those of $\boldsymbol{\beta}_j$. (This is worth bearing in mind when reporting results.) The asymptotic covariance matrix for the estimator of $\boldsymbol{\delta}_j$ would be computed using

$$\text{Asy.Var.}\left[\hat{\boldsymbol{\delta}}_j\right] = \mathbf{G}_j \,\text{Asy.Var}\left[\hat{\boldsymbol{\beta}}\right]\mathbf{G}_j'$$

where $\boldsymbol{\beta}$ is the full parameter vector. It can be shown that

$$\text{Asy.Var.}\left[\hat{\boldsymbol{\delta}}_j\right] = \Sigma_l \Sigma_m\ \mathbf{V}_{jl}\,\text{Asy.Cov.}[\hat{\boldsymbol{\beta}}_l,\ \hat{\boldsymbol{\beta}}_m']\mathbf{V}_{jm}',\ j=0,...,J,$$

where
$$\mathbf{V}_{jl} = [\mathbf{1}(j = l) - P_l]\{P_j\mathbf{I} + \boldsymbol{\delta}_j\mathbf{x}'\} - P_j\boldsymbol{\delta}_l\mathbf{x}'$$

and
$$\mathbf{1}(j = l) = 1 \text{ if } j = l, \text{ and } 0 \text{ otherwise.}$$

E37.6.1 Internal Computation of Partial Effects

This full set of results is produced automatically when your **LOGIT** command includes

; Partial Effects (or just ; Partials).

NOTE: Marginal effects are computed at the sample averages of the Rhs variables in the model.

There is no conditional mean function in this model, so marginal effects are interpreted a bit differently from the usual case. What is reported are the derivatives of the probabilities. (Note this is the same as the ordered probability models.) These derivatives are saved in a matrix named *partials* which has J+1 rows and K columns. Each row is the vector of partial effects of the corresponding probability. Since the probabilities will always sum to one, the column sums in this matrix will always be zero. That is,

MATRIX ; List ; 1 ' partials $

will display a row matrix of zeros. The elasticities of the probabilities, $(\partial P_j/\partial x_k)\times(x_k/Pj)$ are placed in a $(J+1)\times K$ matrix named *elast_ml*. The format of the results is illustrated in the example below.

```

Figure E37.2 Matrices Created by MLOGIT

Marginal effects are computed by averaging the effects over individuals rather than computing them at the means. The difference between the two is likely to be quite small. Current practice favors the averaged individual effects, rather than the effects computed at the means. **MLOGIT** also reports elasticities with the marginal effects. An example appears above.

E37.6.2 Partial Effects Using PARTIALS

The **; Partials** specification in the **MLOGIT** command computes the partial effects at the means of the variables. The post estimation command, **PARTIAL EFFECTS** (or just **PARTIALS**), can be used to compute average partial effects, and to compute various simulations of the outcome. For example, we compute the partial effects on Prob(*hsat* = 5|**x**) for the model estimated above with

```
SAMPLE      ; All $
REJECT      ; hsat > 5 $
LOGIT       ; Lhs = hsat ; Rhs = one,educ,hhninc,age,hhkids ; Partials $
PARTIALS    ; Effects: educ / hhninc / age / hhkids ; Summary $
```

The first results below are those reported earlier. The second set are the average partial effects. (The similarity is striking.)

```

```

The various optional specifications in **PARTIALS** may be used here. For example,

```
PARTIALS    ; Effects: hhkids & hhninc=.05(.5)3 ; Outcome = 4 ; Plot $
```

plots the effect of *hhkids* on Prob(*hsat*=4) for several values of *hhninc*.

E37.7 Predicted Probabilities

Predicted probabilities can be computed automatically for the multinomial logit model. Since there are multiple outcomes, this must be handled a bit differently from other models. The procedure is as follows: Request the computation with

; Prob = name

as you would normally for a discrete choice model. However, for this model, *LIMDEP* does the following:

1. A namelist is created with name consisting of up to the first four letters of '*name*' and *prob* is appended to it. Thus, if you use **; Prob = pfit**, the namelist will be named *pfitprob*.

2. The set of variables, one for each outcome, are named with the same convention, with *prjj* instead of *prob*.

For example, in a five outcome model, the specification

; Prob = job

produces a namelist

jpbprob = *jobpr*00, *jobpr*01, *jobpr*02, *jobpr*03, *jobpr*04.

For our running example,

; Prob = hsat

produces the namelist named *hsatprob* and variables *hsatpr00*, *hsatpr01*, …, *hsatpr05*. The variables will then contain the respective probabilities. You may also use

; Fill

with this procedure to compute probabilities for observations that were not in the sample. Observations which contain missing data are bypassed as usual.

E37.8 Generalized Maximum Entropy (GME) Estimation

This is an alternative estimator for the multinomial logit model. The GME criterion is based on the entropy of the probability distribution,

$$E(p_0,...,p_J) = -\Sigma_j\, p_j \ln p_j.$$

The implementation of the GME estimator in *LIMDEP*'s multinomial logit model is done by augmenting the likelihood function with a term that accounts for the entropy of the choice probability set. Let

H = the number of support points for the entropy distribution.

and V = an H specific set of weights. These are

$$
\begin{aligned}
V &= -1/\sqrt{N},\ +1/\sqrt{N} && \text{for } H = 2\\
&= -1/\sqrt{N},\ 0,\ +1/\sqrt{N} && \text{for } H = 3\\
&= -1/\sqrt{N},\ -.5/\sqrt{N},\ [0],\ +.5/\sqrt{N},\ +1/\sqrt{N} && \text{for } H = 4 \text{ or } 5\\
&= \ ...\ [0],\ +.33/\sqrt{N},\ +.67/\sqrt{N},\ +1/\sqrt{N} && \text{for } H = 6 \text{ or } 7\\
&= \ ...\ [0],\ +.25/\sqrt{N},\ +.50/\sqrt{N},\ +.75/\sqrt{N},\ +1/\sqrt{N} && \text{for } H = 8 \text{ or } 9
\end{aligned}
$$

(You may optionally choose to scale the entire V by $1/\sqrt{N}$). Then,

$$\Psi_{ij} = \sum_{h=1}^{H} \exp[V_h \boldsymbol{\beta}_j' \mathbf{x}_i]$$

Then, the additional term which augments the contribution to the log likelihood for individual i is

$$F_{\Psi i} = \sum_{j=0}^{J} \ln \Psi_{ij}$$

This estimator is invoked simply by adding

; GME = the number of support points, H

to the **LOGIT** command. You may choose to scale the weighting vector with

; Scale

You may also choose the GME estimator in the command builder, as shown in Figure E37.1 earlier.

In the example below, we have treated the self reported health satisfaction measure as a discrete choice (doubtlessly inappropriately – just for the purpose of a numerical example). The first set of estimates given are the GME results. The model is refit by maximum likelihood in the second set. As can be seen, the GME estimator triggers some additional results in the table of summary statistics. It also brings some relatively modest changes in the estimated parameters.

E37.9 Technical Details on Optimization

Newton's method is used to obtain the estimates in all cases. The log likelihood function for the multinomial logit model is

$$\log L = \Sigma_t \Sigma_j d_{tj} \log P_{tj},$$

where P_{tj} is the probability defined earlier and $d_{tj} = 1$ if $y_t = j$, 0 otherwise, $j = 0,...,J$ or d_{tj} equals the proportion for choice j for individual t in the grouped data case. The first and second derivatives are

$$\partial \log L / \partial \boldsymbol{\beta}_j = \Sigma_t (d_{tj} - P_{tj})\mathbf{x}_t.$$

$$\partial^2 \log L / \partial \boldsymbol{\beta}_l \partial \boldsymbol{\beta}_m' = \Sigma_t -[\mathbf{1}(l=m)P_{tl} - P_{tl}P_{tm}]\mathbf{x}_t\mathbf{x}_t'.$$

The negative inverse of the Hessian provides the asymptotic covariance matrix.

The log likelihood function for the multinomial logit model is globally concave. With the exception of OLS and possibly the Poisson regression model, this is the most benign optimization problem in *LIMDEP*, and convergence should always be routine. As such, you should not need to change the default algorithm or the convergence criteria. If you do observe convergence problems, such as more than a handful of iterations, you should suspect the data. Occasionally, a data set will contain some peculiarities that impede Newton's method. In most cases, switching the algorithm to BFGS with

; Alg = BFGS

will solve the problem.

E37.10 Panel Data Multinomial Logit Models

The random parameters model described in Chapter R24 is useful for constructing two types of panel data structures for the multinomial logit model, random effects and a dynamic model.

E37.10.1 Random Effects and Common (True) Random Effects

The structural equations of the multinomial logit model are

$$U_{ijt} = \boldsymbol{\beta}_j'\mathbf{x}_{it} + \varepsilon_{ijt},\ t = 1,...,T_i,\ j = 0,1,...,J,\ i = 1,...,N,$$

where U_{ijt} gives the utility of choice j by person i in period t – we assume a panel data application with $t = 1,...,T_i$. The model about to be described can be applied to cross sections, where $T_i = 1$. Note also that as usual, we assume that panels may be unbalanced. We also assume that ε_{ijt} has a type 1 extreme value (Gumbel) distribution and that the J random terms are independent. Finally, we assume that the individual makes the choice with maximum utility. Under these (IIA inducing) assumptions, the probability that individual i makes choice j in period t is

$$P_{ijt} = \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_{it})}{\sum_{j=0}^{J}\exp(\boldsymbol{\beta}_j'\mathbf{x}_{it})}.$$

Note that this is the MLOGIT form of the model – the Rhs data are in the form of individual characteristics, not attributes of the choices. That would be handled by **CLOGIT**, discussed in Chapter E38. We now suppose that individual i has latent, unobserved, time invariant heterogeneity that enters the utility functions in the form of a random effect, so that

$$U_{ijt} = \boldsymbol{\beta}_j'\mathbf{x}_{it} + \alpha_{ij} + \varepsilon_{ijt},\ t = 1,...,T_i,\ j = 0,1,...,J,\ i = 1,...,N.$$

The resulting choice probabilities, conditioned on the random effects, are

$$P_{ijt} \mid \alpha_{i1},...,\alpha_{iJ} = \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_{it} + \alpha_{ij})}{\sum_{j=0}^{J}\exp(\boldsymbol{\beta}_j'\mathbf{x}_{it} + \alpha_{ij})}.$$

To complete the model, we assume that heterogeneity is normally distributed with zero means and $(J+1)\times(J+1)$ covariance matrix, Σ. For identification purposes, one of the coefficient vectors must be normalized to zero and one of the α_{ij}s is set to zero. We normalize the first element – subscript 0 – to zero. For convenience, this normalization is left implicit in what follows. It is automatically imposed by the software. To allow the remaining random effects to be freely correlated, we write the $J\times 1$ vector of nonzero αs as

$$\boldsymbol{\alpha}_i = \boldsymbol{\Gamma}\,\mathbf{v}_i$$

where $\boldsymbol{\Gamma}$ is a lower triangular matrix to be estimated and $\mathbf{v}_i$ is a standard normally distributed (mean zero, covariance matrix, $\mathbf{I}$) vector.

The preceding extends the random effects model to the multinomial logit framework. It is also of the form of *LIMDEP*'s other random parameter models, which is how we do the estimation, by maximum simulated likelihood. (See Section R24.7.) There are two additional versions of the essential structure:

1. Independent effects: $\boldsymbol{\Gamma}$ = A diagonal matrix.
2. True random effects: $\boldsymbol{\Gamma}$ = A diagonal matrix,
   and $v_{ji} = v_i$ = the same random variable in all utility functions.

Thus, in the second case, the preference heterogeneity is a choice invariant characteristic of the person.

The command structure for this model has two parts. In the first, the logit model is fit without the effects in order to obtain the starting values. In the second, we use a standard form of the random parameters model, as described in Chapter R24.

```
MLOGIT    ; Lhs  = dependent variable
          ; Rhs  = list of variables including one $
MLOGIT    ; Lhs  = dependent variable
          ; Rhs  = list of variables including one
          ; RPM ; Fcn = one(n)
          [; Halton]
          [; Pts = ...]
          ; Pds  = panel specification  $
```

The items in the square brackets are optional. This requests the type 1, independent effects model. To estimate the second model, type 2, true random effects model, add

; Common Effect

to the commands. To fit the general model with freely correlated effects, use, instead,

; Correlated

Partial effects for this model are obtained using the procedure shown in Section E37.6.2.

To illustrate this estimator, we constructed an example using the health care data. The Lhs variable is health satisfaction. We restricted the sample by first, keeping only groups with T_i = 7. We then eliminated all observations with Lhs variable greater than four. This leaves a dependent variable that takes five outcomes, 0,1,2,3,4, and a total sample of 905 observations in 394 groups ranging in size from one to seven. So, the resulting panel is unbalanced. The Rhs variables are *one*, *age*, *income* and *hhkids* that is kids in the household. We fit all three models described above.

The commands are as follows:

```
REJECT      ; _groupti < 7 $
REJECT      ; hsat > 4 $
REGRESS     ; Lhs = one  ; Rhs = one ; Str = id ; Panel $
MLOGIT      ; Lhs = hsat ; Rhs = one,age,hhninc,hhkids $
MLOGIT      ; Lhs = hsat ; Rhs = one,age,hhninc,hhkids
            ; RPM ; Fcn = one(n)
            ; Halton ; Pts = 50
            ; Pds  = _groupti
            ; Common $
MLOGIT      ; Lhs  = hsat; Rhs = one,age,hhninc,hhkids ; Quietly $
MLOGIT      ; Lhs  = hsat; Rhs = one,age,hhninc,hhkids
            ; RPM ; Fcn = one(n)
            ; Halton ; Pts = 50
            ; Pds  = _groupti $
MLOGIT      ; Lhs  = hsat; Rhs = one,age,hhninc,hhkids ; Quietly $
MLOGIT      ; Lhs  = hsat; Rhs = one,age,hhninc,hhkids
            ; RPM ; Fcn = one(n)
            ; Halton ; Pts = 50
            ; Pds  = _groupti
            ; Correlated $
```

These are the initial values, without latent effects.

E37.10.2 A Dynamic Multinomial Logit Model

The preceding random effects model can be modified to produce the dynamic multinomial logit model analyzed in Gong, van Soest and Villagomez (2000). Then

$$P_{ijt} \mid \alpha_{i1},\ldots,\alpha_{iJ} = \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_{it} + \boldsymbol{\gamma}_j'\mathbf{z}_{it} + \alpha_{ij})}{\sum_{j=1}^{J}\exp(\boldsymbol{\beta}_j'\mathbf{x}_{it} + \boldsymbol{\gamma}_j'\mathbf{z}_{it} + \alpha_{ij})} \quad t = 1,\ldots,T_i,\ j = 0,1,\ldots,J,\ i = 1,\ldots,N$$

where $\mathbf{z}_{it}$ contains lagged values of the dependent variables (these are binary choice indicators for the choice made in period t) and possibly interactions with other variables. The $\mathbf{z}_{it}$ variables are now endogenous, and conventional maximum likelihood estimation is inconsistent. The authors argue that Heckman's treatment of initial conditions is sufficient to produce a consistent estimator. (We used this method to set up a dynamic probit model in Section E31.2.6.) The core of the treatment is to treat the first period as an equilibrium, with no lagged effects,

$$P_{ij0} \mid \theta_{i1},\ldots,\theta_{iJ} = \frac{\exp(\boldsymbol{\delta}_j'\mathbf{x}_{i0} + \theta_{ij})}{\sum_{j=1}^{J}\exp(\boldsymbol{\delta}_j'\mathbf{x}_{i0} + \theta_{ij})},\ t = 0,\ j = 0,1,\ldots,J,\ i = 1,\ldots,N$$

where the vector of effects, θ, is built from the same primitives as α in the later choice probabilities. Thus, $\boldsymbol{\alpha}_i = \boldsymbol{\Gamma}\mathbf{v}_i$ and $\boldsymbol{\theta} = \boldsymbol{\Phi}\,\mathbf{v}_i$, for the same $\mathbf{v}_i$, but different lower triangular scaling matrices. This treatment slightly less than doubles the size of the model – it amounts to a separate treatment for the first period.) Full information maximum likelihood estimates of the model parameters, $(\boldsymbol{\beta}_1,\ldots,\boldsymbol{\beta}_J,\boldsymbol{\gamma}_1,\ldots,\boldsymbol{\gamma}_J,\boldsymbol{\delta}_1,\ldots,\boldsymbol{\delta}_J,\boldsymbol{\Gamma},\Phi)$ are obtained by maximum simulated likelihood, by modifying the random effects model. The likelihood function for individual i consists of the period 0 probability as shown above times the product of the period $1,2,\ldots,T_i$ probabilities defined earlier.

In order to use this procedure, you must create the lagged values of the variables, and the products with other variables if any are to be present – that is, the elements of $\mathbf{z}_{it}$. Then, starting values for both parameter vectors must be provided for the iterations. The program below shows the several steps involved. In terms of the broad command structure, the essential new ingredient will be the addition of

; Rh2 = the variables in z

to the model definition. However, again, several steps must precede this, as shown in the command set below.

To construct this estimator in generic form, we assume the dependent variable is named *y* and the independent variables are to be contained in a namelist *x*. Several commands remain application specific. These are modified for the specific model. We need a time variable first. For convenience, periods are numbered 1,...,*T* with *t* = 1 being the initial period.

```
    NAMELIST   ; x = the x variables in the model, including one $
    SAMPLE     ; All $
    CREATE     ; time = Trn(-T,0)  $    Fixed number of periods
or  CREATE     ; time = Ndx(ID,1) $     Unbalanced panel, variable T(i)
```

Compute the binary variables for the outcomes - endogenous variables.

```
CREATE      ; dit1 = (y=1) ; dit2 = (y=2) ; dit3 = (y=3) ... and so on ... $
```

Create lagged values of the dummy variables and interactions of lagged dummy variables with other variables in the model if desired. You will name variables according to your application. This is just a template. (And repeat likewise for a second, third, ... *x* variable.)

```
CREATE      ; dit1lag = dit1[-1] ; dit2lag = dit2[-1]
            ; dit3lag = dit3[-1] ... and so on $
CREATE      ; d1x1lag = dit1lag*x1 ; d2x1lag = dit2lag*x1 ... $
NAMELIST    ; z = dit1L,dit2L,...,d1x1L,...,... for the z variables $
```

Fit the time invariant model for the first period and retain the coefficients.

```
REJECT      ; time > 1 $
MLOGIT      ; Lhs = y ; Rhs = x $
MATRIX      ; delta = b $
```

Fit the dynamic part for 2,...,T_i and again, save the coefficients.

```
INCLUDE     ; New ; T > 1 $
MLOGIT      ; Lhs = y ; Rhs = x,z $
MATRIX      ; betagama = b $
```

The full model for all periods is a random parameters model.

```
SAMPLE      ; All $
MLOGIT      ; Lhs = y ; Rhs = x
            ; Rh2 = z ?  This indicates the dynamic MNL model.
            ; Start = delta,betagama
            ; RPM ; (options including ; Halton, ; Pts = replications)
            ; Panel specification
            ; Fcn = one(n) ; Common $ (; Correlated may be specified)
```

E38: Conditional Logit Models

E38.1 Introduction

This chapter and Chapters E39 and E40 will describe the major extension of the MLOGIT model of Chapter E37. An individual is assumed to have preferences defined over a set of alternatives (travel modes, occupations, food groups, etc.)

$$U(\text{alternative } 1) = \boldsymbol{\beta}_1'\mathbf{x}_{i1} + \boldsymbol{\gamma}_1'\mathbf{z}_i + \varepsilon_{i1}$$

...

$$U(\text{alternative } J) = \boldsymbol{\beta}_J'\mathbf{x}_{iJ} + \boldsymbol{\gamma}_J'\mathbf{z}_i + \varepsilon_{iJ}$$

$$\text{Observed } Y_i = \text{choice } j \text{ if } U_i(\text{alternative } j) > U_i(\text{alternative } k)\ \forall\ k \neq j.$$

In this expanded specification, we use $\mathbf{x}_{ij}$ to denote the *attributes* of choice j that face individual i – attributes generally differ across choices and across individuals. We use $\mathbf{z}_i$ to denote *characteristics* of individual i, such as age, income, gender, etc. Characteristics differ across individuals, but not across choices. The 'disturbances' in this framework (individual heterogeneity terms) are assumed to be independently and identically distributed with identical extreme value distribution; the CDF is

$$F(\varepsilon_j) = \exp(-\exp(-\varepsilon_j))$$

Based on this specification, the choice probabilities,

$$\text{Prob[choice } j \text{]} = \text{Prob}[U_j > U_k],\ \forall\ k \neq j$$

$$= \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_{ji} + \boldsymbol{\gamma}_j'\mathbf{z}_i)}{\sum_{m=1}^{J}\exp(\boldsymbol{\beta}'\mathbf{x}_{mi} + \boldsymbol{\gamma}_m'\mathbf{z}_i)},\ j = 1,...,J,$$

where 'i' indexes the observation, or individual, and 'j' and 'm' index the choices. We note at the outset, the IID assumptions made about ε_j are quite stringent, and lead to the 'Independence from Irrelevant Alternatives' or IIA implications that characterize the model. Much (perhaps all) the research on forms of this model consists of development of alternative functional forms and stochastic specifications that avoid this feature. We return to that aspect in Section E40.4, and leave it unresolved for the present.

The observed data consist of the vectors, $\mathbf{x}_{jt}$ and $\mathbf{z}_i$ and the outcome, or choice, y_i. (We also consider a number of variants.) A well known example is travel mode choice. Samples of observations often consist of the attributes of the different modes and the choice actually made. Usually, no characteristics of the individuals are observed beyond their actual choice, though survey data may include familiar sociodemographics such as age and income. Models may also contain mixtures of the two types of choice determinants. Chapters E38-E40 present the various aspects of this model contained in *LIMDEP*. This chapter describes basic model specification and estimation. Chapter E39 describes extensions of the model that allow for different types of data, different specifications of the utility functions and a built in feature of the estimation for modeling choice strategy of the individual. Chapter E40 develops the post estimation features, partial effects, prediction and model simulation.

Notes on the Conditional Logit Model, MLOGIT, CLOGIT and NLOGIT

For the present, we have labeled the model estimated by the program described in this chapter as the 'conditional logit model.' It will be clear shortly that this is a meaningless distinction. The only significance to the use of CLOGIT (conditional logit) here and MLOGIT (multinomial logit) in the preceding chapter is to differentiate the commands used in *LIMDEP*. The models are, in fact, the same. We will demonstrate this with an example below. Indeed, in the contemporary literature the model we are examining here above is generically called the 'multinomial logit model,' and the artificial distinction we have drawn based on characteristics vs. attributes has largely faded from view.

The internal programs that do the estimation for MLOGIT and CLOGIT are different, however. MLOGIT is a specific estimation module in *LIMDEP*. CLOGIT is likewise a particular estimation module, but it is also the gateway to *NLOGIT*, a separate package of analysis tools for analysis of discrete choice models. The models estimated by *NLOGIT* Version 5 are extensions of the basic multinomial logit fit by CLOGIT. These include:

- nested logit,
- generalized nested logit,
- nested logit with covariance heterogeneity,
- multinomial probit,
- heteroscedastic extreme value,
- mixed (random parameters) logit,
- latent class logit,
- error components logit,
- generalized mixed logit,
- scaled mixed logit,
- random regret logit model,
- nonlinear random parameters logit,
- Box-Cox nested logit,
- latent class mixed logit,

and a few others. These models are not in *LIMDEP*. (Development of *NLOGIT* began in the late 1990s with the construction of full information maximum likelihood estimators for the nested logit model (hence the name, '*NLOGIT*'). The package has evolved into a large group of estimators for the models listed above, as well as a separate set of tools for estimation and analysis of discrete choice models. *NLOGIT* Version 5 consists of all of *LIMDEP* as described in these manuals plus the analysis tools for discrete choice. Further information about *NLOGIT* and its features may be found on the website for the program, www.nlogit.com.

E38.2 The Conditional Logit Model – CLOGIT

In the multinomial logit model described in Chapter E37, there is a single vector of characteristics that describes the individual, and a set of J parameter vectors. In the 'discrete choice' setting of this chapter, these are essentially reversed. The J (not J+1 – we will be changing the notation slightly here) alternatives are each characterized by a set of K 'attributes,' $\mathbf{x}_{ij}$. Respondent 'i' chooses among the J alternatives. In the example we will use throughout this discussion, a sampled individual making a trip between Sydney and Melbourne chooses one of four modes of travel, air, train, bus or car. The attributes include cost, travel time and terminal time, which differ by mode, and characterize the choice, not the person. The data also include a characteristic of the chooser, household income. It will emerge shortly however, that MLOGIT and CLOGIT are not different models at all. The estimator described here accommodates both cases, and mixtures of the two. For example, for the commuting application just noted, we also have income for the person and traveling party size, both of which are choice invariant.

For the present, we develop the model with a single parameter vector, $\boldsymbol{\beta}$. The model underlying the observed data is assumed to be the following random utility specification:

$$U(\text{choice } j \text{ for individual } i) = U_{ij} = \boldsymbol{\beta}'\mathbf{x}_{ij} + \boldsymbol{\gamma}'\mathbf{z}_i + \varepsilon_{ij},\ j = 1,...,J.$$

The random, individual specific terms, $(\varepsilon_{i1},\varepsilon_{i2},...,\varepsilon_{iJ})$ are once again assumed to be independently distributed across the utilities, each with the same type 1 extreme value distribution

$$F(\varepsilon_{ij}) = \exp(-\exp(-\varepsilon_{ij})).$$

Under these assumptions, the probability that individual i chooses alternative j is

$$\text{Prob}[U_{ij} > U_{im}] \text{ for all m} \neq \text{j}.$$

It has been shown that for independent extreme value (Gumbel) distributions, as above, this probability is

$$\text{Prob}[y_i = j] = \frac{\exp\left(\boldsymbol{\beta}'\mathbf{x}_{ij} + \boldsymbol{\gamma}_j'\mathbf{z}_i\right)}{\sum_{m=1}^{J}\exp\left(\boldsymbol{\beta}'\mathbf{x}_{im} + \boldsymbol{\gamma}_m'\mathbf{z}_i\right)}$$

where y_i is the index of the choice made. As before, we note at the outset that the IID assumptions made about ε_j are quite stringent, and induce the 'Independence from Irrelevant Alternatives' or IIA features that characterize the model. We will return to this restriction later in Chapter E40. Regardless of the number of choices, there is a single vector of K parameters to be estimated. This model does not suffer from the proliferation of parameters that appears in the MLOGIT model described in Section E37.2.

For convenience in what follows, we will refer to the estimator as CLOGIT, keeping in mind, this refers to a command and class of models in *LIMDEP*, not a separate program.

The basic setup for this model consists of observations on n individuals, each of whom makes a single choice among J_i choices, or alternatives. There is a subscript on J_i because ultimately, we will not restrict the choice sets to have the same number of choices for every individual. The data will typically consist of the choices and observations on K 'attributes' for each choice. The attributes that describe each choice, i.e., the variables that enter the utility functions, may be the same for all choices, or may be defined differently for each utility function. The estimator described in this chapter allows a large number of variations of this basic model. In the discrete choice framework, the observed 'dependent variable' usually consists of an indicator of which among J_i alternatives was *most* preferred by the respondent. All that is known about the others is that they were judged inferior to the one chosen. But, there are cases in which information is more complete and consists of a subjective ranking of all J_i alternatives by the individual. CLOGIT allows specification of the model for estimation with 'ranks data.' In addition, in some settings, the sample data might consist of aggregates for the choices, such as proportions (market shares) or frequency counts. CLOGIT will accommodate these cases as well.

E38.3 Clogit Data for the Applications

The documentation of the CLOGIT program below includes numerous applications based on the data set clogit.dat, that is distributed with *LIMDEP*. These data provide a compact illustration of how data should be arranged for CLOGIT. The data set is a survey of the transport mode chosen by a sample of 210 travelers between Sydney and Melbourne (about 500 miles) and other points in nonmetropolitan New South Wales. As will be shown, the clogit data will generally consist of a record (row of data) for each alternative in the choice set, for each individual. Thus, the data file contains 210 observations, or 840 records. The variables in the data set are as follows:

Original Data

mode = 0/1 for four alternatives: air, train, bus, car
(this variable equals one for the choice made, labeled *choice* below),
ttme = terminal waiting time,
invc = invehicle cost for all stages,
invt = invehicle time for all stages,
gc = generalized cost measure = Invc + Invt × value of time,
chair = dummy variable for chosen mode is air,
hinc = household income in thousands,
psize = traveling party size.

Transformed Variables

aasc = choice specific dummy for air (generated internally),
tasc = choice specific dummy for train,
basc = choice specific dummy for bus,
casc = choice specific dummy for car,
hinca = *hinc* × *aasc*,
psizea = *psize* × *aasc*.

The table below lists the first 10 observations in the data set. In the terms used here, each 'observation' is a block of four rows. The mode chosen in each block is boldfaced.

mode	*choice*	*ttme*	*invc*	*invt*	*gc*	*chair*	*hinc*	*psize*	*aasc*	*tasc*	*basc*	*casc*	*hinca*	*psizea*	*obs.*

E38.3.1 Setting Up the Data

The clogit data are arranged as follows, where we use a specific set of values for the problem to illustrate. Suppose you observe 25 individuals. Each individual in the sample faces three choices and there are two attributes, *q* and *w*. For each observation, we also observe which choice was made. Suppose further that in the first three observations, the choices made were two, three, and one, respectively. The data matrix would consist of 75 rows, with 25 blocks of three rows. Within each block, there would be the set of attributes and a variable *y*, which, at each row, takes the value one if the alternative is chosen and zero if not. Thus, within each block of *J* rows, *y* will be one once and only once. For the hypothetical case, then, we have:

	y	*q*	*w*
i=1	0	$q_{1,1}$	$w_{1,1}$
	—>1	$q_{2,1}$	$w_{2,1}$
	0	$q_{3,1}$	$w_{3,1}$
i=2	0	$q_{1,2}$	$w_{1,2}$
	0	$q_{2,2}$	$w_{2,2}$
	—>1	$q_{3,2}$	$w_{3,2}$
i=3	—>1	$q_{1,3}$	$w_{1,3}$
	0	$q_{2,3}$	$w_{2,3}$
	0	$q_{3,3}$	$w_{3,3}$

and so on, continuing to *i* = 25, where '—>'marks the row of the respondent's actual choice. The clogit.dat data set shown earlier illustrates the general construction of the data set. Note that for purposes of CLOGIT, the data are set up in the same fashion as a panel data set in other settings.

When you **READ** the data for this model, the data set is not treated any differently. *Nobs* would be the total number of rows in the data set, in the hypothetical case, 75, not 25, and 840 for clogit.dat. The separation of the data set into the above groupings would be done at the time this particular model is estimated.

NOTE: Missing values are handled automatically by this estimator. Do not reset the sample or use **SKIP** with **CLOGIT**. Observations which have missing values are bypassed as a group. We note an implication of this: the multiple imputation programs in *LIMDEP* cannot be used to fill missing values in a multinomial choice setting.

Thus far, it is assumed that the observed outcome is an indicator of which choice was made among a fixed set of up to 500 choices. There are numerous possible variations:

- Data on the observed outcome may be in the form of frequencies, market shares or ranks.
- The number of choices may differ across observations.
- The choice set may be extremely large. A method of fitting models with up very large choice sets is discussed below

E38.3.2 Checking Data Validity

CLOGIT does a full check of the data for bad observations (usually coding errors or missing values) before estimation is done. The program output will contain a simple count of the number of invalid observations that have been bypassed. For example, we sprinkled some missing values into the clogit.dat data set, and fit a model. The initial output contains the count:

```
+-------------------------------------------------------+
|WARNING:   Bad observations were found in the sample. |
|Found   3 bad observations among     210 individuals. |
|You can use ;CheckData to get a list of these points. |
+-------------------------------------------------------+
```

```
-----------------------------------------------------------------------------
Discrete choice (multinomial logit) model
Dependent variable               Choice
Log likelihood function      -181.67965
Estimation based on N =    207, K =   7
Inf.Cr.AIC  =  377.359 AIC/N =    1.823
R2=1-LogL/LogL* Log-L fncn R-sqrd R2Adj
Constants only   -279.9949  .3511 .3437
Chi-squared[ 4]          =    196.63055
Prob [ chi squared > value ] =   .00000
Response data are given as ind. choices
Number of obs.=   210, skipped    3 obs
--------+--------------------------------------------------------------------
```

You may request the program to show you exactly where the problem observations are by adding

; Check Data

to the command. A complete listing of the bad observations is produced – note in a large data set, this could be quite long. For the preceding, we obtained

```
+-----------------------------------------------------------+
| Inspecting the data set before estimation.               |
| These errors mark observations which will be skipped.    |
| Row Individual = 1st row then group number of data block |
+-----------------------------------------------------------+
    1      1  Individual data, LHS variable is not 0 or 1
    9      3  Missing value found for characteristic or attribute in utility
   17      5  Missing value found for LHS variable
```

E38.3.3 Types of Data on the Choice Variable

Data on the dependent (Lhs) variable may come in four forms:

- **Individual Data:** The Lhs variable consists of zeros and a single one which indicates the choice that the individual made. The data sets shown earlier are individual data.
- **Proportions Data:** The Lhs variable consists of a set of sample proportions or market shares. Values range from zero to one, and they sum to 1.0 over the set of choices in the choice set. Observed proportions may equal 1.0 or 0.0 for some observations.
- **Frequency Data:** The Lhs variable consists of a set of frequency counts for the outcomes. Frequencies are nonnegative integers for the outcomes in the choice set and may be zero.
- **Ranks Data:** The Lhs variable consists of a complete set of ranks of the alternatives in the individual's choice set. Thus, if there are *J* alternatives available, the observation will consist of a full set of the integers 1,...,*J* not necessarily in that order, which indicate the individual's ranking of the alternatives. The number of choices may still differ by observation. Thus, we might have [(unranked),0,1,0,0,0] in the usual case, and [(ranked) 4,1,3,2,5] with ranks data. Note that the positions of the ones are the same for both sets, by definition. (See Beggs, Cardell, and Hausman (1981).) You may also have partial rankings. For example, suppose respondents are given 10 choices and asked to rank their top three. Then, the remaining six choices should be coded 4.0. A set of ranks might appear thusly: [1,4,2,4,3,4,4,4,4,4]. The ties must only appear at the lowest level. Ties in the data are detected automatically. No indication is needed. For later reference, we note the following for the model based on ranks data:
  - You may have observation weights, but no choice based sampling.
  - The IIA test described in Chapter E40 is not available.

The first three data types can be detected automatically by **CLOGIT**. You generally do not have to give any additional information about the data set, since the type of data being provided can usually be deduced from the values. The ranks data are an exception for which you must use

CLOGIT ; ... as before ...; Ranks $

If you are using frequency or proportions data, and your data contain zeros or ones, then certain kinds of observations cannot be distinguished from erroneous individual data, and they may be flagged as such. For example, in a frequency data set, the observation [0,0,1,1,0,0] is a valid observation, but for individual data, it looks like a badly coded observation. In order to avoid this kind of ambiguity, if you have frequency data containing zeros, add

; Frequencies

to your **CLOGIT** command. (You may use this in any event to be sure that the data are always recognized correctly.) If you have proportions data, instead, you may use

; Shares

to be sure that the data are correctly marked. (Again, this will only be relevant if your data contain zeros and/or ones.)

Data are checked for validity and consistency. An unrecognizable mixture of the three types will cause an error. For example, a mixture of frequency and proportions data cannot be properly analyzed. For the ranks data, an error will occur if the set of ranks is miscoded or incomplete or if ties are detected for any ranks other than the lowest.

E38.3.4 Simulated Choice Data

For some kinds of experiments and simulations, you might want to draw a random sample of choices given known utility functions. CLOGIT allows simulation of the Lhs variable in a choice model using

$$Y = j^* \text{ from } \text{Max}(U_{ij})$$

where $U_{ij} = v_{ij}$ + a simulated random term. You must provide the utility values as the Lhs variable. The choice outcome is then simulated by adding a type 1 extreme value error term to each utility value, and choosing the j associated with the largest simulated utility. Request this computation by adding

; MCS (for Monte Carlo Simulation)

to the **CLOGIT** command. (The utilities are not lost. You can reuse them, for example to do another simulation. On the other hand, the simulated data are lost at the end of the estimation.) Keep in mind, if you want to reuse the data for a simulation, you have to reset the seed for the random number generator. You might for example want to fit different models with the same simulated data set.

E38.3.5 Entering Data on a Single Line

The clogit data are generally provided as if in a panel data set, in blocks of J_i observations per individual, where J_i is the number of choices. The following describes an alternative format in which data for these models are provided in one line per individual. This construction can only be used for discrete choice models with a fixed number of alternatives available to each individual. This feature is not available for cases in which the choice set varies across individuals. (We have seen this arrangement of data called the ‘wide form,’ with the data arranged as earlier in the ‘long form.’)

In general, discrete choice models require that the data set be arranged with a line of data (observation) for each alternative in the model, essentially as a panel. For purposes of the discussion, it will be useful to consider an example. Suppose individuals choose among four alternatives, (*air,train,bus,car*), and the attributes are *cost* and *traveltime*, which vary across choice, and *income* which is fixed. The actual data for an observation would consist of four variables on four records, arranged as follows: (The y_j variable consists of three zeros and a one to indicate the choice made.)

The arrangement is as follows:

$$\begin{array}{cc} & \begin{array}{cccc} \text{Choice} & \text{Cost} & \text{Time} & \text{Income} \end{array} \\ \begin{array}{c} \text{Air} \\ \text{Train} \\ \text{Bus} \\ \text{Car} \end{array} & \begin{bmatrix} y_{air} & cost_{air} & time_{air} & income \\ y_{train} & cost_{train} & time_{train} & income \\ y_{bus} & cost_{bus} & time_{bus} & income \\ y_{car} & cost_{car} & time_{car} & income \end{bmatrix} \end{array}$$

The model observation would be constructed from the four variables, and would, with alternative specific constants for the first three alternatives, ultimately appear as follows:

$$\begin{array}{cc} & \begin{array}{ccccc} \text{choice} & \text{cost} & \text{time} & \text{constants} & \text{income} \end{array} \\ \mathbf{X}_i = & \begin{bmatrix} y_{air} & c_a & t_a & 1 & 0 & 0 & income & 0 & 0 \\ y_{train} & c_t & t_t & 0 & 1 & 0 & 0 & income & 0 \\ y_{bus} & c_b & t_b & 0 & 0 & 1 & 0 & 0 & income \\ y_{car} & c_c & t_c & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix} \end{array}$$

This setup normally requires four lines of data. But, an alternative way to arrange the same data would be in a single line of data, consisting of

Choice(coded 0,1,2,3) ca ct cb cc ta tt tb tc one income

from which it would be straightforward to construct the observation above.

The command for this arrangement will contain the following to set this up: First, the choice set is specified as follows:

; Lhs = the name of the choice variable (here, *choice***)**
; Choices = the list of J choice labels [coding of Lhs variable]

The coding is contained in square brackets. If the dependent variable is coded as consecutive integers, such as 0,1,2,3, then just put the first value in the brackets. Thus, 0,1,2,3 is indicated with [0], while 1,2,3,4 is [1]. For our example, this is going to appear

; Lhs = choice
; Choices = air,train,bus,car [0]

If the coding is some other set of integers, put the set of integers in the square brackets. Suppose, for example, in our model, we eliminated *train* as a choice. Then, the coding might be [0,2,3].

NOTE: It is only the square brackets in the **; Choices** specification which indicates that you will be using this data arrangement instead of the standard one.

Second, for variables which provide attributes which vary by choice, such as *cost* and *time* above, a **; Rhs** specification must contain blocks of *J* variable names. For the example, this might be

; Rhs = cair,ctrain,cbus,ccar,tair,ttrain,tbus,tcar

For variables which are to be interacted with alternative specific constants, as well as the constants themselves, use **; Rh2** instead of **; Rhs**. Thus, for the example above, we might use

; Rh2 = one,income

NOTE: To request a set of alternative specific constants, include *one* in the Rh2 list, not the Rhs list.

Notice that when these interactions are created, the last one in the set is dropped. In the example above, only three constants and three income terms appear in the four choice model.

Third, for the Rhs groups, a name is created for the group, *attrib*01, *attrib*02, and so on. If you would like to provide your own names for the blocks, use

; Attr = list of k labels

To combine all of these in our example, we might use

```
; Lhs  = mode
; Choices = air,train,bus,car [ 0 ]
; Rhs  = cair,ctrain,cbus,ccar,tair,ttrain,tbus,tcar
; Rh2 = one,income
; Attr = cost,time
```

E38.3.6 Converting Wide Data Sets to the Long Format

The single line format for multinomial choice modeling is clumsy, and will become extremely unwieldy if the choice set has more than a few alternatives or the model has more than two or three attributes. A utility program is provided for you to convert single line choice data to the more convenient format.

We wish to transform the data set so that one observation in the second form shown above becomes three observations in the first form above. The general command is

```
CLCONVERT ; Lhs     = one or more choice variables
          ; Choices = the J names for the choices in the choice set
          ; Rhs     = K sets of J variable names – the attributes
          ; Rh2     = M characteristics variables
          ; Names   = names for new choice variables,
                      names for new attribute variables,
                      names for new characteristic variables $
```

For the example above, the command would be

CLCONVERT ; Lhs = choicei
; Choices = car,train,bus
; Rhs = ctime,ttime,btime,ccost,tcost,bcost
; Rh2 = agei,incomei
; Names = choice,time,cost,age,income $

This command is set up to resemble a model command to make it simple to construct. But, it does nothing but rearrange the data set.

Some points to note about **CLCONVERT** are:

- It is only for choice settings with fixed numbers of choices for every observation.
- You can recode more than one choice variable with the other data.
- You can rearrange the entire data set, not just the variables for a particular model. The appearance of the command as a model command is only for convenience.
- After the data are converted, the new data are placed at the top of the data array, regardless of where they were before. You can, for example, convert rows 201 to 250 in your data set. If this is a three choice setting, the new data will be observations 1 to 150.

There are also several conventions that must be followed:

- The new names must not be in use for anything else already in your project, including other variables. **CLCONVERT** cannot replace existing variables.
- You must provide the **; Names** and **; Choices** specifications. These are mandatory.
- You must provide at least one of **; Rhs** or **; Rh2** variable. Either is optional, but at least one of the two must be present.
- Note that the count of Rhs variables is an exact multiple of the number of choices in the **; Choices** list.
- The number of names in the **; Names** list is the sum of
    - the number of Lhs variables
    - the number of sets of Rhs variables
    - the number of Rh2 variables.

When **CLCONVERT** is executed, the sample is reset to the number of observations in the new sample. There is an additional option with **CLCONVERT**. After the data are converted, you can discard the original data set with

; Clear

This leaves the entire data set consisting of the variables that are in your **; Names** list. (Use this with caution. The operation cannot be reversed.)

To illustrate the operation of this command, suppose the data set consists of these three observations:

$$\begin{bmatrix} choicei1 & choicei2 & ctime & ttime & btime & ccost & tcost & bcost & agei & incomei \\ 2 & 3 & 44 & 29 & 56 & 125 & 40 & 25 & 37 & 56.6 \\ 1 & 1 & 19 & 44 & 20 & 160 & 18 & 50 & 42 & 98.6 \\ 3 & 2 & 28 & 55 & 15 & 85 & 50 & 9 & 10 & 22.0 \end{bmatrix}.$$

We wish to convert this data set to *NLOGIT*'s multiple line format. There are three choices in the choice set, so there will be three rows of data for each observation. The command and the results are as follows:

IMPORT $

```
choicei1,choicei2,ctime,ttime,btime,ccost,tcost,bcost,agei,incomei
2,3,44,29,56,125,40,25,37,56.6
1,1,19,44,20,160,18,50,42,98.6
3,2,28,55,15, 85,50, 9,10,22.0
```

ENDDATA $
CLCONVERT ; Lhs = choicei1,choicei2
; Choices = car,train,bus
; Rhs = ctime,ttime,btime,ccost,tcost,bcost
; Rh2 = agei,incomei
; Names = Choice1,Choice2,time,cost,age,income ; Clear $

```
=================================================================
Data Conversion from One Line Format for NLOGIT
Original data were cleared. This is now the whole data set.
The new sample contains      9 observations.
=================================================================
Choice set in new data set has  3 choices:
CAR      TRAIN    BUS
-----------------------------------------------------------------
There were  2 choice variables coded 1,..., 3 converted to binary
Old variable = CHOICEI1, New variable = CHOICE1
Old variable = CHOICEI2, New variable = CHOICE2
-----------------------------------------------------------------
There were  2 sets of variables on attributes converted.  Each
set of  3 variables is converted to one new variable
New Attribute variable TIME     is constructed from
CTIME    TTIME    BTIME
New Attribute variable COST     is constructed from
CCOST    TCOST    BCOST
-----------------------------------------------------------------
There were  2 characteristics that are the same for all choices.
Old variable = AGEI    , New variable = AGE
Old variable = INCOMEI , New variable = INCOME
=================================================================
```

E38.4 Command for the Discrete Choice Model

The essential command for the discrete choice models is

CLOGIT ; Lhs = variable which indicates the choice made
; Choices = a set of J names for the set of choices
; Rhs = choice varying attributes in the utility functions
; Rh2 = choice invariant variables, including *one* for ASCs $

(The command **DISCRETE CHOICE** may also be used.)

The command builder for this model is found in Model:Discrete Choice/Discrete Choice. The model and the choice set are set up on the Main page. The Rhs variables (attributes) and Rh2 variables (characteristics) are defined on the Options page. Note in the two windows on the Options page, the Rhs of the model is defined in the left window and the Rh2 variables are specified in the right window.

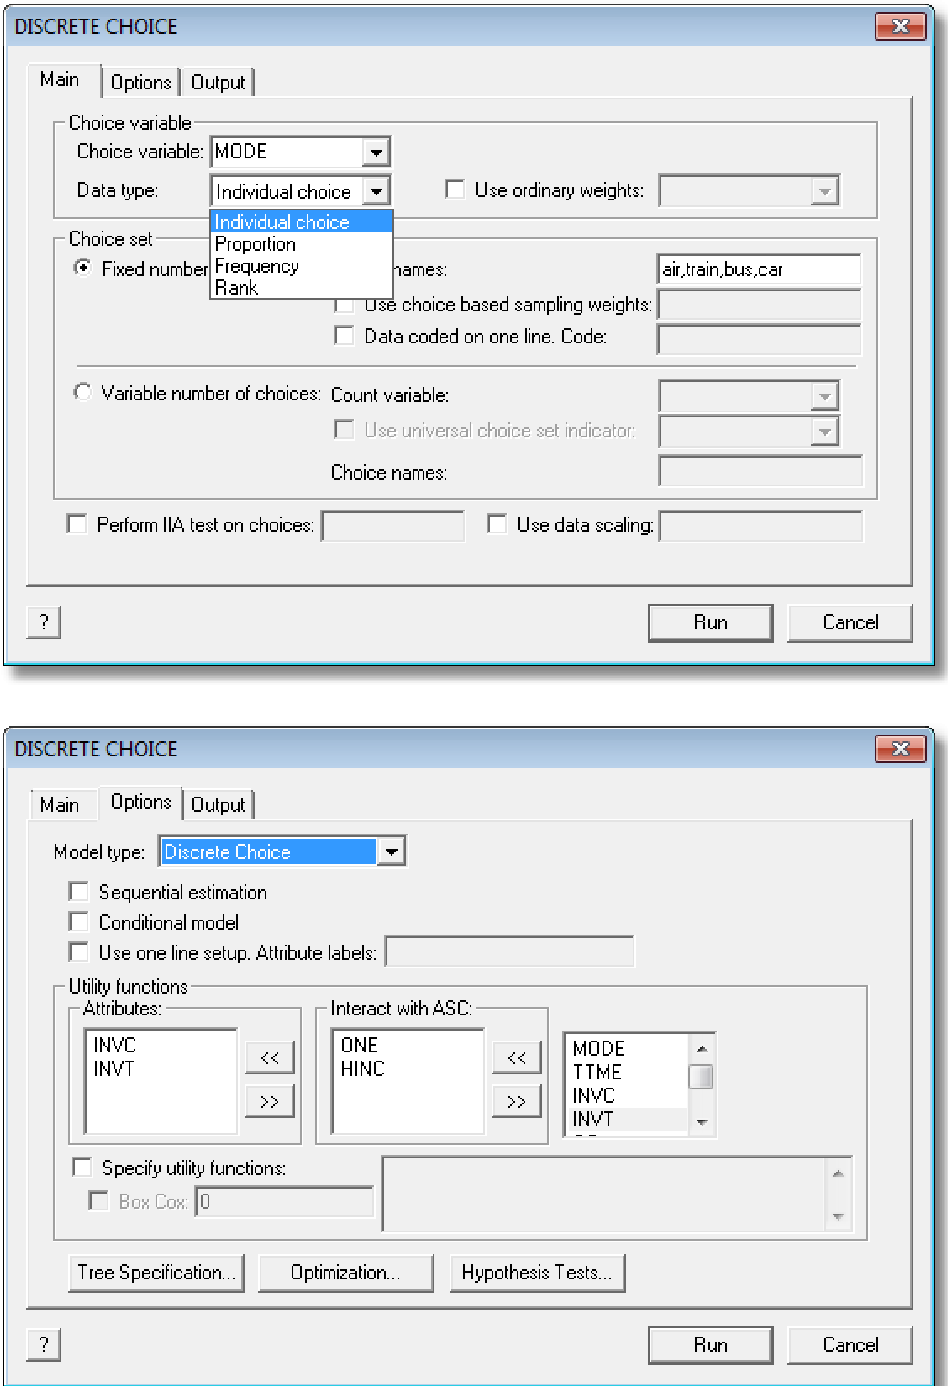

Figure E38.2 Command Builder for the Conditional Logit Model

A set of exactly J choice labels must be provided in the command. These are used to label the choices in the output. The number you provide is used to determine the number of choices there are in the model. Therefore, the set of the right number of labels is essential. Use any descriptor of eight or fewer characters desired – these do not have to be valid names, just a set of labels, separated in the list by commas.

The internal limit on J, the number of choices, is 500.

There are K attributes (Rhs variables) measured for the choices. The next chapter will describe variations of this for different formulations and options. The total number of parameters in the utility functions will include K_1 for the Rhs variables and $(J\text{-}1)K_2$ for the Rh2 variables. The total number of utility function parameters is thus $K = K_1 + (J\text{-}1)K_2$.

The internal limit on K, the number of utility function parameters, is 300.

The random utility model specified by this setup is precisely of the form

$$U_{i,j} = \beta_1 x_{i,1} + \beta_2 x_{i,2} + ... + \beta_{K1} x_{i,K1} + \gamma_{1,j} z_{i,1} + ... + \gamma_{K2,j} z_{i,K2} + \varepsilon_{i,j}$$

where the x variables are given by the Rhs list and the z variables are in the Rh2 list. By this specification, the same attributes and the same characteristics appear in all equations, at the same position. The parameters, β_k appear in all equations, and so on. There are various ways to change this specification of the utility functions – i.e., the Rhs of the equations that underlie the model, and several different ways to specify the choice set. These will be discussed at various points below.

Unlabeled Choice Sets

In some situations, particularly in choice experiments and survey data, the choices will not be a well defined set of alternatives such as (air, train, bus, car), but, rather will simply be a set of unordered choices distinguished only by the different attributes. For example, in a marketing experiment, the choice set might consist of (first, second, third, none of these). When the choice set does not have natural labels, you may use

; Choices = number_name

to define the list. For our example, we might use

; Choices = 3_brand, none

which produces the list (*brand*1,*brand*2,*brand*3,*none*).

Standard Model Specifications for the Conditional Logit (CLOGIT) Model

This is the full list of general that apply to this model.

Controlling Output from Model Commands

; Partial Effects	displays partial effects. (Use **; Effects: specification**.)
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix	displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Choice	uses choice based sampling (sandwich with weighting) estimated matrix. (This is specified in the **; Choices = list** specification for this model.)
; Cluster = name	requests computation of the cluster form of corrected covariance estimator.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm. Newton's method is best. BFGS is occasionally needed.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Prob = name	saves probabilities as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E38.5 Results for the Conditional Logit Model

The output for the CLOGIT estimator may contain a description of the model before the statistical results. The description consists of a table that shows the sample proportions (and a 'tree' structure that is not useful here) and one that lists the components of the utility functions. You can request these two listings by adding

; Show Model

to your **CLOGIT** command. Starting values for the iterations are either zeros or the values you provide with **; Start = list**. As such, there is no initial listing of OLS results. Output begins with the final results for the model. Here is a sample: The command is

```
CLOGIT    ; Lhs = mode ; Choices = air,train,bus,car
          ; Rhs = invc,invt,gc
          ; Rh2 = one,hinc
          ; Show Model $
```

The full set of results is as follows:

```
Sample proportions are marginal, not conditional.
Choices marked with * are excluded for the IIA test.

NOTE: (This is one of our frequently asked questions.) The '*R*-squareds' shown in the output are R^2s in name only. They do not measure the fit of the model to the data. It has become common for researchers to report these with results as a measure of the improvement that the model gives over one that contains only a constant. But, users are cautioned not to interpret these measures as suggesting how well the model predicts the outcome variable. It is essentially unrelated to this.

To underscore the point, we will examine in detail the computations in the diagnostic measures shown in the box that precedes the coefficient estimates. Consider the example below, which was produced by fitting a model with five coefficients subject to two restrictions, or three free coefficients – *npfree* = 3. (The effect is achieved by specifying **; Choices = air,(train),(bus),car**.

There are 210 individuals in the data set, but this model was fit to a restricted choice set which reduced the data set to $n = 210 - 93 = 117$ useable observations. The original choice set had $J_i = 4$ choices, but two were excluded, leaving $J_i = 2$ in the sample. The log likelihood of -62.58418 is computed as shown in Section E38.6. The 'constants only' log likelihood is obtained by setting each choice probability to the sample share for each outcome in the choice set. For this application, those are 0.49573 for air and 0.50427 for car. (This computation cannot be done if the choice set varies by person or if weights or frequencies are used.) Thus, the log likelihood for the restricted model is

$$\text{Log } L_0 = 117\,(\,0.49573 \times \log 0.49573 + 0.50427 \times \log 0.50427\,) = -81.09395.$$

The 'R^2' is 1 - (-62.54818/-81.0939) = 0.22869 (including some rounding error). The adjustment factor is

$$K = (\Sigma_i J_i - n) / [(\Sigma_i J_i - n) - npfree] = (234 - 117)/(234 - 117 - 3) = 1.02632.$$

and the '*Adjusted* R^2' is $1 - K(\log L / \text{Log}L_0)$

$$\textit{Adjusted } R^2 = 1 - 1.02632\,(-62.54818/-81.0939) = 0.20794.$$

Results kept by this estimator are:

Matrices:	*b* and *varb*	=	coefficient vector and asymptotic covariance matrix
Scalars:	*logl*	=	log likelihood function
	nreg	=	N, the number of observational units
	kreg	=	the number of Rhs variables
Last Model:	*b_variable*	=	the labels kept for the **WALD** command

NOTE: This estimator does not use **PARTIALS** or **SIMULATE** after estimation. Self contained routines are contained in the estimator. These are described in Chapter E40.

In the *Last Model*, groups of coefficients for variables that are interacted with constants get labels *choice_variable*, as in *trai_gco*. (Note that the names are truncated – up to four characters for the choice and three for the attribute.) The alternative specific constants are *a_choice*, with names truncated to no more than six characters. For example, the sum of the three estimated choice specific constants could be analyzed as follows:

WALD ; Fn1 = a_air + a_train + a_bus $

```
-----------------------------------------------------------------------------
WALD procedure. Estimates and standard errors for nonlinear
functions and joint test of nonlinear restrictions.
Wald Statistic               =     16.33643

E38.5.1 Robust Standard Errors

The ‘cluster’ estimator described in Chapter R10 is available in CLOGIT. However, this routine does not support hierarchical samples. There may be only one level of clustering. Also, the cluster specification is defined with respect to the CLOGIT groups of data, not the data set. CLOGIT sorts out how many clusters there are and how they are delineated. But, since the row count of the data set is used in constructing the estimator, you must treat a group of NALT observations as one. For example, our sample data used in this section contain 210 groups of four rows of data. Each group of four is an observation. Suppose that these data were grouped in clusters of three choice situations. The estimation command with the cluster estimator would appear

CLOGIT ; ... (the model) ; Cluster = 3 $

The relevant part of the output would appear as follows:

```
+----------------------------------------------------------------------+
| Covariance matrix for the model is adjusted for data clustering.     |
| Sample of    210 observations contained     70 clusters defined by  |
|      3 observations (fixed number) in each cluster.                 |
+----------------------------------------------------------------------+
-----------------------------------------------------------------------------
Discrete choice (multinomial logit) model
Estimation based on N =    210, K =   9
Number of obs.=   210, skipped    0 obs
--------+--------------------------------------------------------------------
        |                  Standard            Prob.      95% Confidence
    MODE|  Coefficient       Error       z    |z|>Z*         Interval
--------+--------------------------------------------------------------------
    INVC|    -.04613**       .01836    -2.51  .0120     -.08211   -.01014
(rows omitted)
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
-----------------------------------------------------------------------------
```

Use **; Cluster** as per the other models in *LIMDEP* – the same construction is used here.

E38.5.2 Descriptive Statistics

You may request a set of descriptive statistics for your model by adding

; Describe

to the model command. For each alternative, a table is given which lists the nonzero terms in the utility function and the means and standard deviations for the variables that appear in the utility function. Values are given for all observations and for the individuals that chose that alternative. For the example shown above, the following tables would be produced:

CLOGIT ; Lhs = mode ; Choices = air,train,bus,car
; Rhs = invc,invt,gc ; Rh2 = one,hinc
; Describe $

E38.6 Estimating and Fixing Coefficients

Maximum likelihood estimates are obtained by Newton's method. Since this is a particularly well behaved estimation problem, zeros are used for the start values with little loss in computational efficiency. The gradient and Hessian used in iterations and for the asymptotic covariance matrix are computed as follows:

d_{ji} = 1 if individual i makes choice j and 0 otherwise

$$P_{ji} = \text{Prob}[y_i = j] = \text{Prob}[d_{ji} = 1] = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_{ji})}{\sum_{m=1}^{J_i}\exp(\boldsymbol{\beta}'\mathbf{x}_{mi})}$$

$$\text{Log } L = \sum_{i=1}^{n}\sum_{j=1}^{J_i} d_{ji}\log P_{ji}$$

$$\overline{\mathbf{x}}_i = \sum_{j=1}^{J_i} P_{ji}\mathbf{x}_{ji},$$

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{n}\sum_{j=1}^{J_i} d_{ji}(\mathbf{x}_{ji} - \overline{\mathbf{x}}_i),$$

$$\frac{\partial^2 \log L}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'} = \sum_{i=1}^{n}\sum_{j=1}^{J_i} P_{ji}(\mathbf{x}_{ji} - \overline{\mathbf{x}}_i)(\mathbf{x}_{ji} - \overline{\mathbf{x}}_i)',$$

Occasionally, a data set will be such that Newton's method does not work – this tends to occur when the log likelihood is flat in a broad range of the parameter space. There is no way that you can discern this from looking at the data, however. If Newton's method fails to converge in a small number of iterations, unless the data make estimation impossible, you should be able to estimate the model by using

; Alg = BFGS

as an alternative. The BFGS algorithm will take slightly longer, but for most data sets, the difference will be a few seconds. If this method fails as well, you should conclude that your model is inestimable.

You may provide your own starting values with

; Start = list of K values

If you have requested a set of alternative specific constants, you must provide starting values for them as well. *Regardless of where 'one' appears in the Rhs list, the ASCs will be the last J-1 coefficients corresponding to that list. If you have Rh2 variables, the coefficients will follow the Rhs coefficients, including the list of ASCs.*

Coefficients may be fixed at specific values during optimization. Use

; Fix = variable name [value]

for example, **; Fix = ttme [.01]**

The following results are obtained from

```
CLOGIT    ; Lhs = mode
          ; Choices = air,train,bus,car
          ; Rhs = gc,ttme
          ; Rh2 = one
          ; Fix = ttme[.01] $
```

-----------------------------------------------------------------------------
```

E38.7 MLOGIT and CLOGIT

When there are no choice varying attributes, CLOGIT is the same model as MLOGIT. From Chapter E37, the functional form for MLOGIT is

$$\text{Prob}(y_i = j|\mathbf{x}_i) = \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_i)}{\sum_{m=1}^{J}\exp(\boldsymbol{\beta}_m'\mathbf{x}_i)}, \; j = 0,\ldots,J,$$

From the introduction in this chapter,

$$\text{Prob}(\text{choice} = j \mid \mathbf{X}_i,\mathbf{z}_i) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_{ji} + \boldsymbol{\gamma}_j'\mathbf{z}_i)}{\sum_{m=0}^{J}\exp(\boldsymbol{\beta}'\mathbf{x}_{mi} + \boldsymbol{\gamma}_m'\mathbf{z}_i)}, \; j = 1,\ldots,J.$$

In the second equation, if $\boldsymbol{\beta}$ equals zero – there are no choice varying attributes – then the second probability is the same as the first, after a simple renaming of the parts; $\boldsymbol{\gamma}_j$ in the second replacing $\boldsymbol{\beta}_j$ in the first, and $\mathbf{z}_i$ replacing $\mathbf{x}_i$. (The alternatives are renumbered, indexing from 1 to J rather than from 0 to J.) The following illustrates the result:

```
? CLOGIT using the original data
CLOGIT      ; Lhs = mode ; Choices = air,train,bus,car
            ; Rhs = one ; Rh2 = hinc
            ; Effects: hinc(*) $
? Create the dependent variable for MLOGIT, using the first row of clogit data
CREATE      ; pick = mode*(0*aasc+1*tasc+2*basc+3*casc) $
CREATE      ; choice = 3 - (pick+pick[+1]+pick[+2]+pick[+3]) $
? Use only the first row for MLOGIT
MLOGIT      ; If[aasc = 1 ] ; Lhs = choice ; Rhs = one,hinc
            ; Partial Effects
            ; Labels = car,bus,train,air $
```

We have normalized MLOGIT so that *choice* = 0 means pick *car* and *choice* = 3 means pick *air*. The elasticities then correspond to those in the CLOGIT results, and the coefficients are the same.

E39: Specifications of the Conditional Logit Models

E39.1 Introduction

Chapter E38 described how to fit the generic form of the multinomial logit model for multinomial choice. This chapter presents some modifications of the basic command that accommodate more general choice sets (possibly varying across individuals) and a convenient alternative command format that allows more general specifications of the utility functions. Two modifications of the estimator are described, one for the case in which certain attributes are ignored by some of the sampled individuals and a second that is based on the maximum entropy criterion rather than maximum likelihood.

E39.2 Choice Sets

In the standard case, data on the Lhs variable will consist of a column of J-1 zeros and a one for the choice made, when reading down the J rows of data for the individual. We allow other types of data on the choice variable. If you have grouped data, the values will be proportions or frequencies, instead. For proportions data, within each observation (J data points), the values of the Lhs variable will sum to one when summed *down* the J rows. (This will be the only difference in the grouped data treatment.) With frequencies, the values will simply be a set of nonnegative integers. An example of a setting in which such data might arise would be in marketing, where the proportions might be market shares of several brands of a commodity. Alternatively, the choice variable might be a set of ranks, in which case, instead of zeros and ones, the Lhs variable would take values 1,2,...,J (not necessarily in that order) within, and reading down, each block.

E39.2.1 Fixed and Variable Numbers of Choices

When every individual in the sample chooses from the same choice set, and all alternatives are available to all individuals, then the data set will appear as in the example developed in Chapter E38, and will consist of n sets of J 'observations.' You indicate this case with a command such as:

```
CLOGIT    ; Lhs = the choice variable
          ; Choices = ... a list of J names for the choices
          ; ... the rest of the command $
```

For example,

```
CLOGIT    ; Lhs = mode
          ; Choices = air,train,bus,car
          ; etc. $
```

There are many cases in which the choice set will vary from one individual to another. We consider the random choice model first in which the number of choices is not constant from one observation to the next. Ranks data are considered later. Two possible arrangements that might produce variable sized choice sets are as follows:

- There is a *universal choice set*, from which individuals make their choice. But, not all choices are available to all individuals. Consider, for example, the choice of travel mode among *train, bus, car, ferry*. If respondents are observed at many different locations, one or more of the choices, such as *ferry* or *train*, might be unavailable to them, and those might vary from person to person. In this case, there is a fixed set of J alternatives, but each individual chooses among their own J_i choices. This is called a 'labeled' choice set.

- Individuals each choose among their own set of J_i alternatives. However, there is no universal choice set. Consider, for example, the choice of which shopping center to shop at. If observations are taken in many different cities, we will observe numerous different choice sets, but there is no well defined universal choice set. This is called an 'unlabeled' choice set.

Unlabeled choice sets often arise in survey data, or 'stated choice experiments.' In a stated choice experiment, an individual might be offered a set of J_i alternatives that are only differentiated by their attributes. Configurations of features in a choice set of cars or appliances might be such a case. In this instance, the choices are simply numbered, 1,2,…

Either of these cases can be accommodated with **CLOGIT**. For both cases, you will provide a variable which gives the number of choices for each observation. This variable is then a second **; Lhs** specification. The command for an unlabeled choice set, which is the simpler case, becomes

```
CLOGIT    ; Lhs = y,nij
          ; ... specification of the utility functions
          ; ... the rest of the command $
```

Note that the **; Choices = list** is not defined in the command, since in this case, there is no clearly defined choice set. Nothing else need be changed. *LIMDEP* does all of the accounting internally. In this case, it is simply assumed that each individual has their own choice set.

For example, one such data set might appear as follows.

	y	*q*	*w*	*nij*
i=1	0	$q_{1,1}$	$w_{1,1}$	3
	—>1	$q_{2,1}$	$w_{2,1}$	3
	0	$q_{3,1}$	$w_{3,1}$	3
i=2	0	$q_{1,2}$	$w_{1,2}$	4
	0	$q_{2,2}$	$w_{2,2}$	4
	—>1	$q_{3,2}$	$w_{3,2}$	4
	0	$q_{4,2}$	$w_{4,2}$	4
i=3	—>1	$q_{1,3}$	$w_{1,3}$	2
	0	$q_{2,3}$	$w_{2,3}$	2

Note that *nij* is the usual group size variable for a panel in *LIMDEP*. The model command might be

CLOGIT ; Lhs = y,nij ; Rhs = q,w $

Notice, once again, that the command does not contain a definition of the choice set, such as **; Choices = list** specification.

For the case of a universal choice set, suppose that the data set above were, instead:

	Y	*q*	*w*	*nij*	*altij*
i=1	0	$q_{1,1}$	$w_{1,1}$	3	1 (Air)
	—>1	$q_{2,1}$	$w_{2,1}$	3	2 (Train)
	0	$q_{3,1}$	$w_{3,1}$	3	4 (Car)
i=2	0	$q_{1,2}$	$w_{1,2}$	4	1 (Air)
	0	$q_{2,2}$	$w_{2,2}$	4	2 (Train)
	—>1	$q_{3,2}$	$w_{3,2}$	4	3 (Bus)
	0	$q_{4,2}$	$w_{4,2}$	4	4 (Car)
i=3	—>1	$q_{1,3}$	$w_{1,3}$	2	3 (Bus)
	0	$q_{2,3}$	$w_{2,3}$	2	4 (Car)

The specific choice identifier, when it is needed, is provided as a *third* Lhs variable. For this case, the choice set would have to be defined. For example,

CLOGIT ; Lhs = y,nij,altij
; Choices = air,train,bus,car
; Rhs = q,w $

In this case, every individual is assumed to choose from a set of four alternatives, though the *altij* variable indicates that some of these choices are unavailable to some individuals.

Do note that if you are not defining a universal choice set, *LIMDEP* simply uses the largest number of choices for any individual in the sample to determine *J* for the model. As such, an expanded set of choice specific constants is not likely to be meaningful, though you can create one with **; Rh2 = one**. Also, if you do not specify a universal choice set, the variable *altij* will not be meaningful.

E39.2.2 Restricting the Choice Set

The IIA test described later in Section E40.4 is carried out by fitting the model to a restricted choice set, then comparing the two sets of parameter estimates. You can restrict the choice set used in estimation, irrespective of the IIA test, by a slight change in the command. In the **; Choices = list of alternatives** specification, enclose any choices to be excluded in parentheses. For example, in our **CLOGIT** application, the specification

; Choices = air,(train),(bus),car

produces the following display in the model output:

```
+------------------------------------------------------+
|WARNING:   Bad observations were found in the sample. |
|Found  93 bad observations among     210 individuals. |
|You can use ;CheckData to get a list of these points. |
+------------------------------------------------------+
Sample proportions are marginal, not conditional.
Choices marked with * are excluded for the IIA test.

    INVT|    -.01195***      .00395    -3.03  .0025     -.01969   -.00422
      GC|     .08576***      .02654     3.23  .0012      .03374    .13778
    TTME|    -.08222***      .01854    -4.43  .0000     -.11855   -.04588
   A_AIR|    2.12899*       1.20531     1.77  .0773     -.23337   4.49135
 A_TRAIN|        0.0    .....(Fixed Parameter).....
   A_BUS|        0.0    .....(Fixed Parameter).....
--------+--------------------------------------------------------------------
Note: ***, **, * ==>  Significance at 1%, 5%, 10% level.
Fixed parameter ... is constrained to equal the value or
had a nonpositive st.error because of an earlier problem.
```

Note that as in the IIA test, this procedure results in exclusion of some ‘bad’ observations, that is, the ones that selected the excluded choices. Because of the model specification, the ASCs for bus and train have been fixed at zero.

You may combine the choice based sampling estimator with the restricted choice set. All the necessary adjustments of the weights are made internally. Thus, the specification

; Choices = air,(train),(bus),car / .14,.13,.09,.64

produces the following listing:

```
+----------------+------+---+
|Choice   (prop.)|Weight|IIA|
+----------------+------+---+
|AIR       .49573|  .387|   |
|TRAIN     .00000|  .000| * |
|BUS       .00000|  .000| * |
|CAR       .50427| 1.739|   |
+----------------+------+---+
```

E39.2.3 Very Large Choice Sets

The conditional logit estimator can fit a model with up to 500 choices, which is quite large. However, certain applications, such as home purchase choice, have involved many more than that. CLOGIT and the other estimators in *LIMDEP* are bound by certain internal limits. However, it is possible to stretch the estimator a bit more. It turns out that Chamberlain's fixed effects model for the binary logit model described in Section E30.5 can be used to fit a discrete choice model. The log likelihood function for this model is

$$L_c = \frac{\prod_{t=1}^{T_i} \exp[y_{it}\boldsymbol{\beta}'\mathbf{x}_{it}]}{\sum_{\textit{all arrangements of } T_i \textit{ outcomes with the same sum}} \prod_{s=1}^{T_i} \exp[y_{is}\boldsymbol{\beta}'\mathbf{x}_{is}]}$$

$$= \frac{\exp\left[\sum_{t=1}^{T_i} y_{it}\boldsymbol{\beta}'\mathbf{x}_{it}\right]}{\sum_{\textit{all arrangements of } T_i \textit{ outcomes with the same sum}} \exp\left[\sum_{s=1}^{T_i} d_{is}\boldsymbol{\beta}'\mathbf{x}_{is}\right]}.$$

If the group of observations has exactly one '1' and T_i - 1 '0s,' then this is exactly the log likelihood for the discrete choice model that we have analyzed in this chapter. Thus, if the group of observations for individual *i* is treated as if this were a fixed effects model, then this estimator can be used to obtain parameter estimates. The command setup would be

```
LOGIT       ; Lhs = choice
            ; Rhs = the set of variables
            ; Pds = the number of choices $
```

This arrangement will allow up to 200 choices. The only shortcoming (aside from the greatly restricted number of optional features) is that unless you can provide the actual dummy variables, as we do below, it is not possible to specify a set of choice specific constants with this estimator. Two ways to fit the model in our example would be

```
CLOGIT      ; Lhs = mode
            ; Rhs = invc,invt,gc,ttme

E39.3 Weighting

You can, in principle, use any weighting variable you wish with this model to weight observations. The model does not require that weights be the same for all outcomes for a given observation. For example, in a grouped data case, you might have at hand the total number of observations which gave rise to each of the proportions in the proportions data. If so, you could use the information to replicate each observation the appropriate number of times. In this case, use the

; Wts = name

option on the **CLOGIT** command, as you would with any other model. Normally, this variable would take the same value for each of the *J* data vectors associated with observation *i*. (Suppose instead of 0,1,0 for the first observation, we observed .4, .5, .1 based on 200 observations. Then, '*name*' would take the value 200 for the first three observations, etc.) (Of course, you could achieve the same result by providing the frequencies as the Lhs variable.)

E39.4 Choice Based Sampling

The weighting may be based on the outcomes. For example, suppose the model predicts mode of travel, *car, train*, or *horse*. The true population proportions are known to be .6, .35, and .05. But, we deliberately oversample the last category so that the sample proportions are, say, .5, .3, and .2. In estimation, to account for the nonrandom sampling, we would use a weighting scheme which gives observations in which outcome 1 (*car*) received a weight of .6/.5 = 1.2, outcome 2 (*train*), .35/.3 = 1.16667, and outcome 3 (*horse*), .05/.2 = .25. Notice that regardless of the number of observations, the weighting variable in this scenario takes only *J* values, where *J* is the number of outcomes. The Lerman-Manski (1981) correction to the variance matrix of the estimates is used at convergence to obtain the appropriate standard errors. The covariance matrix used is $\mathbf{V} = \mathbf{H}^{-1}\mathbf{D}\mathbf{H}^{-1}$, where **H** is the weighted Hessian and **D** is the weighted sum of the outer products of the first derivatives, as opposed to $\mathbf{V} = \mathbf{H}^{-1}$ which would be used normally.

To request this procedure, it is only necessary for you to provide the *J* population weights. Everything else is automated. The weights are provided after the labels for the outcomes following a slash. The following example is consistent with the discussion above. The unweighted specification would be

```
CLOGIT    ; ... ; Choices = car,train,horse $
```

The choice based sampling weights would be provided in

```
CLOGIT    ; ... ; Choices = car,train,horse / .6,.35,.05 $
```

Notice that you only provide the population weights. The program obtains the sample proportions and computes the appropriate weights for the estimator. This is a bit different from the earlier applications (probit and logit – see Section E27.10), and it is the only estimator in *LIMDEP* for which you provide only the population weights, as opposed to the sampling ratios.

Everything else is the same as before. Note, you *do not* use a weighting (**; Wts**) variable here. Your population weights must sum to 1.0; if not, an error occurs and estimation is halted. If you provide population weights, you must give a full set. Thus, if your list has the slash specification, the number of values after the slash must match exactly the number of labels before it.

The data used in our examples in Chapter E38 are choice based. The example below shows the use of this option to make the appropriate corrections to the estimates:

```
CLOGIT    ; Lhs = mode
          ; Rhs = invc,invt,gc,ttme
          ; Rh2 = one
          ; Choices = air,train,bus,car / .14,.13,.09,.64
          ; Show $
```

The **; Show** parameter requests the display of the table below. Otherwise, only the note in the box of diagnostic statistics indicates use of the choice based sampling estimator.)

```
Sample proportions are marginal, not conditional.
Choices marked with * are excluded for the IIA test.

E39.5 Building the Utility Functions

The model specification thus far builds the utility functions from the common Rhs and Rh2 specifications. For example, in our four outcome model which contains *cost*, *time*, *one* and *income*, the data for the choice variable and the utility functions are contained in

$$\begin{array}{ccccccccc} \text{choice} & \text{cost} & \text{time} & & \text{constants} & & & \text{income} & \\ \end{array}$$

$$\mathbf{Z}_i = \begin{bmatrix} y_{air} & c_a & t_a & 1 & 0 & 0 & income & 0 & 0 \\ y_{train} & c_t & t_t & 0 & 1 & 0 & 0 & income & 0 \\ y_{bus} & c_b & t_b & 0 & 0 & 1 & 0 & 0 & income \\ y_{car} & c_c & t_c & 0 & 0 & 0 & 0 & 0 & 0 \end{bmatrix}.$$

The utility functions are all the same;

$$\begin{aligned} U_{i,air} &= \beta_{cost}cost_{i,air} + \beta_{time}time_{i,air} + \alpha_{air} + \gamma_{air}income_i + \varepsilon_{i,air} \\ U_{i,train} &= \beta_{cost}cost_{i,train} + \beta_{time}time_{i,train} + \alpha_{train} + \gamma_{train}income_i + \varepsilon_{i,train} \\ U_{i,bus} &= \beta_{cost}cost_{i,bus} + \beta_{time}time_{i,bus} + \alpha_{bus} + \gamma_{bus}income_i + \varepsilon_{i,bus} \\ U_{i,car} &= \beta_{cost}cost_{i,car} + \beta_{time}time_{i,car} + \alpha_{car} + \gamma_{car}income_i + \varepsilon_{i,car} \end{aligned}$$

In order to prevent a multicollinearity problem, $\alpha_{car} = \gamma_{car} = 0$. One might want to have different attributes appear in the different utility functions, or impose other kinds of constraints on the parameters, or allow a generic coefficient such as β_1 to differ across groups of observations. In general, these sorts of modifications can be obtained by using transformations of the variables. For example, to have β_1 have one value for air and car and a different value for train and bus, we would use

CREATE ; costac = cost*(aasc + casc) ; costtb = cost*(tasc + basc) $

Then, we would replace *cost* with *costac,costtb* in the Rhs specification of the model. The resulting model would be

$$
\begin{aligned}
U_{i,air} &= \beta_{cost1}cost_{i,air} && + \beta_{time}time_{i,air} + \alpha_{air} + \gamma_{air}income_i + \varepsilon_{i,air}\\
U_{i,train} &= \beta_{cost2}cost_{i,train} && + \beta_{time}time_{i,train} + \alpha_{train} + \gamma_{train}income_i + \varepsilon_{i,train}\\
U_{i,bus} &= \beta_{cost2}cost_{i,bus} && + \beta_{time}time_{i,bus} + \alpha_{bus} + \gamma_{bus}income_i + \varepsilon_{i,bus}\\
U_{i,car} &= \beta_{cost1}cost_{i,car} && + \beta_{time}time_{i,car} + \alpha_{car} + \gamma_{car}income_i + \varepsilon_{i,car}
\end{aligned}
$$

This section will describe how to structure the utility functions individually, rather than generically with Rhs and Rh2 and transformations of variables.

E39.5.1 Alternative Specific Constants and Choice Invariant Variables

The CLOGIT model is homogeneous of degree zero in the generic attributes. Any attribute that does not vary across the choices, such as age, marital status, etc., will simply fall out of the probability. Consider, for example, a model that contains an attribute *cost* that varies by choice, and *income* that does not. The generic discrete choice model would specify

$$
\begin{aligned}
Prob(choice = j) &= \frac{\exp(\beta_1 cost_{i,j} + \beta_2 Income_i)}{\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j} + \beta_2 Income_i)}\\
&= \frac{\exp(\beta_2 Income_i)\exp(\beta_1 cost_{i,j})}{\exp(\beta_2 Income_i)\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j})}\\
&= \frac{\exp(\beta_1 cost_{i,j})}{\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j})}
\end{aligned}
$$

Therefore, the model in that form is not estimable. The answer, as we have seen, is to make the coefficient on choice invariant variables vary with the choices. This includes the constant term, *one*. This is how the MLOGIT model of Chapter E37 arises – in that model, all variables are choice invariant. Here, it produces a hybrid model, which can have both types of variables in the utility functions.

$$
Prob(choice = j) = \frac{\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i)}{\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i)}
$$

This is the form of the model in the earlier example,

$$
\begin{aligned}
U_{i,air} &= \beta_{cost}cost_{i,air} + \beta_{time}time_{i,air} + \alpha_{air} + \gamma_{air}income_i + \varepsilon_{i,air}\\
U_{i,train} &= \beta_{cost}cost_{i,train} + \beta_{time}time_{i,train} + \alpha_{train} + \gamma_{train}income_i + \varepsilon_{i,train}\\
U_{i,bus} &= \beta_{cost}cost_{i,bus} + \beta_{time}time_{i,bus} + \alpha_{bus} + \gamma_{bus}income_i + \varepsilon_{i,bus}\\
U_{i,car} &= \beta_{cost}cost_{i,car} + \beta_{time}time_{i,car} + \alpha_{car} + \gamma_{car}income_i + \varepsilon_{i,car}
\end{aligned}
$$

There remains an indeterminacy in the model after it is expanded in this fashion. Suppose the same constant is added to each γ_j, say θ. The resulting model is

$$
\begin{aligned}
Prob(choice = j) &= \frac{\exp(\beta_1 cost_{i,j} + \alpha_j + (\gamma_j + \theta)Income_i)}{\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j} + \alpha_j + (\gamma_j + \theta)Income_i)}\\
&= \frac{\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i + \theta Income_i)}{\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i + \theta Income_i)}\\
&= \frac{\exp(\theta Income_i)\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i)}{\exp(\theta Income_i)\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i)}\\
&= \frac{\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i)}{\sum_{j=1}^{J}\exp(\beta_1 cost_{i,j} + \alpha_j + \gamma_j Income_i)}
\end{aligned}
$$

So, the identical model arises for any θ. This means that the model still cannot be estimated in this form. The solution to this remaining issue is to normalize the coefficients so that one of the choice varying parameters is equal to zero. **CLOGIT** sets the last one to zero. The same result applies to the choice specific constant terms that you create with *one*.

The basic four choice model which contains *cost*, *time*, *one* and *income* will have utility functions

$$
\begin{aligned}
U_{i,air} &= \beta_{cost}\, cost_{i,air} + \beta_{time}\, time_{i,air} + \alpha_{air} + \gamma_{air}\, income_i + \varepsilon_{i,air}\\
U_{i,train} &= \beta_{cost}\, cost_{i,train} + \beta_{time}\, time_{i,train} + \alpha_{train} + \gamma_{train}\, income_i + \varepsilon_{i,train}\\
U_{i,bus} &= \beta_{cost}\, cost_{i,bus} + \beta_{time}\, time_{i,bus} + \alpha_{bus} + \gamma_{bus}\, income_i + \varepsilon_{i,bus}\\
U_{i,car} &= \beta_{cost}\, cost_{i,car} + \beta_{time}\, time_{i,car} + \varepsilon_{i,car}
\end{aligned}
$$

The simple device you use to construct utility functions in this fashion is to use

; Rhs = list of attributes that vary across choices

and **; Rh2 = list of variables that do not vary across choices**

The Rh2 variables are automatically expanded into a set of *J*-1 interactions with the choice specific constants, as they are in the matrix $\mathbf{Z}_i$ shown above. The implication is that, generally, you do not need to have these variables in your data set. They are automatically created by your command. (Note that our clogit.dat data set actually does contain the superfluous set of four choice specific constants, *aasc*, *tasc*, *basc* and *casc*.)

NOTE: If you include *one* in your Rhs, it is automatically expanded to become a set of alternative specific constants. That is, *one* is automatically moved to the Rh2 list if it is placed in the Rhs list.

The model specification for the four utility functions shown above would be

; Rhs = cost,time ; Rh2 = one,income

Note that the distinction between Rh2 and Rhs variables is that all variables in the first category are expanded by interacting with the choice specific binary variables. (The last term is dropped.)

HINT: There are many different possible configurations of alternative specific constants (ASCs) and alternative specific variables. In estimating a model, it is not possible to determine a priori if a singularity will arise as a consequence of the specification. You will have to discern this from the estimation results for the particular model.

The constant term, *one* fits the hint above. Recognizing this, *LIMDEP* assumes that if your Rhs list includes *one*, you are requesting a set of alternative specific constants. As such, when the Rhs list includes *one*, *LIMDEP* will create a full set of *J*-1 choice specific constants. Note the earlier examples.

Finally, while it is necessary for choice invariant variables to appear in Rh2, it is not necessary that all variables in the Rh2 list actually be choice invariant. Indeed, one could specify the preceding model with choice specific coefficients on the *cost* variable; it would appear

$$
\begin{aligned}
U_{i,air} &= \gamma_{cost,air}\, cost_{i,air} + \beta_{time}\, time_{i,air} + \alpha_{air} + \gamma_{air}\, income_i + \varepsilon_{i,air}\\
U_{i,train} &= \gamma_{cost,train}\, cost_{i,train} + \beta_{time}\, time_{i,train} + \alpha_{train} + \gamma_{train}\, income_i + \varepsilon_{i,train}\\
U_{i,bus} &= \gamma_{cost,bus}\, cost_{i,bus} + \beta_{time}\, time_{i,bus} + \alpha_{bus} + \gamma_{bus}\, income_i + \varepsilon_{i,bus}\\
U_{i,car} &= \gamma_{cost,car}\, cost_{i,car} + \beta_{time}\, time_{i,car} + \varepsilon_{i,bus}
\end{aligned}
$$

Note also, that there is no need to drop one of the time coefficients because the variable *cost* varies by choices. You *can* estimate a model with four separate coefficients for *cost*, one in each utility function. However, it is not possible to do it by including *cost* in the Rh2 list as described above, because this form will automatically drop the last term (the one in the *car* utility function). You could obtain this form, albeit a bit clumsily, by creating the four interaction terms yourself and including them on the Rhs. We already have the alternative specific constants, so the following would work

```
CREATE     ; cost_a = gc * aasc
           ; cost_t  = gc * tasc
           ; cost_b = gc * basc
           ; cost_c  = gc * casc $
CLOGIT     ; ...  ; Rhs  = time,cost_a,cost_t,cost_b,cost_c
                  ; Rh2 = one,income $
```

Having to create the interaction variables is going to be inconvenient. The alternative method of specifying the model described in the next section will be much more convenient. This method also allows you much greater flexibility in specifying utility functions.

E39.5.2 Building the Utility Functions

The utility functions need not be the same for all choices. Different attributes may enter and the coefficients may be constrained in different ways. The following more flexible format can be used instead of the **; Rhs = list** and **; Rh2 = list** parts of the command described above. This format also provides a way to supply starting values for parameters, so this can also replace the **; Start = list** specification. Finally, you will also be able to use this format to fix coefficients, so it will be an easy way to replace the **; Rst = list** and **; Fix = name[value]** specifications.

We begin with the case of a fixed (and named) set of choices, then turn to the cases of variable numbers of choices. We replace the Rhs/Rh2 setup with explicit definitions of the utility functions for the alternatives. Utility functions are built up from the format

```
; Model:  U(choice 1) = linear equation  /
          U(choice 2) = linear equation /
          ...
          U(choice J) = linear equation $
```

Though we have shown all *J* utility functions, for a given model specification, you could, in principle, not specify a utility function in the list. The implied specification would be $U_{ij} = \varepsilon_{ij}$. The **: U(list)** is mandatory if the command contains **; Model =….** *LIMDEP* now scans for the '*U*' and the parentheses. For example:

```
; Model:  U(air) = ba + bcost * gc
```

Note that the specification begins with '**; Model:**' – the colon ('**:**') is also mandatory. Parameters always come first, then variables. Constant terms need not multiply variables. Thus, *ba* in this *could* be an '*Air specific constant*.' (It depends on whether *ba* appears elsewhere in the model.) Notice that the utility function defines both the variables and the parameters. Usually, you would give an equation for each choice in the model. For example:

```
CLOGIT     ; Lhs = mode
           ; Choices = air,train,bus,car
           ; Model:  U(air)   = ba +  bcost * gc + btime * ttme /
                     U(car)   = bc +  bcost * gc   /
                     U(bus)   = bb +  bcost * gc   /
                     U(train) =       bcost * gc + btime * ttme $
```

Utility functions are separated by slashes. Note also that the alternative specific constants stand alone without multiplying a variable. Your utility definitions now provide the names for the parameters. The estimates produced by this model command are as follows:

```
-----------------------------------------------------------------------------
Discrete choice (multinomial logit) model
Dependent variable               Choice
Log likelihood function      -223.43803
--------+--------------------------------------------------------------------
        |                Standard            Prob.      95% Confidence
    MODE|  Coefficient     Error         z    |z|>Z*         Interval
--------+--------------------------------------------------------------------
      BA|    1.55491***      .37580     4.14  .0000      .81835   2.29147
   BCOST|    -.02021***      .00435    -4.65  .0000     -.02873   -.01168
   BTIME|    -.08680***      .01122    -7.73  .0000     -.10880   -.06481
      BC|   -3.65316***      .46378    -7.88  .0000    -4.56216  -2.74417
      BB|   -3.91983***      .45611    -8.59  .0000    -4.81379  -3.02586
--------+--------------------------------------------------------------------
```

One point that you might find useful to note. The order of the parameters in this list is determined by moving through the model definition from beginning to end. Each time a new parameter name is encountered, it is added to the list. Looking at the model command above, you can now see how the order in the displayed output arose.

The last example in the preceding subsection, which has four separate coefficients on a *cost* variable could be specified using

```
CLOGIT    ; Lhs = mode ; Choices = air,train,bus,car
          ; Model:  U(air)   = bc*invc+bt*invt+aa+cha*hinc+cga*gc /
                    U(train) = bc*invc+bt*invt+at+cht*hinc+cgt*gc  /
                    U(bus)   = bc*invc+bt*invt+ab+chb*hinc+cgb*gc /
                    U(car)   = bc*invc+bt*invt               +cgc *gc $
```

The estimates are

```
--------+--------------------------------------------------------------------
        |                Standard            Prob.      95% Confidence

--------+--------------------------------------------------------------------
```

E39.5.3 Shorthand Notations for Sets of Utility Functions

There are several shorthands which will allow you to make the model specification much more compact. If the utility functions for several alternatives are the same, you can group them in one definition. Thus,

```
; Model: U(air)  = b0 + bcost * gc   /
         U(car)  = b0 + bcost * gc   $
```

could be specified as **; Model: U(air, car) = b0 + bcost * gc $**

For the model we have been considering, i.e.,

; Choices = air,train,bus,car

all of the following are the same

```
; Model: U(air)    = b1 * ttme + bcost * gc   /
         U(train)  = b1 * ttme + bcost * gc   /
         U(bus)    = b1 * ttme + bcost * gc   /
         U(car)    = b1 * ttme + bcost * gc   $
```

and **; Model: U(air,train,bus,car) = b1 * ttme + bcost * gc $**
and **; Model: U(*) = b1 * ttme + bcost * gc $**
and **; Rhs = ttme, gc**

The last will use the variable names instead of the supplied parameter names for the two parameters, but the models will be the same.

E39.5.4 Alternative Specific Constants and Interactions

You can also specify alternative specific constants in this format, by using a special notation. When you have a **U(a1, a2, ..., aJ)** for *J* alternatives, then you may specify, instead of a single parameter, a list of parameters enclosed in pointed brackets, to signify interaction with choice specific constants. Thus, **<b1,b2,...,bL>** indicates *L* interactions with choice specific dummy variables. *L* may be any number up to the number of alternatives. Use a zero in any location in which the variable does not appear in the corresponding equation. For example,

```
; Choices = air,train,bus,car
; Model: U(air)    = ba + bcost * gc   /
         U(car)    = bc + bcost * gc   /
         U(bus)    =      bcost * gc   /
         U(train)  = bt + bcost * gc   $
```

could be specified as **; Model: U(air,car,bus,train) = <ba,bc,0,bt> + bcost * gc $**

NOTE: Within a < ... > construction, the correspondence between positions in the list is with the **U(... list ...)** list, *not* with the original **; Choices** list. Note these are different (deliberately) in the example above.

Note the considerable savings in notation. The same device may also be used in interactions with attributes. For example:

```
; Model: U(air)   = ba + bcprv * gc  /
         U(car)   = bc + bcprv * gc  /
         U(bus)   =      bcpub * gc  /
         U(train) = bt + bcpub * gc  $
```

There are two cost coefficients, but the variable *gc* is common. This entire model can be collapsed into the single specification

```
; Model: U(air,car,bus,train) = <ba,bc,0,bt> +
         <bcprv,bcprv,bcpub,bcpub> * gc $
```

Parameters inside the brackets need not all be different if you wish to impose equality constraints. The example above imposes the two equality constraints shown in the model specification.

E39.5.5 Equality Constraints

There is no requirement that parameters be unique across any specification. Equality constraints may be imposed anywhere in the model, just by using the same parameter name. For example, nothing precludes

```
; Model: U(air,car,bus,train) = <ba,bc,0,bt> +
         <ba,bc,bcpub,bcpub> * gc $
```

This forces two of the slope coefficients to equal the alternative specific constants. Expanded, this specification would be equivalent to

```
; Model: U(air)   = ba + ba    * gc  /
         U(car)   = bc + bc    * gc  /
         U(bus)   =      bcpub * gc  /
         U(train) = bt + bcpub * gc  $
```

E39.6 Starting and Fixed Values for Parameters

The default starting values for all slope parameters in the utility functions specified as above are 0.0. You may provide a starting value for any parameter defined in a utility equation by including the value in parentheses after the *first* occurrence of the parameter definition.

For example:

```
; Model: U(air)   = ba(.53) + bcprv(-1.25) * gc  /
         U(car)   = bc      + bcprv        * gc  /
         U(bus)   =           bcpub        * gc  /
         U(train) = bt(.04) + bcpub        * gc  $
```

Starting values of 0.53 for *ba*, -1.25 for *bcprv*, and 0.04 for *bt* are given. The other parameters, *bcpub* and *bc* both start at 0.0. Note that the starting value for *bcprv* is given with the first occurrence of this name in the model. It is not necessary to give additional starting values for *bcprv*; the first will suffice. (If a parameter name appears more than once in a model definition, one might inadvertently give different starting values for the definitions. For example, if the second line above were **U(car) = bc+bcprv(1.3)*gc/** then values of -1.25 and 1.3 are being given for the same parameter, *bcprv*. The *last* definition is the one that controls. Thus, in this example, the starting value for *bcprv* would be 1.3, not -1.25. Note that this is not meant to be an option that is used for any purpose. This is only meant to explain how this erroneous specification will be handled.)

In a multiple parameter specification, the same value is given to all parameters that appear in the specification. Thus, in our earlier example:

```
; Model:U(air,car,bus,train) = <ba,bc,0,bt> (1.27439) + bcost * gc
```

the three parameters, *ba*, *bc*, and *bt*, are all started at 1.27439.

E39.6.1 Fixed Values

Any parameter that appears in the model may be fixed at a given value, rather than estimated. This might be useful, for example, for testing hypotheses. To fix a parameter, use the setup described above as if you were providing a starting value. But, instead of enclosing the value in parentheses, enclose it in square brackets. For example, in the model above, the coefficient *bcost* might be fixed at 0.05 with the command

```
; Model: U(air,car,bus,train) = <ba,bc,0,bt> (1.27439) + bcost [0.05] * gc
```

The fixed value will appear in the model output with all of the other estimated results, with a notation that this coefficient has been fixed rather than estimated.

E39.6.2 Starting Values and Fixed Values from a Previous Model

Each time you fit a model with **CLOGIT**, the coefficients and the names that you gave them are stored permanently for later use. (This is separate from the coefficients saved for the **WALD** testing procedure discussed in Section R14.4.) You may reuse these coefficients in the current model by specifying starting or fixed values with a simple '**[ ]**' or '**( )**' with no specific values provided. For example,

bcost ( ) * gc

would instruct **CLOGIT** to examine the previous model that you fit. If you had used the name *bcost* for one of the coefficients, then the estimated value from that model would be used as the starting value for this model.

E39.7 Modeling Choice Strategy

In some occasions in survey data, particularly in stated preference experiments, respondents will indicate that they did not consider certain attributes among a set of attributes in making their choices. When this aspect of the data is known, it has been conventional to insert zeros for the attribute in the choice model, thereby removing that attribute from the utility function. However, in fact, that does not remove the attribute from the choice probability; it forces it to enter with a peculiar, possibly extreme value. Consider, for example, a price variable. If a respondent indicates that they ignored price in a choice, then setting the 'price' to zero in the choice set would force a peculiar value on the choice process. Hensher, Rose, and Greene (2005b) argued that if a respondent truly ignores an attribute in a choice situation, then what should be zero in the choice model is not the attribute, but its coefficient in the utility function. That restriction definitely removes the attribute from the choice consideration by taking it out of the model altogether.

Accommodating this idea requires, in essence, that there be a possibly different model for each respondent. That is, one with possibly different zero restrictions imposed for different individuals. **CLOGIT** allows you to automate precisely this formulation in all discrete choice models with a special data coding.

For respondents who ignore attributes (it must be known in the data), simply code the attribute with value -888 for this respondent.

With this data convention, the program automatically detects these values and adjusts the model accordingly. You do not have to add any other codes to any **CLOGIT** commands to signal this aspect of the data. The model output will contain a diagnostic box noting when this option is being used when **CLOGIT** finds these values in the data.

The following applies to this feature:

1. At least some respondents must actually consider the attribute. It cannot be omitted from the model for everyone.

2. In computing elasticities (see Section E40.2), if **; Means** is used, it may distort the means slightly. How much so depends on how many observations are in use and how often the attribute is ignored. No generalizations are possible.

3. In computing descriptive statistics with the **; Describe** option (see Section E38.5.2), this may distort the means because the -888 values are not skipped, they are changed to 0.0. Output will contain a warning to this effect if it is noticed.

E39.8 Generalized Maximum Entropy Estimator

The CLOGIT multinomial logit model may be estimated using the generalized maximum entropy estimator described in Section E37.8 for the MLOGIT model. The estimator is the same – the difference between there and here is only the constraint on the parameter vectors – there is only a single parameter vector in the CLOGIT model. The computations are identical; the only difference is the format of the data. The estimator is requested by adding

; GME

or **; GME = number of support points**

to the **CLOGIT** command. In the application below, we reestimate the model used in several examples, using GME instead of MLE. The MLE is shown at the end of the results for ease of comparison. The command would be

CLOGIT ; Lhs = mode ; Rhs = one,gc,ttme
; Choices = air,train,bus,car
; GME = 5 $

```

E40: Post Estimation Results for Conditional Logit Models

E40.1 Introduction

This chapter completes the documentation of the conditional logit (CLOGIT) model with four post estimation calculations:

- Partial effects and elasticities
- Predictions of probabilities, utilities and several other variables,
- Specification testing for the IIA assumption
- Model simulation and examination of the effects of changing scenarios on market shares.

E40.2 Partial Effects and Elasticities

In the discrete choice model, the effect of a change in attribute '*k*' of alternative '*j*' on the probability that individual *i* would choose alternative '*m*' (where *m* may or may not equal *j*) is

$$\delta_{im}(k|j) = \partial \text{Prob}[y_i = m]/\partial x_i(k|j) = [\mathbf{1}(j = m) - P_{ij}]P_{im}\beta_k.$$

You can request a listing of the effects of a specific attribute on a specified set of outcomes with

; Effects: attribute [list of outcomes]

The outcomes listing defines the variables '*j*' in the definition above. The attribute is the '*k*th.' A calculated partial effect is then listed for all alternatives (i.e., all '*m*') in the model. You can request additional tables by separating additional specifications with slashes. For example:

; Effects: gc [car, train] / ttme [bus,train]

HINT: It may generate quite a lot of output if your model is large, but you can request an analysis of 'all' alternatives by using the wildcard, **attribute [*]**.

The table below is produced by

```
CLOGIT    ; Lhs  = mode ; Choices = air,train,bus,car
          ; Rhs  = invc,invt,gc
          ; Rh2 = one,hinc
          ; Effects: gc [*] $
```

```
Derivative wrt change of X in row choice on Prob[column choice]
--------+----------------------------------
GC      |     AIR    TRAIN      BUS      CAR
--------+----------------------------------
     AIR|   .0060   -.0020   -.0012   -.0028
   TRAIN|  -.0020    .0062   -.0018   -.0024
     BUS|  -.0012   -.0018    .0043   -.0013
     CAR|  -.0028   -.0024   -.0013    .0066
```

The effects are computed by averaging the individual specific results, so the report contains the average partial effects. Since the mean is computed over a sample of observations, we also report the standard deviation of the estimates.

As noted in the tables, the marginal effects are computed by averaging the individual sample observations. An alternative way to compute these is to use the sample means of the data, and compute the effects for this one hypothetical observation. Request this with

; Means

For the table above, the results would be as follows:

```
Derivative wrt change of X in row choice on Prob[column choice]
--------+----------------------------------
GC      |     AIR    TRAIN      BUS      CAR
--------+----------------------------------
     AIR|   .0073   -.0030   -.0014   -.0028
   TRAIN|  -.0030    .0076   -.0016   -.0031
     BUS|  -.0014   -.0016    .0044   -.0015
     CAR|  -.0028   -.0031   -.0015    .0073
```

Note that the changes are substantive. The literature is divided on this computation. Current practice favors the first (default) approach.

The results above are only the average partial effects. In order to obtain a full listing of the effects and an estimator of the sample variance, use

; Full

For the preceding, we obtain

```

```

The ‘standard errors’ in these results are computed as the sample standard deviations of the sample of observations on the derivatives. These are not identical to what would be obtained if the delta method were applied to the nonlinear function used to obtain the elasticities though they should be reasonably close.

E40.2.1 Elasticities

Rather than see the partial effects, you may want to see elasticities,

$$\eta_{im}(k|j) = \partial \log \mathrm{Prob}[y_i = m]/\partial \log x_i(k|j) = x_i(k|j)/P_{im} \times \delta_{im}(k|j)$$

$$= [\mathbf{1}(j = m) - P_{ij}]\, x_i(k|j)\beta_k$$

Notice that this is not a function of P_{im}. The implication is that all the cross elasticities are identical. This will be obvious in the results, as shown in the example below.

You may request elasticities instead of partial effects simply by changing the square brackets above to parentheses, as in

; Effects: attribute (list of outcomes)

The first set of results above would become as shown in the following table:

```
Elasticity wrt change of X in row choice on Prob[column choice]
--------+----------------------------------
GC      |     AIR    TRAIN      BUS      CAR
--------+----------------------------------
     AIR|  2.6002  -1.1293  -1.1293  -1.1293
   TRAIN| -1.2046   3.5259  -1.2046  -1.2046
     BUS|  -.5695   -.5695   3.6181   -.5695
     CAR|  -.8688   -.8688   -.8688   2.5979
```

With **; Full**, the expanded set of elasticities is produced.

```

```

The force of the independence from irrelevant alternatives (IIA) assumption of the multinomial logit model can be seen in the identical cross elasticities in the tables above. The table also shows two other aspects of the model. First, the meaning of the raw coefficients in a multinomial logit model, all of sign, magnitude and significance, are ambiguous. It is always necessary to do some kind of post estimation such as this to determine the implications of the estimates. Second, in light of this, we can see that the particular model estimated must be misspecified. The estimates imply that as the generalized cost of each mode rises, it becomes more attractive. The *gc* coefficient has the 'wrong' sign.

Elasticities and partial effects in the CLOGIT model are computed by averaging the individual observations on these quantities. Observations receive equal weight ($1/n$) in the average. A problem can arise when computing elasticities in this fashion. If an observation in the sample has an extreme configuration of attributes for some reason, then the elasticity or marginal effect for that observation can be extremely large (up to 10,000,000 for some cases). With the simple weighting $w_i = 1/n$, regardless of the rest of the sample, this observation (or observations if it happens more than once), will cause the average to be huge, producing nonsense values. *LIMDEP* provides two alternative methods of computing marginal effects and elasticities:

1. If elasticities are computed just once at the sample means of the attributes, extreme values will almost surely be averaged out, and the end result will almost always be reasonable values. You can request this computation with

   ; Effects:... (as usual) ; Means

2. Some authors have advocated a probability weighted average scheme instead. This uses a weight which differs by alternative. The computation uses

   $$w(t,j) = \text{Estimated } P(t,j) \,/\, \Sigma_t \text{ Estimated } P(t,j)$$

   where t indexes individual observations and j indexes alternatives. By this construction, if an individual probability is very small, the resulting extreme value for the marginal effect is multiplied by a very small probability weight, which offsets the extreme value. This likewise produces reasonable values for elasticities in almost all cases. You can request this computation with

   ; Effects:... (as usual) ; Pwt

   This weighting scheme does cause a problem. In the simple discrete choice model, the elasticities are

   $$\eta_{im}(k|j) = \partial \log \text{Prob}[y_i = m]/\partial \log x_i(k|j) = x_i(k|j)/P_{im}\times\delta_{im}(k|j)$$

   which means that the cross elasticity of change in probability j when the x in the attributes for choice m changes is the same for all of the alternatives. (E.g., the elasticity of the probabilities of alternatives 2,3,... with respect to changes in $x(k)$ in the attributes of alternative 1 are all equal to $\beta_k P(1)x(1,k)$. This will be true for individual observations. But, when probability weights are used, this will not be true for the weighted averages. It is true for the unweighted averages. The implication will be that the elasticities computed with **; Pwt** will suggest that the IIA property of the model has been relaxed. But, it has not. This is a result of the way the elasticity is computed. The IIA property of the model remains. The following shows the comparison of using **; Pwt** to the unweighted case for our example.

(Probability weighted)

```
Elasticity wrt change of X in row choice on Prob[column choice]
--------+------------------------------------
GC      |      AIR    TRAIN      BUS      CAR

   TRAIN| -1.2046   3.5259  -1.2046  -1.2046
     BUS|  -.5695   -.5695   3.6181   -.5695
     CAR|  -.8688   -.8688   -.8688   2.5979
```

E40.2.2 Saving Elasticities in the Data Set

You can save the individual estimates of the own and cross elasticities as a variable in the data set by using

; Effects: attribute(alternative) = variable

This must provide the name of a specific attribute and a specific alternative. Only one variable may be saved by the model command. The following extends our earlier example by saving the elasticities with respect to the generalized cost of air. This saves as a variable the estimates that are averaged to produce the first row of the table of unweighted elasticities above. The table of descriptive statistics confirms the computations. Figure E40.1 shows the first few observations in the data area.

```
CLOGIT     ; Lhs = mode ; Choices = air,train,bus,car
           ; Rhs = invc,invt,gc ; Rh2 = one,hinc
           ; Effects: gc(air) = gcair $
CREATE     ; alt = Trn(-4,0) $
DSTAT      ; Rhs = gcair ; Str = alt $
```

```

```

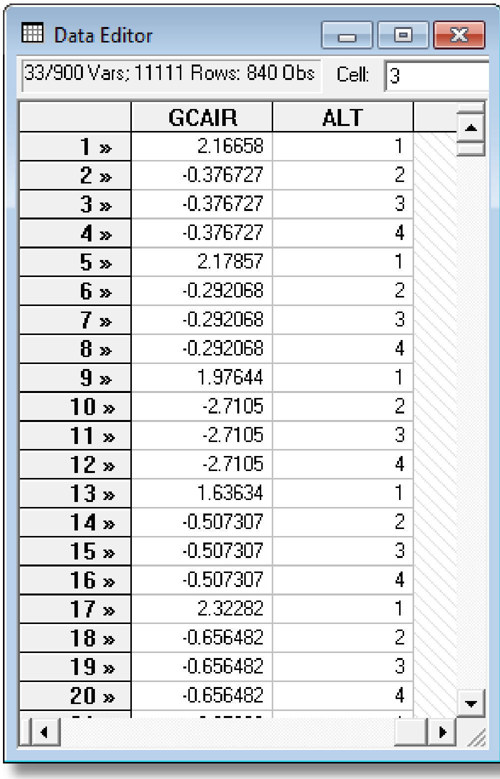

Figure E40.1 Estimated Elasticities

E40.2.3 Exporting Results in a Spreadsheet

Model results and estimated partial effects or elasticities may be exported to a spreadsheet file. Before doing this, you must open the export file with

OPEN ; Export = filename $

The file will be written in the generic .csv format, so you should open the file with a .csv extension, for example

OPEN ; Export = “C:\workspace\elasticities.csv” $

The request to export the results is then done by adding

; Export = table

to your model command. Once the export file is open, you can use it for a sequence of models.

The spreadsheet file below was created with this sequence of commands:

```
OPEN     ; Export = "C:\ … \elasticities.csv" $
CLOGIT   ; Lhs = mode ; Choices = air,train,bus,car
         ; Rhs = gc,ttme,invc,invt ; Rh2 = one,hinc
         ; Export output
         ; Export = table
         ; Effects: gc(*),ttme(*) ; Full $
```

The **; Export output** setting requests that the model estimates also be included in the export file. This is followed by the tables of elasticities. The figure shows the results after the file has been read into *Excel*.

	A	B	C	D	E

Figure E40.3 Exported Elasticities in Matrix Format

HINT: The export file is created while the computations are being done. However, there is a delay between when results are computed (by *LIMDEP*) and when they arrive in the file (by *Windows*). You should not try to open the export file (for example in *Excel*) while *LIMDEP* is still creating it. The results will be incomplete. Open the export file after you exit *LIMDEP*. Also, you should not try to write to an export file from *LIMDEP* while it is open by another program, such as *Excel*. This will cause a write error. You cannot modify with another program a spreadsheet file that *Excel* is using.

E40.3 Predicted Probabilities and Logsums (Inclusive Values)

There are several variables in addition to the elasticities that you can save in the data area while they are created by **CLOGIT**.

E40.3.1 Fitted Probabilities

There are some models which make use of the predicted probabilities from the discrete choice model. See, for example, Lee (1983). Or, you may have some other use for them. You can compute a column of predicted probabilities for the discrete choice model. Each 'observation' consists of J_i rows of data, where the number of choices may be fixed or variable. Use the command

CLOGIT ; Lhs = ... ; ...
; Prob = name $

The variable *name* will contain the predicted probabilities. The probabilities will sum to 1.0 for each observation, that is, *down* each set of J_i choices. The **; Prob** option will put the probabilities in the right places in your data set regardless of the setting of the current sample. For example, if you happen to be estimating a model after having **REJECTED** some observations, the predictions will be placed with the outcomes for the observations actually used. Unused rows of the data matrix are left undefined.

If your model has 14 or fewer choices, you can also include

; List

in your command to request a listing of the predicted probabilities. These will be listed a full observation at a time, rowwise, with an indicator of the choice that was made by that individual. For example, the first 10 observations (individuals) in the sample for the model above are

CLOGIT ; Lhs = mode ; Choices = air,train,bus,car
; Rhs = gc,ttme,invc,invt ; Rh2 = one ; Rh2 = hinc
; List $

```
PREDICTED PROBABILITIES (* marks actual, + marks prediction.)
Indiv    AIR       TRAIN     BUS       CAR
    1   .0918     .1574     .1124     .6384*+
    2   .1110     .1481     .0790     .6618*+
    3   .4621 +   .1106     .0953     .3320*
    4   .2112     .2639     .1240     .4008*+
    5   .1976     .2711     .1379     .3935*+
    6   .0901     .1306*    .1181     .6612 +
    7   .8128*+   .0462     .0392     .1018
    8   .3101     .0908     .0868     .5123*+
    9   .1098     .1867     .1312     .5724*+
   10   .1892     .2881     .1840     .3387*+
```

The '+' and '*' indicate the actual and predicted choices, respectively. Where these mark the same probability, the model predicted the outcome correctly. The predicted choice is the one that has the largest fitted probability

E40.3.2 Computing and Listing Model Probabilities

You can use an estimated model to compute (list and/or save) all probabilities, utilities, elasticities, and all descriptive statistics and crosstabulations for any specified set of observations, whether they were used in estimating the model or not. For example, this feature will allow you to compute predicted probabilities for a 'control' sample, to assess how well the model predicts outcomes for observations outside the estimation sample. To use this feature, use the following steps.

Step 1. Set up the full model for estimation, and estimate the model parameters.

Step 2. Reset the sample to specify the observations for which you wish to simulate the model.

Step 3. Use the *identical* **CLOGIT** command, but add the specification **; Prlist** to the command.

The sample that you specify at Step 2 may contain as many observations as you wish; it may be just one individual or it may be an altogether different set of data – as long as the variables match in name and form the variables in the original model.

NOTE: The observations in the new sample must be consistent with the specification of the model. The usual data checking is done to ensure this.

WARNING: You must not change the specification of the model between Steps 1 and 3. The coefficient vector produced by Step 1 is used for the simulation at Step 3. But it is not possible to check whether the coefficient vector used at Step 3 is actually the correct one for the model command used at Step 3. It will be if your model commands at Steps 1 and 3 are identical.

The following sequence fits the model in the preceding examples using the first 200 observations (800 data rows), then simulates the probabilities for the remaining 10 observations in the full sample:

```
SAMPLE      ; 1-800 $
CLOGIT      ; Lhs = mode ; Choices = air,train,bus,car
            ; Rhs = invc,invt,gc,ttme ; Rh2 = one $
```

```

```

This arrangement of the model may also include

; Describe
; Show Model to display the model configuration
; Effects: desired elasticities or marginal effects
; Prob = name to save probabilities
; Ivb = name to save inclusive values

All of these computations are done for the current sample. This process is the same as the full model computations listed earlier. But, with **; Prlist** in place, the model estimated previously is used; it is not reestimated.

E40.3.3 Utilities and Inclusive Values

The utility functions used to compute the probabilities are

$$U_{ij} = \boldsymbol{\beta}'\mathbf{x}_{ij}.$$

These may be saved in the data set as a new variable with the specification

; Utility = name

The *inclusive value*, or *log sum*, for the discrete choice model is

$$IV_i = \log \Sigma_j \exp(\boldsymbol{\beta}'\mathbf{x}_{i,j}).$$

Inclusive values are used for a number of purposes, including computing consumer surplus measures. You can keep the inclusive values for your model and data with the specification

; Ivb = name

The specification Ivb stands for 'inclusive value for branch.' Inclusive values are stored the same way that predicted probabilities are stored. Since each observation has only one inclusive value, the same value will be stored for all rows (choices) for the observation (person). An example is given below

E40.3.4 Fitted Values of the Choice Variable

The actual and predicted outcomes for the model are saved with

; Fittedy = name and **; Actualy = name**

The actual value is the index of the choice actually made, repeated in each row of the choice set for the observation. The fitted value is the index of the alternative that has the largest probability based on the estimated model. The example below combines all of these features in a single command.

```
SAMPLE    ; All $
CLOGIT    ; Lhs = mode
          ; Choices = air,train,bus,car
          ; Rhs = invc,invt,gc,ttme ; Rh2 = one
          ; Utility = utility ; Prob = probs ; Ivb = incvalue
          ; Actualy = actual ; Fittedy = fitted $
```

Figure E40.4 Model Predictions

E40.4 Hypothesis and Specification Tests of IIA

We consider two types of hypothesis tests. The first is a specification test of the IID extreme value specification. The model assumptions induce the most prominent shortcoming of the multinomial logit model, the *independence from irrelevant alternatives* (IIA) property. The fact that the ratio of any two probabilities in the model involves only the utilities for those two alternatives produces a number of undesirable implications, including the striking pattern in the elasticities in the model shown earlier. We consider a test of the IIA assumption. The second part of this section considers more conventional hypothesis tests about the coefficients in the model.

E40.4.1 Testing the IIA Assumption

Hausman and McFadden (1984) proposed a specification test for this model to test the inherent assumption of the independence from irrelevant alternatives (IIA). (IIA is a consequence of the initial assumption that the stochastic terms in the utility functions are independent and extreme value distributed. Discussion may be found in standard texts on qualitative choice modeling, such as Hensher, Rose and Greene (2005a) and Greene (2011).) The procedure is, first, to estimate the model with all choices. The alternative specification is the model with a smaller set of choices. Thus, the model is estimated with this restricted set of alternatives and the same model specification. The set of observations is reduced to those in which one of the smaller set of choices is made. The test statistic is

$$q = [\mathbf{b}_r - \mathbf{b}_u]'[\mathbf{V}_r - \mathbf{V}_u]^{-1}[\mathbf{b}_r - \mathbf{b}_u]$$

where '*u*' and '*r*' indicate unrestricted and restricted (smaller choice set) models and **V** is an estimated variance matrix for the estimates. To use *LIMDEP* to carry out this test, it is necessary to estimate both models. In the second, it is necessary to drop the outcomes indicated. This is done with the

; Ias = list

specification. The list gives the names of the outcomes to be dropped. This procedure is automated as shown in the following example:

```
CLOGIT    ; Lhs = mode
          ; Choices = air,train,bus,car
          ; Rhs = invc,invt,gc,ttme $
CLOGIT    ; Lhs = mode
          ; Choices = air,train,bus,car
          ; Ias = car
          ; Rhs = invc,invt,gc,ttme $
```

```

In order to compute the coefficients in the restricted model, it is necessary to drop those observations that choose the omitted choice(s). In the example above, 59 observations were skipped. They are marked as bad data because with *car* excluded, no choice is made for those observations. As a consequence, the log likelihood functions are not comparable. The Hausman statistic is used to carry out the test. In the preceding example, the large value suggests that the IIA restriction should be rejected.

Note that you can carry out several tests with different subsets of the choices without refitting the benchmark model. Thus, in the example above, you could follow with a third model in which **; Ias = bus** instead of **car**.

There is a possibility that restricting the choice set can lead to a singularity. It is possible that when you drop one or more alternatives, some attribute will be constant among the remaining choices. Thus, you might induce the case in which there is a 'regressor' which is constant across the choices. In this case, *LIMDEP* will send up a diagnostic about a singular Hessian (it is). Hausman and McFadden (1984) suggest estimating the model with the smaller number of choice sets *and* a smaller number of attributes. There is no question of consistency, or omission of a relevant attribute, since if the attribute is always constant among the choices, variation in it is obviously not affecting the choice. After estimation, the subvector of the larger parameter vector in the first model can be measured against the parameter vector from the second model using the Hausman statistic given earlier. This possibility arises in the model with alternative specific constants, so it is going to be a common case. The examples below suggest one way you might proceed in such as case.

The first step is to fit the original model using the entire sample and retrieve the results.

```
CLOGIT    ; Lhs = mode
          ; Choices = air,train,bus,car
          ; Rhs = invc,invt,gc,ttme,one $
MATRIX    ; bu = b(1:4) ; vu = Varb(1:4,1:4) $
```

The variable choice takes values 1,2,3,4,1,2,3,4... indicating the indexing scheme for the choices.

```
CREATE    ; choice = Trn(-4,0) $
```

Chair is a dummy variable that equals one for all four rows when choice made is *air*. Now restrict the sample to the observations for choices *train, bus, car*.

```
REJECT    ; chair = 1 | choice = 1 $
```

Fit the model with the restricted sample (choice set) and one less constant term.

```
CLOGIT    ; Lhs = mode
          ; Choices = train,bus,car
          ; Rhs = invc,invt,gc,ttme,one $
```

Retrieve the restricted results and compute the Hausman statistic.

```
MATRIX      ; br = b(1:4) ; vr = Varb(1:4,1:4)
            ; db = br - bu ; vdb = Nvsm(vr,-vu) $
CALC        ; List
            ; q = Qfr(db,vdb)
            ; 1 - Chi(q,4) $
```

The results are:

```
[CALC] Q       =     33.7844338
[CALC] *Result*=       .0000008
Calculator: Computed   2 scalar results
```

NOTE: (We've been asked this one several times.) The difference matrix in this calculation, *vdb*, might be nonsingular (have an inverse), but not be positive definite. In such a case, the chi squared can be negative. If this happens, the right conclusion is probably that it should be zero.

E40.4.2 Lagrange Multiplier, Wald, and Likelihood Ratio Tests

CLOGIT keeps the usual statistics for the classical hypothesis tests. After estimation, the matrices *b* and *varb* will be kept and can be further manipulated for any purposes, for example, in the **WALD** command. You can use

; Test: ... restrictions

as well within the **CLOGIT** command to set up Wald tests of linear restrictions on the parameters. Likelihood ratio tests can be carried out by using the scalar *logl*, which will be available after estimation. The value of the log likelihood function for a model which contains only *J*-1 alternative specific constants will be reported in the output as well (see the sample outputs above). If your model actually contains the ASCs, *LIMDEP* will also report the chi squared test statistic and its significance level for the hypothesis that the other coefficients in the model are all 0.0.

HINT: *LIMDEP* can detect that a model contains a set of ASCs if you have used *one* in an **; Rhs** specification. But, it cannot determine from a set of dummy variables that you, yourself, provide, if they are a set of ASCs, because it inspects the model, not the data, to make the determination. As such, there is an advantage, when possible, to letting *LIMDEP* set up the set of alternative specific constants for you.

Finally, an LM statistic for testing the hypothesis that the starting values are not significantly different from the MLEs (the standard LM test) is requested by adding

; Maxit = 0

to the **CLOGIT** command.

E40.5 Examining Scenarios and Model Simulations

Another way to analyze the estimated model is to examine the effect on predicted ‘market’ shares of changes in the attribute levels. We compute the shares as

$$S(\textit{alternative } j) = N \times \sum_{i=1}^{N} \hat{P}_{ij}$$

Thus, save for the rounding error which is distributed, the model predicts the number of individuals in the sample who will choose each alternative. The crosstab described earlier summarizes this calculation. For our application,

```
CLOGIT    ; Lhs  = mode
          ; Choices = air,train,bus,car
          ; Rhs  = invc,invt,gc,ttme
          ; Rh2 = one,hinc
          ; Crosstab $
```

```

The feature described here is used to examine what becomes of these predictions when the value of an attribute changes. For example, how the predictions change when the generalized cost of air travel changes.

The simulator is used as follows:

Step 1. Fit the model.

Step 2. Use the identical model specification, but add to the command

; Simulation [= a subset of the choices, if desired – see below]
; Scenario = what changes and how

We take the base case first, in which all alternatives are considered in the simulation. A scenario is defined using

; Scenario: attribute (choices in which it appears) = the change

The change is defined using

= specific *value* to force the attribute to take this value in all cases
or = [*] *value* to multiply observed values by the value
or = [+] *value* to add '*value*' to the observed values.

The results of the computation will show the market shares before and after the change.

For example, we will refit our transport mode model, then examine the effect of increasing by 25% the terminal time spent waiting for air transport.

```

```

The model predicts the base case using the actual data, shown in the left side and what would become of this case if the scenario is assumed. In this case, each person's *ttme* for *air* travel is increased by 25%, and the probabilities are recomputed. We see a fairly strong effect is predicted; 26 of 58 people who chose *air* are now expected to take other modes, eight changing to *train*, four to *bus*, and 15 to *car* (and one apparently deciding to walk – this is rounding error).

You may combine up to five scenarios in each simulation. This allows you to have simultaneous changes in attributes. Use

```
; Scenario: attribute (choices in which it appears) = the change /
            attribute (choices in which it appears) = the change /
  ...
```

For example, suppose terminal time for both *air* and *train* increased by 25%. We would extend our previous setup as follows:

```
SAMPLE      ; 1-840 $
CLOGIT      ; Lhs = mode ; Rhs = one,gc,ttme
            ; Choices = air,train,bus,car $
CLOGIT      ; Lhs = mode ; Rhs = one,gc,ttme
            ; Choices = air,train,bus,car
            ; Simulation ; Scenario:  ttme (air)     = [*] 1.25  /
                                      ttme (train)  = [*] 1.25  $
```

```

+----------+--------------+--------------+------------------+
```

You may also compare the effects of different scenarios as well. For example, rather than assume that *ttme* for both *air* and *train* changed, you might compare the two scenarios. To do a pairwise comparison of scenarios, separate them with ‘&’ in the command. For example,

```
CLOGIT      ; Lhs = mode ; Rhs = one,gc,ttme
            ; Choices = air,train,bus,car
            ; Simulation ; Scenario: ttme (air)    = [*] 1.25 &
                                     ttme (train) = [*] 1.25  $
```

produces the following:

```
+--------------------------------------------+
| Discrete Choice (One Level) Model          |

Simulations and scenarios can be combined and extended. You may have multiple scenarios and each scenario can involve several attributes. Separate the specifications within a scenario with slashes (/) and separate scenarios with ampersands (&). Finally, you can use the simulator to restrict the choice set. The computed probabilities are computed assuming only the specified alternatives are available. To do this, use

; Simulation = the subset of alternatives

To continue the example, we simulate the model assuming that people could not drive, and examine what the effect of increasing terminal time in airports would do to the market shares for the remaining three alternatives.

E41: Models for Count Data

E41.1 Introduction

This chapter and Chapters E42-E44 describe estimators for models for count data. Applications are discussed in Cameron and Trivedi (1986), Winkelmann (2008) and Hilbe (2011). Another important reference is Hausman, Hall, and Griliches (1984). Major surveys for practitioners are Winkelmann (2008), Cameron and Trivedi (1998, 2005) and Hilbe (2011).

The basic formulation is the *Poisson regression model*. For a discrete random variable, Y, observed over a period of length T_i, and observed frequencies, y_i, i =1,...,n, where y_i is a nonnegative integer count, and regressors $\mathbf{x}_i$, the Poisson regression model is

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\exp(-T_i\lambda_i)(T_i\lambda_i)^{y_i}}{y_i!}, \; y_i = 0,1,...; \; \log \lambda_i = \boldsymbol{\beta}'\mathbf{x}_i.$$

In this model, λ_i is both the mean and variance of y_i *per unit of time*; that is

$$\text{E}(Y/T_i|\mathbf{x}_i) = \lambda_i.$$

The scale variable, T_i, might measure the size of a population observed, instead, as it would be if the model were one of the incidence of a disease in a set of locations. As long as the intensity variable, T_i is observed, the model may be conveniently defined in terms of

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \log T_i).$$

Then, we revert to the familiar linear index model, in which $\log T_i$ enters the regression with a coefficient of one. An example appears below. A multiplicative model is obtained if any of the components of $\mathbf{x}_i$ enter λ_i logarithmically. (For an application, see McCullagh and Nelder, (1983).) The partial effects in this nonlinear regression model are,

$$\frac{\partial E[y_i \,|\, \mathbf{x}_i]}{\partial \mathbf{x}_i} = \lambda_i\boldsymbol{\beta}$$

The Poisson model has the restrictive equidispersion property that

$$\text{Var}[Y|\mathbf{x}_i] = E[Y|\mathbf{x}_i] = \lambda_i.$$

The *negative binomial regression model* is an extension of the Poisson regression model that allows the variance of the process to differ from the mean. An alternative interpretation that also fits well with several of the extensions considered in the next chapter is that the negative binomial model results from the introduction of a certain kind of unobserved individual heterogeneity into the Poisson regression model.

The probabilities in the negative binomial model are given by

$$\text{Prob}(\text{Y} = y_i|\mathbf{x}_i) \quad = \quad \frac{\theta^\theta \lambda_i^{y_i}}{\Gamma(\theta) y_i!} \frac{\Gamma(y_i + \theta)}{(\lambda_i + \theta)^{y_i + \theta}}$$

where θ is the overdispersion parameter. The connection between the two models is that the Poisson model results if $\alpha = 1/\theta = 0$. (A derivation appears in Section E41.4.5, the technical details section for the negative binomial model.) The formulation of the density that we use for optimization is

$$\text{Prob}(Y = y_i|\mathbf{x}_i) \quad = \quad \frac{\Gamma(\theta + y_i)}{\Gamma(\theta)\Gamma(y_i + 1)} u_i^\theta (1 - u_i)^{y_i}$$

where $u_i \quad = \quad \theta / (\theta + \lambda_i)$

and $\theta \quad = \quad 1/\alpha.$

The negative binomial model has the property that

$$\text{Var}[y_i] \;=\; \text{E}[y_i]\{1 \;+\; \alpha\text{E}[y_i]\}.$$

This is a natural form of 'overdispersion' in that the overdispersion rate is

$$\text{Var}[y_i]/\text{E}[y_i] \;=\; 1 \;+\; \alpha\text{E}[y_i].$$

We have reparameterized the probability distribution in terms of θ because this simplifies the formulation and computation of the log likelihood and its derivatives. Greene (2008), defines the class of Negbin P models by a relationship between mean and variance functions,

$$E[y_i|\mathbf{x}_i] = \lambda_\text{i} \text{ and } \text{Var}[y_i|\mathbf{x}_i] = \lambda_i + \alpha\lambda_i^P.$$

The model already considered, the standard case, is Cameron and Trivedi's model Negbin 2, or NB2. An alternative form labeled Negbin 1 or NB1 is obtained by using $P = 1$. The density is obtained by replacing θ with $\theta\lambda_\text{i}$ in $\text{Prob}(Y = y_i|\mathbf{x}_i)$. More generally, replacing θ with $\theta\lambda_i^{2-P}$ produces the Negbin P family. For NB2, this produces, after a bit of manipulation,

$$\text{Prob}(Y = y_i|\mathbf{x}_i) \quad = \quad \frac{\Gamma(\theta\lambda_i + y_i)}{\Gamma(\theta\lambda_i)\Gamma(y_i + 1)} w_i^{\theta\lambda_i} (1 - w_i)^{y_i}$$

where $w_i \quad = \quad \theta / (\theta + 1).$

This is not a simple reparameterization of the model; it is a different model. An example given in Section E41.4.4 demonstrates. We also consider the fully general form of the negative binomial model, NBP in Section E41.4.4.

We also provide many variants of each model. (The list of different functional forms that have been derived is surprisingly long. Hilbe (2011), for example, lists more than ten.) Several of these different formulations arise in a model of the sort that produces the negative binomial model, but in which the heterogeneity term derives from a normal distribution, rather than a log-gamma distribution. The resulting models are a bit simpler to estimate and appear to be more stable with respect to ill-behaved data sets. Other formulations arise through the effects of different sampling mechanisms, such as censoring, and other functional forms such as the gamma, generalized Poisson and Poly-Aeppli models.

Data for the count data models are often censored or truncated. The data are said to be censored if a range of values of the dependent variable is collapsed into a single value. Consider, for example, a survey which asks how many times an individual visited a certain facility. The responses might be 0, 1, 2, and 3 or more. Values above three are converted to three, so the data are censored. We allow censoring to be 'on the right,' as in our example, or 'on the left,' which would be the case if all values of y_i less than or equal to a certain value were converted to that value. Data are said to come from a truncated distribution, or be 'truncated,' (for convenience – it is the distribution, not the data that is truncated) if values in a certain range are simply not observed. To continue our example, if the analyst discarded observations with values of three or more, the remaining observations would come from a truncated distribution. The range of y_i for this example would be 0,1,2 instead of 0,1,2,... as in the original population. Another common application is 'on site sampling.' A visitor to a site of some sort, such as a recreation site, is asked how many times they have visited the site. By construction, on site samples are truncated at zero. Like censoring, we allow truncation to be on the right or the left.

This chapter will develop the various functional forms of the models for count data. Chapter E42 will document models that contain heterogeneity, censoring or truncation. Chapter E43 extends the Poisson and negative binomial models to two part formulations such as zero inflation, hurdle and sample selection models. Finally, Chapter E44 documents the panel data estimators.

E41.2 The Poisson Regression Model

The basic command for the Poisson regression model is

```
POISSON     ; Lhs = dependent variable
            ; Rhs = regressors
            ; ... other options $
```

The default model assumes that the time period or unit of space in which the outcome is observed is the same for all observations. When this is not the case, and the scaling is observed, use

```
            ; Exposure = scale variable
```

to provide it. An example appears below.

All of the general options for nonlinear models for controlling the iterative process and listing and keeping fitted values are available. These include:

; List	to display fitted values
; Keep = name	to retain predicted values
; Res = name	to retain residuals
; Maxit = n	to set maximum iterations or **; Maxit = 0** for LM tests
; Tlf, ; Tlb, ; Tlg	to set the convergence criteria
; Output = value	to control technical output during iterations
; Covariance Matrix	to display the estimated asymptotic covariance matrix, same as **; Printvc**
; Test: spec	to define Wald tests of linear restrictions

and so on. You may provide starting values and impose fixed values and restrictions in this model with

; Start = list	to give starting values
; Rst = list	to specify constraints
; CML: spec	to define a constrained maximum likelihood estimator

The coefficient vector is $\boldsymbol{\beta} = [\beta_1,\beta_2,...,\beta_K]$. *LIMDEP* uses zeros for the starting values for estimation. The estimated Hessian for the Poisson model is based on the actual second derivatives of the log likelihood. Partial effects are requested with

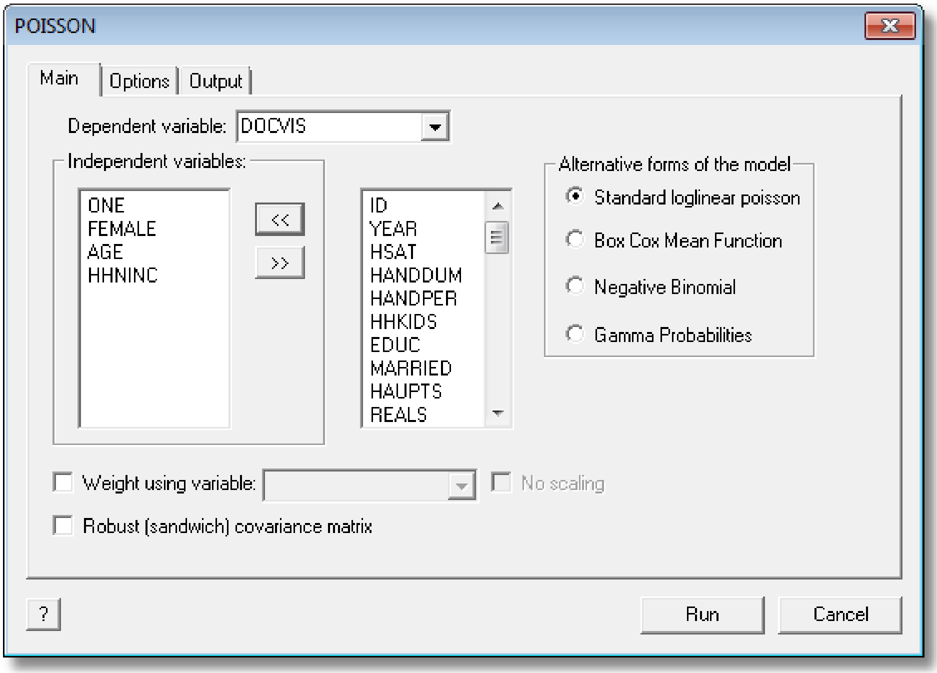
; Partial Effects

Partial effects are computed by averaging the individual estimates. A simpler estimator can be produced by doing the entire computation at the means of the data. Request this by adding

; Means

to the model command.

The command builder for this model can be found in Model:Count Data/Poisson. The basic model is specified on the Main and Options pages which are shown in Figure E41.1.



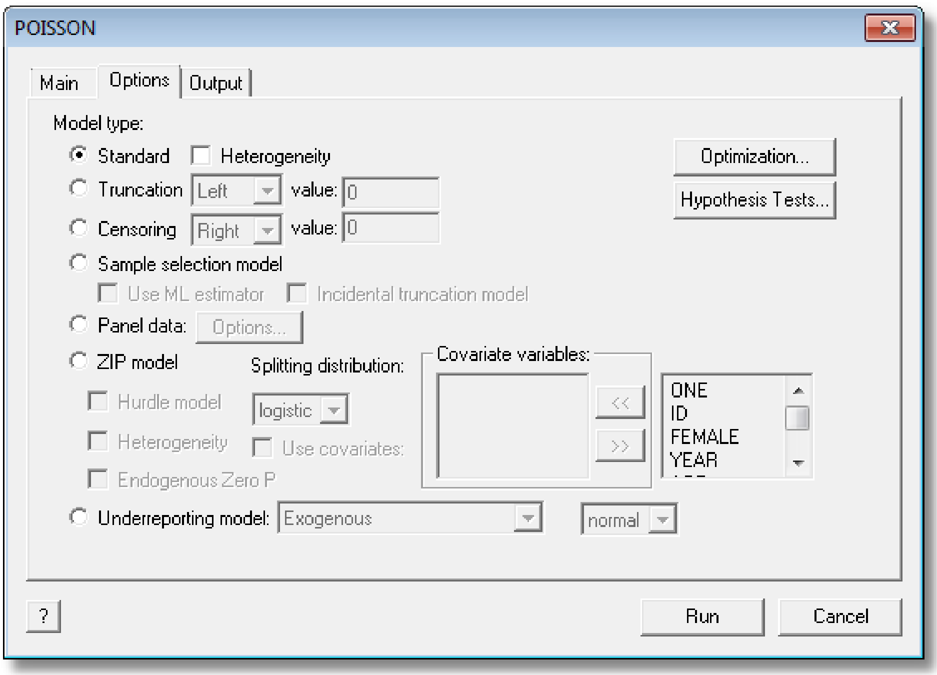


Figure E41.1 Command Builder for the Poisson Model

E41.2.1 Results for the Poisson Model

Estimation for the Poisson model begins with an ordinary least squares regression of the Lhs variable on the regressors. These results are presented only for comparison purposes, if you request them with

; OLS

and are not used as the starting values for the iterations. (Experience has shown clearly that **0** is a superior starting point for the iterations.) Perhaps a still better point would replace the starting value for the constant with the log of the mean of the Lhs variable. However, the model is so simple to estimate that is of little consequence. The model output consists of the standard results for maximum likelihood estimators, including the iterations, log likelihood function, restricted log likelihood function, and two goodness of fit statistics,

$$\text{Chi squared} = \Sigma_i(y_i - \hat{\lambda}_i)^2/\hat{\lambda}_i$$

and

$$\text{G squared} = 2\Sigma_i y_i \log(y_i/\hat{\lambda}_i) \text{ (with } 0\log(0) = 0))$$

(See Agresti (1984). Note, $y\log y = 0$ when $y = 0$.) Significance values are not computed for these because the degrees of freedom is dependent on the application. **CALC** can be used to compute the appropriate probability. We do, however, present the chi squared statistic for testing the hypothesis that the slopes are all zero, including the significance level and degrees of freedom. This computation assumes that there is a constant term in the model. (It is easily shown that in this case, the MLE of λ is $\bar{y}$, from which it follows that the MLE of β_0 is $\log\bar{y}$, and the remaining computations follow.)

The output for the Poisson model also contains two R^2 measures based on these fit measures,

$$R_p^2 = 1 - [\Sigma_i(y_i - \hat{\lambda}_i)^2/\hat{\lambda}_i] / [\Sigma_i(y_i - \bar{y})^2/\bar{y}] \quad \text{(p = Pearson)}$$

$$R_d^2 = 1 - [\Sigma_i y_i \log(y_i/\hat{\lambda}_i)] / [\Sigma_i y_i \log(y_i/\bar{y})] \quad \text{(d = deviance)}$$

In both cases, the fit measure assesses the improvement in the fit that results from using $\hat{\lambda}_i$ instead of $\bar{y}$ to predict y_i.

The **; List** specification produces a listing of:

1. actual y_i,
2. predicted y_i = estimate of $E[y_i] = \hat{\lambda}_i$,
3. residual = $y_i - \hat{\lambda}_i$,
4. ‘var1’ = estimate of $\boldsymbol{\beta}'\mathbf{x}$,
5. ‘var2’ = computed probability for observed y_i.

The partial effects in the Poisson (and negative binomial model) are

$$\partial E[y_i|\mathbf{x}_i]/\partial \mathbf{x}_i = \lambda_i \boldsymbol{\beta}.$$

The **; Partial Effects** specification will produce a listing of these slopes computed at the sample means of the data.

Results saved for the Poisson model are:

Matrices: *b* and *varb* as usual

Scalars: *nreg*, *kreg*, *logl*, and *exitcode* for the model
ybar and *sy* = mean and standard deviation for dependent variable

Last Model: *b_variable*

Last Function: Conditional mean function, $\lambda = \exp(\boldsymbol{\beta}'\mathbf{x})$

The exponential regression function is used for **PARTIALS** and **SIMULATE**.

E41.2.2 Application of the Poisson Model

To illustrate the Poisson and related models, we will use the German health care data introduced in Section E2.4 and used in several earlier applications. The examples below will fit count data models to the count of doctor visits, *docvis*. Poisson regression of *docvis* on *one*, *age*, *hhninc* and *educ* produces the results below:

An example (developed further below) is the following:

```
SAMPLE      ; All $
NAMELIST    ; x = one,age,hhninc,educ,female $
POISSON     ; Lhs = docvis ; Rhs = x
            ; OLS ; Partial Effects $
```

```

```

To examine the use of the duration, or exposure variable, T_i discussed earlier, we consider a constructed example. As noted earlier, the data are an unbalanced panel. If we consider not the year by year count of doctor visits but the total number of visits by the individual, then the counts will differ partly because of the differing number of years. The following shows how to account for this effect. (We are also making use of the result that the sum of Poisson variables has a Poisson distribution.)

```
SAMPLE      ; All $
SETPANEL    ; Group = id ; Pds = ti $
NAMELIST    ; x = one,age,hhninc,educ,female $
CREATE      ; sumy = Group Sums(docvis, Pds =_groupti) $
CREATE      ; sumy = Int(sumy + .1) ; date  = Ndx(id,1) $
REJECT      ; date > 1 $
POISSON     ; Lhs = sumy ; Rhs = x $
POISSON     ; Lhs = sumy ; Rhs = x ; Exposure = ti $
```

The results show that accounting for the length of exposure does, indeed, change the results noticeably.

E41.2.3 Testing for Overdispersion

Cameron and Trivedi (1990) have proposed a number of tests for over- or underdispersion in the Poisson regression model. Probably the simplest, and by their results, the optimal test in the set they considered, involves simple least squares regressions. The crux of the test is that under the hypothesis of the Poisson model, $(y - E[y])^2 - E[y]$ has mean 0. The testing framework is built around

$$H_0\text{: } \mathrm{Var}[y_i|\mathbf{x}_i] = \mu_i$$

$$\text{vs.} \quad H_1\text{: } \mathrm{Var}[y_i|\mathbf{x}_i] = \mu_i + \alpha g(\mu_i).$$

They detail the several assumptions needed to carry out the tests. Among them is the important one that under either hypothesis, the Poisson model gives consistent estimates of $E[y_i] = \mu_i$. The reader is referred to their paper for the necessary background. The test they propose, their T_{opt}, is carried out by testing the significance of the single coefficient in the linear OLS regression of

$$z_i = [(y_i - \mu_i)^2 - y_i] / (\mu_i\sqrt{2})$$

on

$$w_i = g(\mu_i) / (\mu_i\sqrt{2}).$$

They suggest two possibilities:

$$g(\mu_i) = \mu_i$$

and

$$g(\mu_i) = \mu_i^2.$$

Under the null hypothesis of equidispersion, the statistics have limiting chi squared distributions with one degree of freedom.

The two statistics are reported in the standard output for the Poisson model, as shown in the example below.

```
Poisson Regression
Dependent variable                    SUMY
Log likelihood function    -56253.06502
Restricted log likelihood  -74728.12052
Chi squared [    4 d.f.]    36950.11101
Significance level               .00000
McFadden Pseudo R-squared      .2472303
Estimation based on N =    7293, K =   5
Inf.Cr.AIC  =********* AIC/N =   15.428
Exposure variable for count data = TI
Chi- squared =123910.94497  RsqP= .3443
G  - squared = 88390.28781  RsqD= .2948
Overdispersion tests: g=mu(i)  : 14.829
Overdispersion tests: g=mu(i)^2: 15.415
```

Since the critical value from the chi squared table for one degree of freedom is 3.84, we would reject the null hypothesis on this basis, and proceed to a less restrictive model.

E41.2.4 Robust Covariance Matrices

The estimator of the asymptotic covariance matrix for the Poisson model based on the actual and expected (they are the same) second derivatives is

$$\text{Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \left[-\frac{\partial^2 \log L}{\partial\hat{\boldsymbol{\beta}}\partial\hat{\boldsymbol{\beta}}'}\right]^{-1} = \left[\sum_{i=1}^{n} \hat{\lambda}_i \mathbf{x}_i\mathbf{x}_i'\right]^{-1} = [\mathbf{X}'\boldsymbol{\Lambda}\mathbf{X}]^{-1},$$

where $\boldsymbol{\Lambda}$ is a diagonal matrix of predicted values. The BHHH estimator is the inverse of

$$\text{OPG} = \left[\sum_{i=1}^{n} \left(\frac{\partial \log P_i}{\partial\hat{\boldsymbol{\beta}}}\right)\left(\frac{\partial \log P_i}{\partial\hat{\boldsymbol{\beta}}}\right)'\right]^{-1} = \left[\sum_{i=1}^{n} (y_i - \hat{\lambda}_i')^2 \mathbf{x}_i\mathbf{x}_i'\right]^{-1} = [\mathbf{X}'\mathbf{D}^2\mathbf{X}]^{-1}$$

where **D** is a diagonal matrix of residuals. The Poisson model is one in which the MLE is robust to certain misspecifications of the model, such as the failure to incorporate latent heterogeneity in the mean (i.e., one fits the Poisson model when the negative binomial is appropriate.) In this case, a robust covariance matrix,

$$\text{Robust Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = [\mathbf{X}'\boldsymbol{\Lambda}\mathbf{X}]^{-1}[\mathbf{X}'\mathbf{D}^2\mathbf{X}]\,[\mathbf{X}'\boldsymbol{\Lambda}\mathbf{X}]^{-1}$$

is appropriate to accommodate this failure of the model. This computation is requested with

; Robust or ; HC2 (heteroscedasticity correction 2)

added to the command. For the model estimated earlier, the command produces the following results. The rather large increase in the standard errors produced by the robust estimator suggests that, indeed, there is something missing in the Poisson specification. As noted earlier, there is ample evidence of overdispersion in the data. The corrected results appear second.

```

```

A related calculation is used when observations occur in groups which may be correlated. This is rather like a panel; one might use this approach in a random effects kind of setting in which observations have a common latent heterogeneity. The parameter estimator is unchanged in this case, but an adjustment is made to the estimated asymptotic covariance matrix. The calculation is done as follows: Suppose the n observations are assembled in G clusters of observations, in which the number of observations in the ith cluster is n_i. Thus,

$$\sum_{i=1}^{G} n_i = n.$$

Denote by $\boldsymbol{\beta}$ the full set of model parameters in whatever variant of the model is being estimated. Let the observation specific gradients and Hessians be

$$\mathbf{g}_{ij} = \frac{\partial \log L_{ij}}{\partial \boldsymbol{\beta}}$$

$$\mathbf{H}_{ij} = \frac{\partial^2 \log L_{ij}}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'}.$$

The uncorrected estimator of the asymptotic covariance matrix based on the Hessian is

$$\mathbf{V}_H = -\mathbf{H}^{-1} = \left(-\sum_{i=1}^{G} \sum_{j=1}^{n_i} \mathbf{H}_{ij}\right)^{-1}.$$

The corrected asymptotic covariance matrix is

$$\text{Est.Asy.Var}\left[\hat{\boldsymbol{\beta}}\right] = \mathbf{V}_H \left(\frac{G}{G-1}\right)\left[\sum_{i=1}^{G} \left(\sum_{j=1}^{n_i} \mathbf{g}_{ij}\right)\left(\sum_{j=1}^{n_i} \mathbf{g}_{ij}\right)'\right] \mathbf{V}_H.$$

Note that if there is exactly one observation per cluster, then this is $G/(G-1)$ times the sandwich (robust) estimator discussed above. Also, if you have fewer clusters than parameters, then this matrix is singular – it has rank equal to the minimum of G and JK, the number of parameters. This estimator is requested with

; Cluster = variable (as in panel data setups) or
number of observations in a cluster

(Further details on this estimator appear in Section R10.2) An extension for stratified and clustered (within strata) data may also be requested with

; Stratum = the specification

Since our data set is a panel, these results apply to the models estimated here. Using *id* as the clustering variable, we obtain the results below:

```
+---------------------------------------------------------------+
| Covariance matrix for the model is adjusted for data clustering.    |

The continued increases in the standard errors compared to the results with the robust covariance matrix shown earlier suggest that the grouping of the observations is distorting the estimated covariance matrix.

E41.2.5 Scaling the Asymptotic Covariance Matrix MLE

In order to correct the Poisson estimator's asymptotic covariance matrix, a scale factor is suggested,

$$W = [1/(n\text{-}K)]\Sigma_i[(y_i - \exp(\boldsymbol{\beta}'\mathbf{x}_i))^2 / \exp(\boldsymbol{\beta}'\mathbf{x}_i).$$

This correction factor will account for over or underdispersion as well as degrees of freedom. To request this estimator, use

; HC1 (Heteroscedasticity correction 1)

An example appears below. In the example, the scaling makes a considerable difference in the estimated standard errors. In fact, for that model of doctor visits, there is an extreme preponderance of zeros so that the Lhs variable actually is considerably overdispersed. The two tests listed in the diagnostic statistics box shown earlier are consistent with this.

DOCVIS	Coefficient	Standard Error	z	Prob. |z|>Z*	95% Confidence Interval

E41.2.6 Technical Details for the Poisson Model

The log likelihood and its derivatives for the Poisson regression model are:

$$\log L = \Sigma_i[-\lambda_i + \boldsymbol{\beta}'\mathbf{x}_i y_i - \ln y_i!],$$

$$\mathbf{g} = \Sigma_i \partial \log \text{Prob}[Y = y_i]/\partial\boldsymbol{\beta} = \Sigma_i(y_i - \lambda_i)\mathbf{x}_i$$

$$\mathbf{H} = \Sigma_i \partial^2 \log \text{Prob}[Y = y_i]/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' = \Sigma_i[-\lambda_i \mathbf{x}_i \mathbf{x}_i']$$

Estimation is by Newton's method,

$$\mathbf{b}_{k+1} = \mathbf{b}_k - [\mathbf{H}_k]^{-1}\mathbf{g}_k,$$

which converges readily. For this model, the iteration is equivalent to iteratively reweighted least squares,

$$\mathbf{b}_{k+1} = [\mathbf{X}'\boldsymbol{\Lambda}_k\mathbf{X}]^{-1}[\mathbf{X}'\boldsymbol{\Lambda}_k\mathbf{z}],$$

where $\boldsymbol{\Lambda}_k$ is a diagonal matrix of fitted variances, λ_i, at iteration k, while

$$z_i = \log\lambda_i + (y_i - \lambda_i)/\lambda_i$$

based on the current parameter estimates.

E41.3 Quantile Regression for Count Data

The quantile regression estimator for count data was proposed by Machado and Silva (2005). The approach is not a Poisson model. Rather, the estimator develops conditional quantiles, $Q(y|\mathbf{x},\alpha)$ where α is the desired quantile of the distribution. The estimator uses a loglinear, i.e., exponential, predictor for the model. The linear programming methods are similar to those used for QREG for continuous data. A difference for the count data case is that the authors provide an analytic approach for estimating the asymptotic covariance matrix while bootstrapping is used in the continuous case. Methods used for computing this estimator are provided by Machado and Silva (2005).

The model is requested with

```
QCREG    ; Lhs = dependent variable
         ; Rhs = independent variables (including one) $
```

The default model is the conditional median, quantile = 0.5. Other quantiles are requested by adding

; Qnt = the quantile, strictly between 0.0 and 1.0.

You may produce results for multiple quantiles by specifying several quantiles in the **; Qnt** specification. For example, in our last application below, we use

; Qnt = .4, .5, .6, .7, .8.

The exponential function, λ_i is the conditional quantile here, not the conditional mean. Note that the count distribution is unlikely to be symmetric, so the conditional median will not equal the conditional mean in any event. Partial effects may be requested with

; Partial Effects.

The **PARTIALS** and **SIMULATE** commands may be used after estimation. However, it should be noted, once again, that these estimators are operating on the conditional quantile function, not the conditional mean.

We applied these to the health care data, and estimated the 0.4 quantile, the median (0.5) and the 0.75 quantiles. The Poisson model is compared to the conditional median.

```
QCREG    ; Lhs = docvis ; Rhs = one,age,educ,hhninc,female,public
         ; Qnt = .4 ; Partial Effects $
QCREG    ; Lhs = docvis ; Rhs = one,age,educ,hhninc,female,public
         ; Qnt = .5 ; Partial Effects $
POISSON  ; Lhs = docvis ; Rhs = one,age,educ,hhninc,female,public
         ; Partials Effects $
QCREG    ; Lhs = docvis ; Rhs = one,age,educ,hhninc,female,public
         ; Qnt = .75 ; Partial Effects $
```

```

```

The quantile estimator is estimated by perturbing the sample data slightly with random draws to make the data continuous. This creates some simulation 'chatter' (noise) in that the results are slightly dependent on the random draws. To reduce this outcome, the authors suggest averaging the results over several series of draws. The default in *LIMDEP*'s estimator is not to do this average – implicitly using m = 1 random sample and one estimator. You can use additional estimates by specifying m with

; Pts = m.

In the results below, we have fit the model with m = 1, then a second time, averaging the results over m = 5 repetitions.

CALC ; Ran(123457) $
QCREQ ; … $

E41.4 Overdispersion: The Negative Binomial Model

The negative binomial model has served as the most common extension of the Poisson model to allow for overdispersion or latent heterogeneity. We consider several other models as well an extension of the negative binomial model to allow individual variation in the overdispersion parameter and, in the next section, three models based on different functional forms that allow underdispersion as well.

E41.4.1 The Negative Binomial Model

The negative binomial model can be obtained by introducing heterogeneity into the conditional mean of the Poisson. Thus, if

$$f(y_i \mid \lambda_i, \varepsilon_i) = \text{Poisson with } \lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i)$$

where

$$\exp(\varepsilon_i) = v_i \sim \text{Gamma with mean 1},$$

$$f(v_i) = \frac{\theta^\theta}{\Gamma(\theta)}\exp(-\theta v_i)v_i^{\theta-1},$$

then the unconditional density is

$$\log \text{Prob}[Y_i = j] = \log L_i$$

$$= \log \Gamma(\theta + y_i) - \log \Gamma(\theta) - \log[\Gamma(y_i+1)] + \theta \log u_i + y_i \log(1 - u_i),$$

where

$$\theta = 1/\alpha$$

and

$$u_i = \theta / (\theta + \lambda_i).$$

The crucial element of the result is that whereas in the Poisson model, $\text{Var}[y_i|\lambda_i] = E[y_i|\lambda_i]$, in the negative binomial model,

$$\text{Var}[y_i|\lambda_i] = E[y_i|\lambda_i] + \alpha\, E[y_i|\lambda_i] > E[y_i|\lambda_i];$$

the model has overdispersion.

The negative binomial regression model is requested by extending the Poisson model. Use

```
NEGBIN      ; Lhs  = ...
            ; Rhs  = ... $

or  POISSON ; Lhs  = ...
            ; Rhs  = ...
            ; Model = Negbin $
```

The full set of estimates for the Poisson model will be given first, followed by the negative binomial estimates. These can be compared for evidence of overdispersion. (The Poisson results will contain two regression based test statistics for the hypothesis of no overdispersion as well. See Section E41.2.3.) The negative binomial model is estimated using only the BFGS algorithm. All other parts of the basic command are identical to those for the Poisson model.

Starting values for the slopes are the Poisson regression parameters estimated earlier. To compute an initial estimate of the overdispersion parameter, α, *LIMDEP* computes the OLS slope in an artificial regression based on the relationship between the Poisson and negative binomial models,

$$[(y_i - \lambda_i)^2 / \lambda_i - 1] = \alpha\lambda_i + w_i.$$

(Certainly, w_i is heteroscedastic, but we are only interested in consistency.) If the resulting estimate is not positive, this suggests that the data are inconsistent with the model. But, *LIMDEP* then uses a value of α = .2, and continues. You may provide your own starting values, as well, with

; Start = slope parameters, value for 1/α

(Be sure to provide the last value.)

NOTE: If you wish to provide your own starting values for the negative binomial model, provide the K values for $\boldsymbol{\beta}$ and $\theta = 1/\alpha$, not α.

Fixed value and linear restrictions may be imposed with

; Rst = list

or **; CML: specification**

Once again, the list in the constraints specification must have a setting for $\theta = 1/\alpha$, either a fixed value or a parameter name.

NOTE: The restrictions are not imposed on the initial Poisson model when it is fit for starting values.

The command builder for the negative binomial model is found at Model:Count Data/NegBin. The dialog for the model specification and options for the model are identical to those for the Poisson model; the model command differs only in the command name.

The negative binomial model occasionally presents convergence problems in estimation, particularly when the data are censored or truncated. To deal with this, or for purposes of hypothesis testing or specification analysis, you may fix the value of α (not θ) with the specification,

; Dsp = value for α

The parameters of the negative binomial model will be estimated by maximum likelihood with α held fixed at this value. The value will be clearly marked as fixed in the final output.

The retrievable results for this model are:

Matrices: *b* and *varb* as usual
Adding **; Par** requests that the estimate of α (not θ) be included with **β** in *b* and *varb*.

Scalars: *nreg*, *kreg*, and *logl* for the model
ybar and *sy* = mean and standard deviation for dependent variable
alpha for the estimate of α for the negative binomial model

Last Function: Conditional mean function, $\lambda = \exp(\boldsymbol{\beta}'\mathbf{x})$

The exponential regression function is used for **PARTIALS** and **SIMULATE**.

E41.4.2 Application

The following refits the Poisson model estimated using, instead, the negative binomial specification. The base Poisson model is shown as well to allow a comparison. These results decisively reject the Poisson model in favor of the negative binomial. The reported results indicate that the NB2 form of the model has been used. It also shows the hypothesis test of the Poisson model as a restriction on the NB model. The hypothesis is decisively rejected by several tests.

```

Based on the model with free dispersion parameter, the likelihood ratio statistic for this restriction would be -2(-60164.22014.14 - (-60375.82426)) = 423.21. This is far larger than the critical chi squared with one degree of freedom of 3.84, so we would reject the hypothesis that α equals 1.5.

E41.4.3 Heterogeneous Negative Binomial Model

The negative binomial model may be extended to allow observed heterogeneity in the dispersion parameter. The structural model is

$$\text{Prob}[Y = y_i] = \frac{\Gamma(\theta_i + y_i)}{\Gamma(\theta_i)\Gamma(y_i + 1)} u_i^{\theta_i}(1 - u_i)^{y_i}$$

$$u_i = \theta_i / (\theta_i + \lambda_i)$$

$$\alpha_i = 1 / \theta_i = \alpha \exp(\boldsymbol{\delta}'\mathbf{z}_i)$$

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$$

The mean of the underlying gamma variate which produces the negative binomial model is one while its variance is α_i. Therefore, this extension is equivalent to allowing heteroscedasticity in the latent heterogeneity. The command for adding this specification to the model is

NEGBIN ; ... as before ; Hfn = variables in $\mathbf{z}_i$ $

NOTE: Do not include *one* in the Hfn list. The leading α provides the constant term.

The heterogeneity model retains all the options of the standard model, including fitted values, lists of predictions, saving results, etc. The new parameters, $\boldsymbol{\delta}$, are kept as a matrix named *deltanb*. The heterogeneity does not affect the conditional mean function, so the partial effects are still based on λ_i.

Note, that $\partial\log L_i/\partial\boldsymbol{\delta} = \partial\log L_i/\alpha_i \times \alpha_i \times \mathbf{z}_i$. This is a minor complication added to the model as already developed. Once again, the BHHH estimator is used for the asymptotic covariance matrix. The following estimates the model shown earlier, now with variance function that is a function of whether the individual is married.

E41.4.4 Negbin 1, Negbin 2 and Negbin P

The literature, mostly associating the result with Cameron and Trivedi's early (1986) work, defines two familiar forms of the negative binomial model. Where

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i),$$

the Negbin 2 form of the probability is

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta + y_i)}{\Gamma(\theta)\Gamma(y_i + 1)} u_i^{\theta}(1 - u_i)^{y_i}$$

where $u_i = \theta / (\theta + \lambda_i)$

and $\theta = 1/\alpha.$

This is the default form of the model in most (if not all) of the received econometrics packages that provide an estimator for this model. This is the form of the model we have used up to this point. The Negbin 1 form of the model results if θ in the preceding is replaced with $\theta_i = \theta\lambda_i$. Then, u_i becomes $u = \theta/(1+\theta)$, and the density becomes

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta\lambda_i + y_i)}{\Gamma(\theta\lambda_i)\Gamma(y_i + 1)} w^{\theta\lambda_i}(1 - w\ )^{y_i}$$

where $w = \theta / (\theta + 1)$

LIMDEP will fit the model with this specification by adding

; Model = NB1

to the **NEGBIN** model command. An example appears below.

We note, this is somewhat more than a simple reparameterization of the model. The results below show that the likelihood function is not quite equal at the maximum, and the parameters are not simple transformations in one model vs. the other. We are not aware of a theory that justifies using one form or the other for the negative binomial model. The two are not nested, so we cannot carry out a likelihood ratio test of one versus the other. The Negbin P family does nest both of them, so this may provide a more general, encompassing approach to finding the right specification. This is examined below.

The results below refit our model using the Poisson specification, Negbin 1 and Negbin 2. Since the conditional mean function in all three cases is

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i),$$

the three sets of parameter estimates should be similar, as they are. However, we have already rejected the Poisson model in favor of either negative binomial model.

The more general Negbin P model is obtained by replacing θ in

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta + y_i)}{\Gamma(\theta)\Gamma(y_i+1)} u_i^{\theta}(1-u_i)^{y_i}$$

where $u_i = \theta / (\theta + \lambda_i)$,

with $\theta\lambda_i^{2-P}$. We have examined the cases of P = 1 and P = 2. For convenience, let $Q = 2 - P$, Then, the density is

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta\lambda_i^Q + y_i)}{\Gamma(\theta\lambda_i^Q)\Gamma(y_i+1)} \left(\frac{\theta\lambda_i^Q}{\theta\lambda_i^Q + \lambda_i}\right)^{\theta\lambda_i^Q} \left(\frac{\lambda}{\theta\lambda_i^Q + \lambda_i}\right)^{y_i}$$

This model is also built into *LIMDEP*. To request it, use

NEGBIN ; all as usual for your count data model
; Model = NBP $

The following reestimates the negative binomial in this more general form.

```

Note that the log likelihood function continues to increase. For this model, the likelihood ratio test against the NB2 model gives chi squared of -2(-60164.22 - (-60029.97)) = 268.5, which far exceeds the critical value of 3.84. The Wald (t) test would be (1.3975 - 2)/.03249 = -18.31, which is likewise significant.

For exploring the functional form, it may be useful to fix the value of P in the estimation. You can use **; Rst = list** in general. For the NBP model, a convenient shorthand if P is the only parameter to be restricted is

; Scale = the desired value.

In the example below, we have used **; Scale = 1.5**.

The model in the NBP form is built into *LIMDEP*, but it is also easy to formulate it as a user defined procedure with **MAXIMIZE**. The general form would be as follows:

```
SAMPLE     ; whatever is appropriate for your application $
NAMELIST   ; x = your set of independent variables
CALC       ; k = Col(x) $
CREATE     ; y = your dependent variable $
NEGBIN     ; Lhs = y ; Rhs = x $
MATRIX     ; b0 = b ; t0 = 1/alpha $
CALC       ; q0 = 0 $
MAXIMIZE   ; Start = b0,t0,q0
           ; Labels = k_c,t,q
           ; Fcn = al  = Exp(c1'x)    |
                   tlq = t*(al^q)      |
                   w  = tlq/(al+tlq)  |
            Lgm(y+tlq) - Lgm(tlq) - Lgm(y+1) + tlq*Log(w) + y*Log(1-w) $
```

A good starting value for Q is helpful. One strategy that might be used is to fix Q in the model at some specific values, by providing specific starting values and using

; Fix = q

In the models already estimated, we fit Q with $Q = 0$ (Negbin 2) and $Q = 1$ (Negbin 1). Experimenting with values between zero and one may be useful. In our estimates below, the estimated value of Q is 0.60429 (consistent with P = 1.3957 using the built in procedure earlier). The data set in use for these applications is particularly rich and well behaved. The estimator for this model was actually quite routine. Parameter estimates for the fully general model (Negbin 1.3957) are shown below.

In the results above, t, the estimate of θ, is an estimate of $1/\alpha$. To compare it to the negative binomial model, we could use the delta method to estimate α and an asymptotic standard error. The estimate would be 3.83039, which suggests much more dispersion than implied by the Negbin 2 model.

E41.4.5 Technical Details

The negative binomial model arises is as a modification of the Poisson model in which the mean is now μ_i, respecified so that

$$\log \mu_i = \log\lambda_i + \varepsilon_i = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,$$

where $\exp(\varepsilon_i)$ has a gamma distribution with mean 1.0 and variance α. (This is one of several variants of the negative binomial model discussed by Cameron and Trivedi (1986).) The resulting conditional probability distribution is

$$\text{Prob}(Y = y_i|\varepsilon_i,\mathbf{x}_i) = \frac{\exp[-(\exp(\varepsilon_i)\lambda_i)][\exp(\varepsilon_i)\lambda_i]^{y_i}}{y_i!},\ y_i = 0,1,...$$

where
$$f[\exp(\varepsilon_i)] = \frac{\theta^\theta}{\Gamma(\theta)} e^{-\theta\exp(\varepsilon_i)}[\exp(\varepsilon_i)]^{\theta-1},\ \theta = 1/\alpha,\ \exp(\varepsilon_i) > 0.$$

The unconditional distribution of y_i is obtained by taking the expectation with respect to $\exp(\varepsilon_i)$ of the conditional probability. For convenience, let $\tau_i = \exp(\varepsilon_i)$. Then

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \int_0^\infty \frac{\exp[-\tau_i\lambda_i][\tau_i\lambda_i]^{y_i}}{y_i!}\frac{\theta^\theta}{\Gamma(\theta)}e^{-\theta\tau_i}\tau_i^{\theta-1}d\tau_i$$

This is a gamma integral that can be simplified considerably. Collecting terms and using results for the gamma integral, this reduces to

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\theta^\theta\lambda_i^{y_i}}{\Gamma(\theta)y_i!}\frac{\Gamma(y_i+\theta)}{(\lambda_i+\theta)^{y_i+\theta}}$$

We have reparameterized the probability distribution in terms of θ because this simplifies the formulation and computation of the log likelihood and its derivatives. The formulation of the result that we use for optimization is

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta+y_i)}{\Gamma(\theta)\Gamma(y_i+1)}u_i^\theta(1-u_i)^{y_i}$$

where $u_i = \theta / (\theta + \lambda_i)$

and $\theta = 1/\alpha$.

For optimization and forming the BHHH estimator, we have

$$\partial\log L_i/\partial\lambda_i = [\theta/u_i - y_i/(1-u_i)]\partial u_i/\partial\lambda_i.$$

$$\partial u_i/\partial\lambda_i = -u_i / (\theta + \lambda_i) = -u_i(1 - u_i) / \lambda_i$$

$$\partial u_i/\theta = u_i(1-u_i)/\theta$$

$$\partial\lambda_i/\partial\boldsymbol{\beta} = \lambda_i\,\mathbf{x}_i.$$

Combining terms, $\partial\log L_i/\partial\boldsymbol{\beta} = [y_iu_i - \theta(1 - u_i)]\mathbf{x}_i.$

Also, $\partial\log L_i/\partial\theta = \Psi(\theta + y_i) - \Psi(\theta) + \log u_i + (1 - u_i) - y_iu_i/\theta$

where $\Psi(z) = d\log\Gamma(z)/dz.$

The Hessian is

$$\partial^2 \log L_i/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' = -(\theta + y_i)u_i\,(1 - u_i)\,\mathbf{x}_i\,\mathbf{x}_i'$$

$$\partial^2 \log L_i/\partial\boldsymbol{\beta}\partial\theta = [-(1-u_i)^2 + y_i u_i(1 - u_i)/\theta]\,\mathbf{x}_i$$

$$\partial^2 \log L_i/\partial\theta^2 = \Psi'(\theta + y_i) - \Psi'(\theta) + (1 - u_i)^2 / \theta + y_i\,(u_i/\theta)^2$$

These are used in computation of the log likelihood function, gradient, and estimate of the asymptotic covariance matrix.

Greene (2008), define the class of Negbin P models by the relationship between mean and variance functions,

$$E[y_i|\mathbf{x}_i] = \lambda_i \text{ and } \mathrm{Var}[y_i|\mathbf{x}_i] = \lambda_i + \alpha\lambda_i^P.$$

The model already considered, the standard case, is their model Negbin 2, or NB2. An alternative form labeled Negbin 1 or NB1 is obtained by using $P = 1$. The density is obtained by replacing θ with $\theta\lambda_i$ in Prob($Y = y_i|\mathbf{x}_i$). This produces, after a bit of manipulation,

$$\mathrm{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta\lambda_i + y_i)}{\Gamma(\theta\lambda_i)\Gamma(y_i + 1)} w_i^{\theta\lambda_i}(1 - w_i)^{y_i}$$

where $w_i = \theta / (\theta + 1)$

and $\theta = 1/\alpha$.

This is not a simple reparameterization of the model; it is a different model. An example given in Section E41.4.2 demonstrates. We also consider the fully general form of their negative binomial model, Negbin P.

The more general Negbin P model is obtained by replacing θ in

$$\mathrm{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta + y_i)}{\Gamma(\theta)\Gamma(y_i + 1)} u_i^{\theta}(1 - u_i)^{y_i}$$

where $u_i = \theta / (\theta + \lambda_i)$

with $\theta\lambda_i^{2-P}$. We have examined the cases of $P = 1$ and $P = 2$. For convenience, let $Q = 2 - P$. Then, the density is

$$\mathrm{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta\lambda_i^Q + y_i)}{\Gamma(\theta\lambda_i^Q)\Gamma(y_i + 1)} \left(\frac{\theta\lambda_i^Q}{\theta\lambda_i^Q + \lambda_i}\right)^{\theta\lambda_i^Q} \left(\frac{\lambda}{\theta\lambda_i^Q + \lambda_i}\right)^{y_i}$$

Derivatives of $\log L_i$ for the general Negbin P model are tedious. We obtain them by writing the density as

$$\log L_i = \log\Gamma(y_i + g_i) - \log\Gamma(g_i) - \log\Gamma(y_i) + g_i \log w_i + y_i \log(1-w_i)$$

where $g_i = \theta\,\lambda_i^Q$ and $w_i = g_i / (g_i + \lambda_i)$.

Then, $\partial\log L_i / \partial\lambda_i = [\Psi(y_i + g_i) - \Psi(g_i) + \log w_i]\,\partial g_i/\partial\lambda_i + [g_i/w_i - y_i/(1-w_i)]\,\partial w_i/\partial\lambda_i$

$$\partial\log L_i / \partial\theta = [\Psi(y_i + g_i) - \Psi(g_i) + \log w_i]\,\partial g_i/\partial\theta + [g_i/w_i - y_i/(1-w_i)]\,\partial w_i/\partial\theta$$

$$\partial\log L_i / \partial Q = [\Psi(y_i + g_i) - \Psi(g_i) + \log w_i]\,\partial g_i/\partial Q + [g_i/w_i - y_i/(1-w_i)]\,\partial w_i/\partial Q.$$

The inner parts are:

$$\partial g_i / \partial\lambda_i = \theta Q\lambda_i^{Q-1} = (Q/\lambda_i)g_i$$

$$\partial g_i / \partial\theta = \lambda_i^Q = (1/\theta)g_i$$

$$\partial g_i / \partial Q = \theta\lambda_i^Q \log\lambda_i = \log\lambda_i\, g_i$$

$$\partial w_i / \partial\lambda_i = [(Q-1)/\lambda_i]w_i(1-w_i)$$

$$\partial w_i / \partial\theta = (1/\theta)w_i(1-w_i)$$

$$\partial w_i / \partial Q = \log\lambda_i\, w_i(1-w_i)$$

Collecting terms, now, let $A_i = [\Psi(y_i + g_i) - \Psi(g_i) + \log w_i]$

$$B_i = [g_i(1 - w_i) - y_i w_i],$$

to obtain

$$\partial\log L_i/\partial\begin{pmatrix}\lambda_i\\ \theta\\ Q\end{pmatrix} = [A_i + B_i]\begin{pmatrix}Q/\lambda_i\\ 1/\theta\\ \log\lambda_i\end{pmatrix} - B_i\begin{pmatrix}1/\lambda_i\\ 0\\ 0\end{pmatrix}.$$

The final element needed is $\partial\log L_i/\partial\beta = \lambda_i\mathbf{x}_i$. We use these and the BHHH estimator to compute the maximum likelihood estimates and their asymptotic standard errors for the NBP model. When this model is estimated, there are three sets of iterations. The Poisson model is estimated first. These results are shown with the results. The Negbin 2 model is then estimated using the Poisson estimates as starting values. The NB2 results are not displayed, but you will observe this second set of iterations. These are used to improve the starting values for the NBP estimates. The starting values for NBP are the NB2 estimates, with $P = 2$ ($Q = 0$).

For all forms of the negative binomial model, when θ is allowed to be heteroscedastic, then $\theta_i = \theta\exp(\boldsymbol{\gamma}'\mathbf{z}_i) = \theta v_i$. To obtain the derivatives for the underlying parameters, let $\Delta_i = \partial\log L_i/\partial\theta_i$. Then, $\partial\log L_i/\partial\theta = \Delta_i v_i$ and $\partial\log L_i/\partial\boldsymbol{\gamma} = \Delta_i\theta_i\mathbf{z}_i$.

E41.5 Other Models for Count Data

There is a huge literature on variants of the Poisson model for counts. (See, e.g., Winkelmann (2003) or Hilbe (2011).) We have included estimators for several of them. In all cases, the models relax the equidispersion assumption of the Poisson model.

E41.5.1 Gamma Model with Under- or Overdispersion

The gamma model proposed by Winkelmann (1995) and also discussed in Cameron and Trivedi (1998) represents a significant innovation. The large majority of the extensions of the Poisson model that have been proposed have accommodated overdispersion – that is, variance greater than the mean. Underdispersion is a phenomenon which has been much less convenient to model directly – some extensions, such as various forms of the 'with zeros' models discussed in Chapter E43, can induce underdispersion, but otherwise involve more structure than desired. This extension provides a straightforward, easily implemented approach to a general model for counts that allows both under- and overdispersion. As this is a new technique (and, to our knowledge, the first implementation in a general econometrics package), a detailed presentation of the mathematical background is presented here.

The gamma (based) probability model for counts is

$$\text{Prob}[y_i = j] = G(\alpha j, \lambda_i) - G(\alpha j + \alpha, \lambda_i)$$

where $$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i) \text{ (as usual)}$$

and $$G(\alpha j, \lambda_i) = 1 \text{ if } j = 0, \text{ or } \frac{1}{\Gamma(\alpha j)}\int_0^{\lambda_i} u^{\alpha j-1}e^{-u}du \text{ if } j > 0, j = 1,...$$

The dispersion parameter is α; there is underdispersion if $\alpha > 1$, overdispersion if $\alpha < 1$, and equidispersion if $\alpha = 1$, which reduces the gamma probability to the Poisson model. The conditional mean function is

$$\text{E}[y_i|\mathbf{x}_i] = \sum_{j=1}^{\infty} jG(\alpha j, \lambda_i)$$

This has no closed form, but an approximation that we use is

$$\text{E}[y_i|\mathbf{x}_i] \approx \lambda_i / \alpha.$$

The Poisson case arises conveniently if $\alpha = 1$. With this approximation, the marginal effects are

$$\frac{\partial E[y_i \mid \mathbf{x}_i]}{\partial \mathbf{x}_i} = \frac{\lambda_i}{\alpha}\boldsymbol{\beta}$$

The gamma model is requested with

POISSON ; ... as usual ... ; Model = gamma $

All other options available with the Poisson model are retained, including the fitted values, restrictions, optimization parameters, etc. Estimation is done via the BFGS algorithm. Since this model is quite complex, the algorithm parameters should not be changed. The only difference beyond the visible output, which is clearly marked, is the new scalar, *alpha*, which is retained by the estimator.

NOTE: The derivatives for this model are computed numerically, not analytically. The BHHH estimator is used to estimate the asymptotic covariance matrix of the MLE.

The gamma model for counts arises as follows: Assume that waiting times between occurrences of events (which are counted to produce the 'count variable') are distributed as a continuous, two parameter gamma variate, with shape parameter α and location parameter $\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$ – we have skipped an introductory step and layered the regression model in at the outset. Then, the density for interarrival times is

$$f(t \mid \alpha, \lambda_i) \quad = \quad \frac{\lambda_i^{\alpha}}{\Gamma(\alpha)} t^{\alpha-1} e^{-\lambda_i t}, t \geq 0, \alpha > 0, \lambda_i > 0.$$

The arrival time of the jth event is

$$Q_j \quad = \quad t_1 + t_2 + \ldots + t_j.$$

The gamma distribution is 'reproductive;' the density of Q_j is

$$f(Q_j \mid \alpha, \lambda_i) \; = \; \frac{\lambda_i^{\alpha j}}{\Gamma(\alpha j)} Q_j^{\alpha j-1} e^{-\lambda_i Q_j}, Q_j \geq 0, \alpha > 0, \lambda_i > 0.$$

The cumulative distribution function is

$$\begin{aligned} F(T \mid \alpha, \lambda_i) \; &= \; \int_0^T \frac{\lambda_i^{\alpha j}}{\Gamma(\alpha j)} u^{\alpha j-1} e^{-\lambda_i u} du, \; \alpha > 0, \lambda_i > 0 \\ &= \; \frac{1}{\Gamma(\alpha j)} \int_0^{\lambda_i T} u^{\alpha j-1} e^{-u} du, \mathrm{j} = 0,1,\ldots \\ &= \; G(\alpha j, \lambda_i T). \end{aligned}$$

The integral is an incomplete gamma function (probability; $G(\alpha j, 0) = 0$ and $G(\alpha j, \infty) = 1$) which must be approximated numerically. Note that $G(0,\lambda_i T) = 1$. If j events occur in a period of length T or less, then equivalently, j or more events occur in the period of fixed length T. Thus,

$$G(\alpha j, \lambda_i T) \quad = \quad \text{Prob}[j \text{ events}] + \text{P}[j\text{+1 events}] \ldots \text{ in period of length } T$$

from which it follows that

$$G(\alpha(j+1), \lambda_i T) \; = \; \text{Prob}[j\text{+1 events}] \ldots$$

so that

$$\text{Prob}[j \text{ events}] \; = \; G(\alpha j, \lambda_i T) \; - \; G(\alpha(j+1), \lambda_i T).$$

We now normalize the period length to $T = 1$ to obtain the distribution for counts of events,

$$\text{Prob}[j \text{ events}] \; = \; G(\alpha j, \lambda_i) \; - \; G(\alpha j + \alpha, \lambda_i)$$

The mean/variance relationship is complicated, but it can be shown that the variance exceeds the mean if $\alpha < 1$, and is less than it if $\alpha > 1$.

E41.5.2 Generalized Poisson Models – GP1, GP2, GPP

The density for the generalized Poisson model suggested by Consul and Jain (1973) is

$$\text{Prob}[Y = y_i \mid \mathbf{x}_i] = \left(\frac{\lambda_i}{1+\theta\lambda_i}\right)^{y_i} \frac{(1+\theta y_i)}{y_i!} \exp\left(-\frac{\lambda_i(1+\theta y_i)}{1+\theta\lambda_i}\right), y_i = 0,1,2,...;\ \lambda_i = e^{\boldsymbol{\beta}'\mathbf{x}_i}.$$

The mean and variance of this random variable are

$$E[y_i \mid \mathbf{x}_i] = \lambda_i,\ \text{Var}[y_i \mid \mathbf{x}_i] = \lambda_i(1+\theta\lambda_i)^2.$$

Marginal effects are identical to those in the base Poisson model. The overdispersion, as in all the negative binomial models, is a 'mean preserving spread;' the mean is unchanged – mass is moved in both directions.

The parameter θ is unrestricted. The model provides for both over- and underdispersion, though the latter is likely to be the more empirically relevant case. Negative values can produce computational problems. However, small negative values consistent with underdispersion are, nonetheless admissible. The generalized Poisson model reverts to the familiar Poisson regression if θ = 0.

This model is requested with

POISSON ; <... the usual setup...>
; Model = GP $

The general options provided for Poisson models, including marginal effects, fitted values, constraints, weights, clustering, etc. are all available. However, truncation and censoring are not available for this model.

The 'nonPoissonness' of the distribution is embodied in the ancillary parameter θ. An extension of the model allows θ to be a linear function of any variables, using

; Hfn = list of variables

The list should include a constant term. (If you omit it, one is automatically inserted.)

As in the case of the negative binomial model, there are GP1, GP2 and GPP forms of the model. The same extension is used. The '*P*' form of the model is obtained by replacing θ with $\theta\lambda_i^{2-P}$ in the general form of the density. The default form is the GP2 model, which is obtained with

; Model = GP or GP2

The others are specified with

; Model = GP1
or **; Model = GPP**.

In all cases, the conditional mean function is still λ_i, so partial effects, the **PARTIALS** command and **SIMULATE** all work as they do for the Poisson and base case negative binomial model. (The GPP form of the model builds on Greene (2008) and was proposed explicitly by Ismail (2010).)

In the example below, we have fit the GPP model, then reported the partial effects for the base Poisson model for comparison. They are surprisingly different.

E41.5.3 Polya-Aeppli Model

The density for the Polya-Aeppli form of the Poisson model is

$$\text{Prob}[Y=0\,|\,\mathbf{x}_i]=\exp(-\lambda_i),$$
$$\text{Prob}[Y=y_i\,|\,\mathbf{x}_i]=\exp(-\lambda_i)(1-\theta)^{y_i}\sum_{j=1}^{y_i}\binom{y_i-1}{j-1}\frac{[\lambda_i(1-\theta)/\theta]^j}{j!},\ y_i=1,2,...$$
$$\lambda_i=e^{\boldsymbol{\beta}'\mathbf{x}_i}$$
$$0<\theta<1.$$

The mean and variance of this random variable are

$$E[y_i\,|\,\mathbf{x}_i]=\frac{\lambda_i}{(1-\theta)},\ \text{Var}[y_i\,|\,\mathbf{x}_i]=\frac{\lambda_i(1+\theta)}{(1-\theta)^2}$$

In order to impose the constraint on θ, *LIMDEP* estimates α then reports θ, where $\theta = \exp(\alpha)/[1+\exp(\alpha)]$. This model is primarily useful for data with excess zeros. Note that the density is of the same form as the Poisson model, in which

$$\text{Prob}[Y=0]=\exp(-\lambda_i),$$
$$\text{Prob}[Y=y_i\,|\,\mathbf{x}_i]=\exp(-\lambda_i)\frac{\lambda_i^{y_i}}{y_i!},\ y_i=1,2,...$$

The Polya-Aeppli model reverts to the Poisson model if $\theta = 0$. The model is requested with

```
POISSON        ; <... the usual setup...>
               ; Model = Polya $
```

The general options provided for Poisson models, including marginal effects, fitted values, constraints, weights, clustering, etc. are all available. However, truncation and censoring are not available for this model.

The Polya-Aeppli model is useful for modeling ‘excess zeros.’ (Note that the zero inflation models described in the next chapter are also specifically designed for that purpose.) Like other Poisson models, the framework is most compatible with values of the Lhs variable that truly are counts, generally of small to moderate numbers of events. Numbers of patents, visits to the medical establishment, visits to recreational sites, highway fatalities, etc. are applications that come to mind. Applications that stretch the definitions, such as one recently reported to us involving counts (in the millions) of financial transactions, are probably best applied in some other modeling platform. The danger here is that in models such as these, there is considerable risk of numerical overflow in attempting to compute the coefficients of the model.

For analysis of the Polya-Aeppli model, Johnson and Kotz (1993) provide some very useful recursions:

$$\text{Prob}[Y=j+1]=\frac{\lambda_i(1-\theta)}{(j+1)}\sum_{m=0}^{j}(j+1-m)\theta^{j-m}\text{Prob}[Y=j]$$

$$\frac{\partial \text{Prob}(Y=y_i)}{\partial \lambda_i}=(y_i/\lambda_i-1)\text{Prob}(Y=y_i)-\frac{(y_i-1)}{\lambda_i}\text{Prob}(Y=y_i-1),\text{ so that}$$

$$\frac{\partial \log \text{Prob}(Y=y_i)}{\partial \boldsymbol{\beta}}=\left[(y_i-\lambda_i)-(y_i-1)\frac{\text{Prob}(Y=y_i-1)}{\text{Prob}(Y=y_i)}\right]\mathbf{x}_i \text{ and}$$

$$\frac{\partial \log \text{Prob}(Y=y_i)}{\partial \theta}=\frac{1}{1-\theta}\left[(y_i-1)\frac{\text{Prob}(Y=y_i-1)}{P(y_i)}-y_i\right].$$

E41.5.4 The Logarithmic Distribution

The logarithmic distribution for a *positive* count variable is

$$\text{Prob}(Y = y_i) = \frac{\alpha\theta^{y_i}}{y_i},\ y_i = 1, 2, \ldots \text{ and } 0 < \theta < 1$$

where $\alpha = -1 / \log(1 - \theta)$.

(See Winkelmann (2008).) We can produce a regression model in this context by the parameterization

$$\theta_i = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1 + \exp(\boldsymbol{\beta}'\mathbf{x}_i)}.$$

The mean is $\quad \text{E}[y|\mathbf{x}] = \dfrac{\alpha\theta}{1-\theta} = \alpha\exp(\boldsymbol{\beta}'\mathbf{x}) = \mu_i$.

After some tedious algebra, we obtain the partial effects:

$$\frac{\partial E[y_i \mid \mathbf{x}_i]}{\partial \mathbf{x}_i} = \mu_i \alpha_i (1 - \alpha_i \theta_i)\boldsymbol{\beta}.$$

We implement the logarithmic model with a user written **MAXIMIZE** command and obtain the partial effects and simulation with **PARTIALS** and **SIMULATE**. The following template procedure can be used:

```
PROC = LogModel(y,x) $
CALC        ; k = Col(x) $
MAXIMIZE    ; Start = k_0 ; Labels = k_b
            ; Fcn = bxi = b1'x                       |
              thetai = Exp(bxi) / (1+Exp(bxi))       |
              ai = -1 / Log(1-thetai)                |
              Log(ai) + y*Log(thetai) - Log(y) $
PARTIALS    ; Parameters = b ; Labels = k_b
            ; Function = bxi = b1'x                  |
              thetai = Exp(bxi) / (1+Exp(bxi))       |
              ai = -1 / Log(1-thetai)                |
              ai*thetai / (1-thetai)
            ; Effects: x ; Summary $
ENDPROC
```

The model is fit using the 1991 data on doctor visits. For comparison, we have fit a Poisson model truncated at zero using the same data. The results are strikingly similar, which suggests that the difference in the functional forms is much less than it might appear at first.

E41.5.5 NegBin X

The NBX model was proposed by Silva and Windmeijer (2001). (See Winkelmann (2008).) Let S be distributed as Poisson(λ_i). Let R_1, R_2, …, R_S be S draws from the logarithmic distribution described in the previous section. (Note, S may be zero.) Then, the random variable with NegBin X distribution is

$$Y = R_1 + R_2 + \ldots + R_S = \sum_{i=1}^{S} R_i \text{ , } S \sim \text{Poisson } (\lambda).$$

The parameter of each draw from the logarithmic distribution is

$$\theta_i = \frac{\exp(\boldsymbol{\gamma}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\gamma}'\mathbf{x}_i)}.$$

and the parameter of the Poisson distribution is

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i).$$

Winkelmann provides the density for y_i,

$$\text{Prob}(y_i|\mathbf{x}_i) = \frac{\Gamma(y_i+\mu_i)\exp(-\lambda_i)}{\Gamma(y_i+1)\Gamma(\mu_i)[1+\exp(-\boldsymbol{\gamma}'\mathbf{x}_i)]^{y_i}}, y_i = 0,1,\ldots$$

where $$\mu_i = E[y_i|\mathbf{x}_i] = \frac{\lambda_i \exp(\boldsymbol{\gamma}'\mathbf{x}_i)}{\log[1+\exp(\boldsymbol{\gamma}'\mathbf{x}_i)]}.$$

The model is constrained thus far in that the variables $\mathbf{x}_i$ appear in both the logarithmic part and the Poisson part. Winkelmann argues that this is the natural specification of the model. The implementation below allows the variables in the logarithmic part of the model to differ from those in the Poisson.

The essential part of the command for the NBX model is

```
POISSON   ; Lhs = dependent variable
          ; Rhs = independent variables
          ; Model = NBX $
```

To relax the assumption that the same variables appear in both parts of the model, use

; Rh2 = full set of variables in the logarithmic part of the model.

In the example below, the NBX model is fit first with the same regressors in both parts of the equation. The built in routine for computing partial effects is used first. Then **PARTIALS** is used to redo the computation. The results of the two routines arises because the built in routine computes the partial effects at the means whereas **PARTIALS** computes the sample average partial effects (APE).

The differences between the two sets of partial effects arises because of the use of data means in the first case and the average partial effects in the second. When **PARTIALS** computes the effects at the means, the same results are obtained. A further small difference in the standard errors is the result of using analytic derivatives for the Jacobian in computing the effects within the command and numerical derivatives by **PARTIALS**. The decomposition of the partial effects produces a part due to the Poisson part of the probability and the remainder due to the logarithmic model component.

E41.5.6 Canonical Negative Binomial Regression Model

Hilbe (2011) recommends an alternative form of the negative binomial that he labels the 'canonical negative binomial' model. The signature feature of the model is that it applies to a discrete random variable with a formal negative binomial distribution – it is not obtained by integrating heterogeneity out of a mixed distribution. Hence the name 'canonical' – it derives from first principles. The conditional (on x_i) density of the random variable is

$$f(y_i \mid \mathbf{x}_i) = \frac{\Gamma(y_i + \theta)\lambda_i^{y_i}(1-\lambda_i)^{\theta}}{\Gamma(y_i+1)\Gamma(\theta)},\ \lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$$

The conditional mean function for this model is

$$E[y_i \mid \mathbf{x}_i] = -\theta \frac{\lambda_i}{\lambda_i - 1}.$$

The resemblance to the more familiar NB2 model is only superficial. It can be seen from the conditional mean function that the parameters in the models are very different. A more transparent way to examine the difference is to examine the partial effects. In the NB2 model,

$$\partial \text{E}[y_i|\mathbf{x}_i]/\partial \mathbf{x}_i = \lambda_i \boldsymbol{\beta}.$$

In the CNB model,

$$\frac{\partial E[y_i \mid \mathbf{x}_i]}{\partial \mathbf{x}_i} = -\theta \frac{-\lambda_i}{(\lambda_i - 1)^2}\boldsymbol{\beta} = -E[y_i \mid \mathbf{x}_i]\left(\frac{\lambda_i}{\lambda_i - 1}\right)\boldsymbol{\beta}.$$

This is a completely different scaling of the parameter vector. The implication seems likely to be that the parameters themselves from the two models will differ substantially if, as is common, the differences tend to even out in the partial effects. We will explore this in an example below.

The canonical NB model is not a built in procedure in *LIMDEP*. However, it is a very straightforward application of the maximize command to obtain the estimates followed by **PARTIALS** and **SIMULATE** to obtain the partial effects and model simulations. The program below is written in the form of a template that requires only the specification of the dependent variable and the namelist containing the regressors. A substantive complication for this estimator is the starting values. The ordinary NB estimates might seem natural, but as the analysis above suggests, the parameters in the NB2 and the CNB models are likely to be quite different. Hilbe suggests -1 for the constant term, zeros for the slopes, and 2 for θ (i.e., .5 for $\alpha = 1/\theta$).

The procedure is generic save for a single line that is modified for the specific application

```
PROC = CNBModel(y,x) $
CALC          ; k = Col(x) $
? MAXIMIZE estimates the model parameters
MAXIMIZE      ; Start = -1,k_0,2
              ; Labels = b0,k_b,theta
              ; Fcn = bx = b0 + b1'x       |
                lambdai = Exp(bx)          |
                y*bx + theta*Log(1-lambdai) + Lgm(y+theta) - Lgm(y+1) - Lgm(theta) $
? PARTIALS computes the partial effects for the variables in the namelist
PARTIALS      ; Parameters = b
              ; Labels = b0,k_b,theta
              ; Covariance = varb
              ; Function = bx = b0 + b1'x |
                lambdai = Exp(bx)          |
                -theta*lambda / (lambdai-1)
              ; Effects: x ; Summary  $
? We compare the results to the NB2 model.  Partials are comparable APEs
NEGBIN        ; Lhs = y ; Rhs = one,x $
PARTIALS      ; Effects: x ; Summary $
ENDPROC $
```

To execute the procedure, we use the health care data, and commands

```
SAMPLE        ; All $
NAMELIST      ; x = age,educ,hhninc,female$
EXECUTE       ; Proc = CNBModel(docvis, x) $
```

The results are as follows: Notice that they begin with several warnings about the computation of the function. Unlike other models that we have examined thus far, this model does involve a computation that is quite likely to produce this result. One of the terms in the log likelihood is log(1-λ_i). The implication is that λ_i must be between zero and one. Since λ_i = exp($\boldsymbol{\beta}'\mathbf{x}_i$), there is no constraint that can be placed on the parameters that will enforce this boundary. It is not unlikely that for some observations, this error will occur. The solver will draw the iterations on the parameters away from these values as it gets closer to a solution.

Maximum repetitions of PROC
```

We note, finally, a possible extension of the model. In the NB1 and NB2 formulations, we allow for heterogeneity in the scale parameter, θ. In particular, the generalized model specifies

$$\theta_i = \theta \exp(\boldsymbol{\delta}'\mathbf{z}_i).$$

It is straightforward to incorporate the same extension in the canonical model, as shown in the revised procedure below:

```
PROC = CNBModel(y,x,z) $

E42: Censoring, Truncation and Heterogeneity in Count Models

E42.1 Introduction

This chapter details several extended models for count data. The basic formulation is the *Poisson regression model*. For a discrete random variable, Y observed over a period of length T_i, and observed frequencies, y_i, i=1,...,n, where y_i is a nonnegative integer count, and regressors $\mathbf{x}_i$,

$$\text{Prob}(Y = y_i|\mathbf{x}_i) \quad = \quad \frac{\exp(-\lambda_i)\lambda_i^{y_i}}{y_i\,!},\ y_i = 0,1,...;\ \ \log \lambda_i = \boldsymbol{\beta}'\mathbf{x}_i.$$

In this model, λ_i is both the mean and variance of y_i;

$$E[y_i|\mathbf{x}_i] \quad = \quad \lambda_i.$$

The partial effects in this nonlinear regression model are,

$$\frac{\partial E[y_i \mid \mathbf{x}_i]}{\partial \mathbf{x}_i} \quad = \quad \lambda_i\boldsymbol{\beta}\ .$$

The *negative binomial regression model* is an extension of the Poisson regression model which allows the variance of the process to differ from the mean. An interpretation which fits well with several of the extensions considered in this chapter is that the negative binomial model results from the introduction of unobserved individual heterogeneity into the Poisson model. The model arises as a modification of the Poisson model in which the mean is μ_i, respecified so that

$$\log \mu_i \ = \ \log\lambda_i \ + \ w_i \ = \ \boldsymbol{\beta}'\mathbf{x}_i + w_i,$$

where $\exp(w_i)$ has a gamma distribution with mean 1.0 and variance α. This random variable y_i then has

$$\text{Var}[y_i \,|\mathbf{x}_i] \ = \ \text{E}[y_i|\mathbf{x}_i]\{1 \ + \ \alpha\text{E}[y_i|\mathbf{x}_i]\}.$$

The models presented in this chapter are extensions of the model with heterogeneity. Different treatments of the source of w_i produce different model specifications. The Poisson model considered above assumes that there is no unobserved 'heterogeneity' across individuals save for that measured in the covariates. The Poisson and negative binomial models can both be extended to allow for unobserved heterogeneity in the conditional mean function, of the form

$$\log\text{E}[y_i|\mathbf{x}_i] \ = \ \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i.$$

Thus, the unobserved individual heterogeneity enters in the form of a normally distributed disturbance. This is the formulation which gives rise to the random effects model in the panel data case, but the models described here apply simply to cross section data. The extension is made for both the Poisson and negative binomial models. Another method of introducing heterogeneity into the Poisson and negative binomial models is to allow random variation in the parameters. This extension allows a large amount of flexibility in the functional form.

E42.2 Censoring and Truncation

The tobit model is a standard tool for accounting for censoring in the linear regression model. Censoring is also observed in count data. Terza (1985) analyzed a survey of shoppers in the Atlanta SMSA who were asked, 'How many times have you been to shopping area X in the past thirty days?' with possible responses 0, 1, 2, and 3 or more. This is a direct counterpart to the tobit model, though in this instance the censoring is at the right of the distribution rather than the left at zero, as is common in the regression case. (See, also, Greene (2011) for an analysis of extramarital affairs self reported in a survey and Gurmu (1991) for a study of health care facility utilization.) Grogger and Carson (1991) analyzed a survey of the number of recreational fishing trips taken by a sample of Alaskan fisherman in which the sample was choice based so as to eliminate any individuals who reported zero trips. In this case, the distribution is truncated, rather than censored. These two cases illustrate direct counterparts to the tobit and truncated regression models.

E42.2.1 Commands for Censoring and Truncation

The Poisson model with right censoring is the Poisson model described earlier with the modification that for some positive integer C, all values of y_i greater than or equal to C are reported as C. Negative binomial models with censoring are obtained analogously by changing the functional form of the probability. Either model may be estimated for a *truncated* distribution, instead of a censored one. Suppose, for the present, that truncation is from below, at a value C. Then, the distribution of *y*s applies only to values *above C*.

Specifying Censoring in the Data

The Poisson regression model with *right censoring* is obtained by adding

; Limit = C

to the command. The censoring limit, '*C*' must be a positive integer. This specification dictates that values of the original variable have been right censored. That is, the observed *y* is the *minimum* of C and a latent Poisson variable, Y_i*. As such, the *largest* value in your sample will be C.

You can specify *left censoring*, instead, with

; Limit = C ; Maximum

to indicate that your observed dependent variable is y_i = Max[Y_i* ,C]. Then, the *smallest* value in your sample will be C.

Specifying a Truncated Distribution

In the right censored regression model, all values at or above a certain value are given that value. Thus, if the censoring is at three, all values of the 'true' y_i at or above three take the value three in the observed sample. With truncation, values in the sample only take values strictly above or below a given limit value. Thus, suppose the distribution of y_i is *left truncated* at one. Then, the observed sample will only take values 2, 3, ... To specify left truncation, use

; Limit = C
; Truncation

where *C* is the lower truncation point. Note that for left truncation, the *smallest* value in your sample will be *C* + 1.

Alternatively, the distribution may be *right truncated* at some *upper* limit, such as four. Then, the sample will only contain the values 0, 1, 2, and 3. Upper (right) truncation is requested by adding

; Limit = C
; Truncation ; Upper

to the command. The *largest* y_i in your sample will be *C* - 1, so if you request upper truncation, *C* must be greater than one. For example,

```
POISSON    ; Lhs = y
           ; Rhs = ...
           ; Limit = 0
           ; Truncation $
```

estimates a model for y_i = 1,2,....

NOTE: In all these formulations for censoring and truncation, *C* may be a fixed integer or a variable. When the censoring limit is a variable, it is also a censoring indicator. That is, the only way to tell if an observation is censored is to compare it to the censoring variable. The implication is that, for example, two observations can have the same value, say 10, and one will be censored and the other will not. The upshot is that when you use a variable censoring limit, that value must be greater than (or less than) the dependent variable for right (left) censored data sets. Your data may also contain a mix of lower, upper or uncensored observations. To specify this, add a second Rhs variable which takes the value -1 for lower censored data, 0 for uncensored observations and +1 for upper censored observations

E42.2.2 Results for the Models with Censoring and Truncation

The models with censoring and truncation are otherwise the same as those for the unmodified Poisson and negative binomial models. All options are the same as well, including fitted values, optimization options, restrictions, hypothesis tests, and so on. The output will contain notations in a few places to indicate the censoring or truncation, as shown in the example below.

NOTE: The fitted values for the dependent variable do not account for censoring or truncation, so the result should be interpreted as applying to the underlying distribution. For relatively simple problems, it is possible to manipulate the results to obtain the mean of the censored or truncated distribution. We return to this issue below.

NOTE: The computation of partial effects by the model command (with **; Partial Effects**) accounts for censoring or truncation when the model is specified with one or the other. The **PARTIAL EFFECTS** (or just **PARTIALS**) command uses the structural conditional mean, λ_i, without accounting for censoring or truncation.

The following illustrates estimation of a model with right censoring. The doctor visits data contain a fairly large number of extremely large values. About 10% of the observations are larger than 10, with the maximum well over 100. A tail this long probably stretches what could be expected of a Poisson model. To accommodate this, we have censored the data at 10 visits and reestimated the model. (Note, the data themselves need not actually be censored. Where we have specified a censoring limit of 10, internally, the program converts all values larger than 10 to 10.) The first results are for a base case Poisson model. We then fit a negative binomial (type 2) model.

```

E42.2.3 Technical Details on Censoring and Truncation

The Poisson model with right censoring is the Poisson model described earlier with the modification that for some integer $C > 0$, all values of y_i greater than or equal to C are reported as C. Define a 'latent' variable, Y^* which is the underlying Poisson variable;

$$\text{Prob}(Y_i^* = j) = \exp(-\lambda_i)\,\lambda_i^{\,j} / j!,\ \ \log \lambda_i = \boldsymbol{\beta}'\mathbf{x}_i.$$

The observed variable is

$$y_i = \text{Min}[Y_i^*, C].$$

Then, $\text{Prob}[y_i = j] = \text{Prob}[Y_i^* = j] = \text{ if } y_i < C$

and $\text{Prob}[y_i = C] = \text{Prob}[Y_i^* \geq C]$

$$= 1 - \text{Prob}[Y_i^* < C]$$

$$= 1 - \sum_{j=0}^{c-1} \text{Prob}[Y_i^* = j].$$

The model with left censoring is obtained by reversing the direction of the inequality in the preceding. Thus, with left censoring,

$$\text{Prob}[y_i = j] = \text{Prob}[Y_i^* = j] \text{ if } y_i > C$$

and $\text{Prob}[y_i = C] = \text{Prob}[Y_i^* \leq C]$

$$= \sum_{j=0}^{c} \text{Prob}[Y_i^* = j] \text{ otherwise.}$$

Negative binomial models with censoring are obtained analogously by changing the functional form of the probability.

For the censored distribution, the contribution of an observation to the log likelihood is

$$\log L_i = \delta_i \log \text{Prob}[Y_i^* = y_i] + (1 - \delta_i)\log\left\{1 - \sum_{j=0}^{C-1} \text{Prob}[Y_i = j]\right\}$$

if the observation is censored at the right and

$$\log L_i = \delta_i \log \text{Prob}[Y_i^* = y_i] + (1 - \delta_i)\log\left\{\sum_{j=0}^{C} \text{Prob}[Y_i = j]\right\}$$

if the observation is censored at the left,

where δ_i = 1 if the observation is not censored and 0 if it is.

To form the gradients of the log likelihood, we denote Prob[Y_i* = j] = Pj and make use of the result

$$\partial \text{Prob}[Y_i^* = j]/\partial\boldsymbol{\beta} = \text{Prob}[[Y_i^* = j] \times \partial \log \text{Prob}[[Y_i^* = j]/\partial\boldsymbol{\beta}$$

$$= P_j(j - \lambda_i)\mathbf{x}_i$$

Combining terms, then, for the Poisson model with right censoring

$$\frac{\partial \log L_i}{\partial\boldsymbol{\beta}} = \left[\delta_i(y_i - \lambda_i) - \frac{1-\delta_i}{1-\sum_{j=0}^{C-1} P_j} P_j(j-\lambda_i)\right]\mathbf{x}_i$$

For left censoring, the only change is the summation in the denominator in the second term. The BHHH estimator based on first derivatives is used for the estimator of the asymptotic covariance matrix. The analogous results for the negative binomial model are obtained by changing the individual term in the square brackets. The necessary results appear below.

If y is right censored (no values larger than C), then

$$E[y|\mathbf{x}] = \sum_{\text{j=0}}^{\text{C}-1} jP_j + \text{C}\left[1 - \sum_{\text{j=0}}^{\text{C}-1} P_j\right].$$

Another form of this which shows the effect of the censoring on the conditional mean is

$$E[y|\mathbf{x}] = \lambda - \sum_{j=C}^{\infty} (j-C)P_j.$$

Since this involves an infinite sum, it is not useable for computations as is. For computation of the conditional mean and the marginal effects, we use, instead,

$$E[y|\mathbf{x}] = \text{C} - \sum_{j=0}^{C-1} P_j\,(C - j).$$

(For convenience, the sum may run to C, as the last term is zero.) Then, the marginal effects are

$$\boldsymbol{\delta} = \frac{\partial E[y\,|\,\mathbf{x}]}{\partial\mathbf{x}} = \left[\sum_{j=0}^{C-1} P_j(j-C)\frac{\partial \log P_j}{\partial\mathbf{x}}\right]\boldsymbol{\beta}$$

$$= \left[\sum_{j=0}^{C-1} P_j(j-C)(j-\lambda)\right]\boldsymbol{\beta}$$

for the Poisson model, and

$$\boldsymbol{\delta} = \left[\sum_{j=0}^{C-1} P_j(j-C)(\theta(1-u) - ju)\right]\boldsymbol{\beta}$$

for the negative binomial model. Analytic derivatives of these expressions are used for the delta method to compute the standard errors for the marginal effects. Denote by $\boldsymbol{\gamma}'$ the parameter vector, either $\boldsymbol{\beta}'$ for the Poisson model or $[\boldsymbol{\beta}',\theta]$ for the negative binomial model. Then, the matrix of derivatives needed for the asymptotic covariance matrix is

$$\frac{\partial \boldsymbol{\delta}}{\partial \boldsymbol{\gamma}'} = \left[\sum_{j=0}^{C-1} P_j(j-C)\frac{\partial \log P_j}{\partial \mathbf{x}}\right][\mathbf{I} \mid \mathbf{0}]$$

$$+\,\boldsymbol{\beta}\left[\sum_{j=0}^{C-1} P_j(j-C)\left(\frac{\partial \log P_j}{\partial \mathbf{x}}\frac{\partial \log P_j}{\partial \boldsymbol{\gamma}'}+\frac{\partial^2 \log P_j}{\partial \mathbf{x}\partial \boldsymbol{\gamma}'}\right)\right]$$

If y is censored at the left (no values smaller than C), then the conditional mean is just

$$E[y|\mathbf{x}] = \lambda + \sum_{j=0}^{C} (C-j)P_j.$$

so the marginal effects are

$$\frac{\partial E[y \mid \mathbf{x}]}{\partial \mathbf{x}} = \left[\lambda + \sum_{j=0}^{C} P_j(C-j)\frac{\partial \log P_j}{\partial \mathbf{x}}\right]\boldsymbol{\beta}$$

The remaining expressions used for analyzing the marginal effects are modified accordingly. With the vector of probabilities in hand, these are straightforward to compute, say at the means of a set of regressors.

Suppose, for the present, that truncation is from below, at a value C. Then, the distribution of ys applies only to values above C – it is left truncated. Thus,

$$\text{Prob}[y_i = j \mid y_i > C] = \frac{\exp(-\lambda_i)\lambda_i^{y_i}/y_i!}{\text{Prob}[y_i > C]}, \text{ for } y_i = C+1, C+2, \ldots.$$

For computational purposes, we use $\text{Prob}[y_i > C] = 1 - \text{Prob}[y_i \le C]$, so the manipulable form of the Poisson distribution is

$$\text{Prob}[y_i = j \mid y_i > C] = \frac{\exp(-\lambda_i)\lambda_i^{y_i}/y_i!}{1-\sum_{j=0}^{C}\exp(-\lambda_i)\lambda_i^{j}/j!}, \text{ for } y_i = C+1, C+2, \ldots.$$

The negative binomial model is formed likewise. Truncation may also be from above, in which case,

$$\text{Prob}[y_i = j \mid y_i < C] = \frac{\exp(-\lambda_i)\lambda_i^{y_i}/y_i!}{\text{Prob}[Y < C]}$$

$$= \frac{\exp(-\lambda_i)\lambda_i^{y_i}/y_i!}{\sum_{j=0}^{C-1}\exp(-\lambda_i)\lambda_i^{j}/j!}, \text{ for } y_i = 0,1,\ldots,C-1$$

for the Poisson model and likewise for the negative binomial. The log likelihood function is the sum of the probabilities. For left truncation (that is, for Y greater than C)

$$\log L_i \;=\; \log \text{Prob}[Y_i = y_i] \;-\; \log\left(1-\sum\nolimits_{j=0}^{C} P_j\right)$$

For right truncation, (that is, if the distribution restricts Y to be less than C),

$$\log L_i \;=\; \log \text{Prob}[Y_i = y_i] \;-\; \log\left(\sum\nolimits_{j=0}^{C-1} P_j\right).$$

The conditional mean functions are considerably more involved in the truncation case. For left truncation,

$$E[y|\mathbf{x}, y > C] \;=\; \frac{\sum_{j=C+1}^{\infty} jP_j}{1-\sum_{j=0}^{C} P_j}$$

By adding and subtracting a term in the numerator, this can be written as

$$E[y|\mathbf{x}, y > C] \;=\; \frac{\lambda \;-\; \sum_{j=0}^{C} jP_j}{1-\sum_{j=0}^{C} P_j}$$

With some algebra (omitted), the marginal effects in this model can be written

$$\boldsymbol{\delta} \;=\; \frac{\partial E[y\,|\,\mathbf{x}, y \;>\; C]}{\partial \mathbf{x}} \;=\; \left(\frac{1 \;-\; \sum_{j=0}^{C}(j - E[y\,|\,\mathbf{x}, y > C])P_j \,\dfrac{\partial \log P_j}{\partial \lambda}}{1 \;-\; \sum_{j=0}^{C} \;P_j}\right)\lambda\,\boldsymbol{\beta}$$

For right truncation,

$$\boldsymbol{\delta} \;=\; \frac{\partial E[y\,|\,\mathbf{x}, y \;<\; C]}{\partial \mathbf{x}} \;=\; \left(\frac{\sum_{j=0}^{C-1}(j - E[y\,|\,\mathbf{x}, y < C])P_j \,\dfrac{\partial \log P_j}{\partial \lambda}}{\sum_{j=0}^{C-1} \;P_j}\right)\lambda\,\boldsymbol{\beta}$$

The functions differ between the Poisson and negative binomial models in the derivative term in the numerator of the scale,

$\partial \log P_j/\partial\lambda, \;=\; (j/\lambda - 1)$ for the Poisson model,

$\partial \log P_j/\partial\lambda \;=\; [ju/L \;-\; \theta(1-u)/\lambda]$ for the negative binomial model.

Standard errors based on the delta method are tedious but follow the same computations as shown earlier. For brevity, they are omitted here.

E42.3 Endogenous Truncation – On Site Sampling

Shaw (1988) examined the Poisson regression model in the context of onsite sampling. This is a type of truncation in that if the count is observed on site, it must equal at least one, and the truncation of the zero observations is a feature of the sampling mechanism. Shaw's important result on the density of the observed count under this assumption is

$$p(y_i \mid \mathbf{x}_i, y_i > 0) = \frac{\exp(-\lambda_i)\lambda_i^{y_i-1}}{(y_i-1)!},\ y_i = 1, 2, \ldots,\ \lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i).$$

This random variable has mean function $\lambda_i + 1$ and variance λ_i. It can be seen that the model can be estimated and analyzed as a Poisson model simply in terms of $w_i = y_i - 1$. The model continues to display (essentially) the equidispersion feature of the Poisson model. Englin and Shonkwiler (1992) proposed an extension of the Shaw model for the negative binomial distribution. The density for this random variable is

$$p(y_i \mid x_i, y_i > 0) = \frac{y_i\Gamma(y_i + 1/\alpha_i)\alpha_i^{y_i}\lambda_i^{y_i-1}[1+\alpha_i\lambda_i]^{-(y_i+1/\alpha_i)}}{\Gamma(y_i+1)\Gamma(1/\alpha_i)}.$$

The conditional mean and variance in the Englin and Shonkwiler's variant of the negative binomial model are

$$\mathrm{E}[y_i|\mathbf{x}_i] = \lambda_i + 1 + \alpha_i\lambda_i$$

and

$$\mathrm{Var}[y_i|\mathbf{x}_i] = \lambda_i + \alpha_i(1 + \lambda_i + \alpha_i\lambda_i).$$

We will allow for additional heterogeneity in the model by parameterizing α_i as

$$\alpha_i = \exp(\boldsymbol{\delta}'\mathbf{z}_i).$$

The model is requested by using the model command

```
NEGBIN    ; Lhs = dependent variable
          ; Rhs = independent variables, including one
          ; Model = NBE $
```

The extended specification for α_i is requested with

; Hfn = list of variables in z (not including one).

Results for this model are indicated by an identifier for the model, but appear otherwise as a variant of the negative binomial model shown in the previous chapter. An example below.

```
-----------------------------------------------------------------------------
NegBin with Endogenous Stratification

```

It should be noted, as in Shaw's case, this model is not the same as the truncated at zero version of the negative binomial model. If the data generating process is not consistent of the model, the results will suggest that. For example, the first result below show the NBE model applied to the positive observations in the 1994 wave of the health care panel show the value of α to be consistent with a Poisson model while the actual negative binomial model shown second is consistent with other results that have suggested the overdispersion in the data.

E42.4 Unobserved Heterogeneity

This section will describe two models for unobserved heterogeneity in the Poisson and negative binomial regression models. The techniques are applied to an example in Greene (2003).

E42.4.1 Latent Heterogeneity in Poisson and Negative Binomial Models

The Poisson and negative binomial models are modified to allow individual heterogeneity. The Poisson model is modified so that

$$y|\mathbf{x},\varepsilon \sim \text{ Poisson with mean } \lambda|\mathbf{x},\varepsilon = \exp(\boldsymbol{\beta}'\mathbf{x} + \varepsilon) \text{ where } \varepsilon|\mathbf{x} \sim N[0,\sigma^2].$$

This is an alternative to the negative binomial model for unobserved heterogeneity in the count data model. The negative binomial model arises if ε has a log-gamma density, that is, $u = \exp(\varepsilon)$ has the gamma density with mean one. The unconditional variance of y can be obtained as

$$\text{Var}[y|\mathbf{x}] = E[\text{Var}[y|\mathbf{x},\varepsilon]] + \text{Var}[E[y|\mathbf{x},\varepsilon]].$$

Conditioned on ε, y has mean and variance equal to $\exp(\boldsymbol{\beta}'\mathbf{x})\times\exp(\varepsilon)$. The second term has a lognormal distribution. Using properties of the lognormal distribution, we find

$$\begin{aligned}
E[y|\mathbf{x}] &= \exp(\boldsymbol{\beta}'\mathbf{x}) \times \exp(\tfrac{1}{2}\sigma^2)\\
\text{Var}[y|\mathbf{x}] &= \exp(\boldsymbol{\beta}'\mathbf{x}) \times \exp(\tfrac{1}{2}\sigma^2) + [\exp(\boldsymbol{\beta}'\mathbf{x})]^2 \times [\exp(2\sigma^2) - \exp(\sigma^2)]\\
&= E[y] \times \{1 + E[y](\exp(\sigma^2) - 1)\}.
\end{aligned}$$

This does induce overdispersion, as might be expected. If $\sigma^2 \rightarrow 0$, $E[y|\mathbf{x}]$ reduces to the Poisson mean, and $\text{Var}[y|\mathbf{x}] = E[y|\mathbf{x}]$. Therefore a positive σ is the difference between this model and the Poisson. Essentially the same result is obtained if $E[\exp(\varepsilon)]$ is normalized to $-\tfrac{1}{2}\sigma^2$, so that $E[u] = 1$, as in the negative binomial case. In this case, the constant term in the regression must be adjusted. In principle, a model without heterogeneity can be obtained by setting σ to zero. But, this is not a well defined hypothesis for likelihood based tests, so we use a Vuong test, instead. The statistic and its implication are presented in the output.

Request this model with

POISSON ; Lhs = ... ; Rhs = ... ; Heterogeneity $

All other options for the Poisson model are available, including controls for the optimization, keeping residuals and predictions, and marginal effects and so on. Starting values for the iterations are the unconstrained Poisson estimates, with a moment estimator of σ. You may provide your own starting values with **; Start = ...** You may also impose constraints with **; Rst** and **; CML:**. Other options as usual are available, such as **; Par** for keeping ancillary parameters, etc.

Predicted values for this model are

$$
\begin{aligned}
E^*[y|\mathbf{x}] &= \int_{-\infty}^{\infty} E[y|\mathbf{x},\varepsilon]\, f(\varepsilon)\, d\varepsilon \\
&= E_{\varepsilon}\,[\, E[y|\mathbf{x},\varepsilon]] \\
&= \int_{-\infty}^{\infty} (1/\sigma)\phi(\varepsilon/\sigma)\exp(\boldsymbol{\beta}'\mathbf{x} + \varepsilon)d\varepsilon.
\end{aligned}
$$

These are requested with **; Keep = name** and **; List** as usual. Residuals kept with **; Res = name** are computed as y-E*[y]. Other saved results are matrices *b* and *varb* as usual, scalars *nreg*, *kreg*, *logl*, and *s* which contains the estimate of σ. The *Last Model* parameters are *b_name* for the Rhs variables.

The same heterogeneity model can be extended to the negative binomial regression. Since the negative binomial model can be interpreted as a Poisson model with gamma heterogeneity, this new variant is likely to be problematic, as it adds heterogeneity to a model which already accommodates heterogeneity – see the example below. Still, if the underlying population is believed to be negative binomial to start with, this model allows normal heterogeneity to be added on to that. The structure is

$$
\begin{aligned}
P(y|\mathbf{x},\varepsilon) &= \{\Gamma(\theta+y)/[\Gamma(\theta)y!]\}\,(u|\varepsilon)^{\theta}\,[1-(u|\varepsilon)]^{y} \\
u|\varepsilon &= \theta / (\theta + \lambda|\varepsilon) \\
\lambda|\mathbf{x},\varepsilon &= \exp(\,\boldsymbol{\beta}'\mathbf{x} + \varepsilon) \\
\varepsilon|\mathbf{x} &\sim N[0,\sigma^2].
\end{aligned}
$$

The unconditional distribution is difficult to derive, and is evaluated by Hermite quadrature, instead.

The command for this model is

NEGBIN ; Lhs = ... ; Rhs = ... ; Heterogeneity $

Other aspects of this model are the same as those for the Poisson model.

E42.4.2 Applications

The foregoing are applied to the health care, with both the Poisson and negative models. The base models are included for comparison. The first set of estimates is for the Poisson model. The starting value for the heterogeneity is shown with the initial estimates. The Poisson model with heterogeneity is an alternative to the negative binomial model shown below.

E42.4.3 Random Constant Poisson Regression

The next section describes estimation of a count data model with random parameters. The models of heterogeneity considered here can be treated and estimated as special cases. In particular, we specify

$$y_i|\mathbf{x}_i,\varepsilon_i \sim \text{Poisson } \lambda_i$$

$$E[y_i|\mathbf{x}_i,\varepsilon_i] = \lambda_i = \lambda|\mathbf{x},\varepsilon = \exp(\alpha_i + \boldsymbol{\beta}'\mathbf{x})$$

$$\alpha_i = \alpha + \varepsilon_i \text{ where } \varepsilon|\mathbf{x} \sim N[0,\sigma^2].$$

This is a special case of the random parameters model, that is estimated by maximum simulated likelihood, rather than by quadrature as are the models above.

The following demonstrates the alternative methods of fitting the Poisson model with normally distributed heterogeneity. (The negative binomial model could be estimated this way as well.) The commands are discussed in more detail below.

E42.4.4 Technical Details

Parameters of the heterogeneity model are estimated by maximum likelihood. The likelihood function is formed as follows: The conditional Poisson density for the observed y is

$$P(y|\varepsilon) = \exp[-E(y|\varepsilon)] \times [E(y|\varepsilon)]^y / y!$$

The unconditional probability is found by integrating ε out of this expression;

$$P(y) = E_\varepsilon[P(y|\varepsilon)] = \int_{-\infty}^{\infty} P(y|\varepsilon)\, f(\varepsilon)\, d\varepsilon$$

$$= \int_{-\infty}^{\infty} P(y\,|\,\varepsilon)\left(\frac{1}{\sigma}\right)\phi\left(\frac{\varepsilon}{\sigma}\right)d\sigma$$

where $\phi(.)$ is the standard normal PDF. This function and its derivatives are evaluated by Hermite quadrature to maximize the log likelihood, which is

$$\text{Log } L = \sum_{i=1}^{n} \log P(y_i).$$

Details on using Hermite quadrature to evaluate log likelihoods of this form are given in Section R23.3.1.

The hypothesis $\sigma = 0$, which would produce the model without heterogeneity, is not well defined – the restricted value is on the boundary of the parameter space. An alternative statistic that can be used for such a test is the Vuong statistic. Define

$$m_i = \log(P_i|H_0 \,/\, P_i|H_1)$$

Thus, m_i is the ratio of the logs of the fitted probabilities for the ith observation under the null and alternative hypotheses. (Minus twice $\overline{m}$ is the likelihood ratio statistic for testing H_0 against a broader alternative H_1. But, that is not the case here.) The test statistic is the standard measure for testing whether a mean is zero,

$$V = \sqrt{n}\;\; \overline{m} \,/\, s_m\,.$$

The limiting distribution of V is normal (0,1). Large values (greater than 2.0) favor H_0; small values (less than -2.0) favor H_1. The intermediate values are inconclusive. The Vuong statistic is reported for several models, including the heterogeneity models shown in the examples below.

E42.5 Heterogeneity in the Form of Random Parameters

The models described above are equivalent to the following formulation in which '*i*' indexes individuals:

$$\begin{aligned}
\beta_{1i} &= \beta_1 + v_{1i} \\
v_i &\sim N[0,\sigma^2] \\
\beta_{ki} &= \beta_k,\ k = 2,...,K \\
\boldsymbol{\beta}_i &= [\beta_{1i}, \beta_{2i}, ..., \beta_{Ki}]' \\
\mathbf{x}_i &= [1, x_{2i}, x_{3i},..., x_{Ki}]' \\
\lambda_i|v_i &= \exp(\boldsymbol{\beta}_i'\mathbf{x}_i) \\
P(y_i|v_i) &= \text{Poisson or negative binomial probability conditioned on } v_i.
\end{aligned}$$

This has reformulated the heterogeneity model as a model with a randomly distributed constant term. The correct log likelihood for this model is obtained by integrating out the heterogeneity term;

$$\log L = \sum_{i=1}^{n} \log \int_{v_{1i}} g(v_{1i}) P(y_i \mid \mathbf{x_i}, v_{1i}) dv_{1i}$$

The preceding applications have made this feasible by approximating the integration with Hermite quadrature (assuming that v_{1i} is normally distributed). (Note that in the negative binomial case with unit mean gamma heterogeneity, the integral has a closed form, which we treated in Section E41.4.5) The approximate log likelihood that was maximized in the previous section is

$$\log L_H = \sum_{i=1}^{n} \log \sum_{h=1}^{H} P(y_i \mid \mathbf{x}_i, v_{1h}) w_h$$

where v_{1h} and w_h are the nodes and weights for the Hermite quadrature.

An alternative approach to maximizing the log likelihood is integration of the simulated log likelihood – see Chapter R24. For the model examined here, the simulated log likelihood function is

$$\log L_S = \sum_{i=1}^{n} \log \frac{1}{R} \sum_{h=1}^{H} P(y_i \mid \mathbf{x}_i, v_{1ir})$$

where v_{1ir} is the *r*th of *R* simulated draws from the distribution of v_{1i}. With a sufficient number of draws, *R*, the estimator converges to the true MLE. This 'random constant term' approach is equivalent to the heterogeneity models in the previous section, though it uses a different method of approximating the log likelihood. Before proceeding to the more general formulation, we will illustrate this particular model with the data described below.

NOTE: Random parameter models are often associated with analysis of panel data. But, this is one of many models in *LIMDEP* that allow random parameter models in a cross section setting.

The random parameters model may be extended to the full parameter vector. We allow for a general model in which some parameters are random and others are not. Also, several extensions of the model are added at this point. The structure of the random parameters model is

$\boldsymbol{\beta}_{1i}$ = $\boldsymbol{\beta}_1$ (K_1 nonrandom parameters)

$\mathbf{x}_{1i}$ = variables multiplied by $\boldsymbol{\beta}_{1i}$

$\boldsymbol{\beta}_{2i}$ = $\boldsymbol{\beta}_2 + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}v_{\mathrm{i}}$ (K_2 random parameters)

where

- $\boldsymbol{\beta}_2$ = the fixed means of the distributions for the random parameters
- $\mathbf{z}_i$ = a set of M observed variables which enter the means (optional)
- $\boldsymbol{\Delta}$ = coefficient matrix, $K_2 \times M$, which forms the observation specific term in the mean
- $\mathbf{v}_i$ = unobservable $K_2 \times 1$ latent random term in the ith observation in $\boldsymbol{\beta}_{2i}$. Each element of $\mathbf{v}_i$ has zero mean and variance one. Each element of $\mathbf{v}_i$ may be distributed as normal, uniform, or triangular. They need not be the same.
- $\boldsymbol{\Gamma}$ = lower triangular or diagonal matrix which produces the covariance matrix of the random parameters, $\boldsymbol{\Omega} = \boldsymbol{\Gamma}\boldsymbol{\Gamma}'$

$\mathbf{x}_{2i}$ = variables multiplied by $\boldsymbol{\beta}_{2i}$

$\boldsymbol{\beta}_i$ = $[\boldsymbol{\beta}_1', \boldsymbol{\beta}_{2\mathrm{i}}']'$

$\mathbf{x}_i$ = $[\mathbf{x}_{1i}', \mathbf{x}_{2i}']'$

$\lambda|\mathbf{v}_i$ = $\exp(\boldsymbol{\beta}_i'\mathbf{x}_i)$

$P(y_i|\mathbf{x}_i,\mathbf{v}_i)$ = Poisson or negative binomial probability given λ_i.

This formulation allows great flexibility in the specification of the model, and accommodates many special cases.

The command for the random parameters model is structured as follows:

```
    POISSON      ; Lhs  = dependent variable
    or NEGBIN    ; Rhs  = list of all variables in xi, including one if the model contains a
                          constant
                 ; Pts  = r (number of replications – this is optional)
                 ; RPM    (for random parameters model)
or               ; RPM  = list of variables in zi
                 ; Fcn  = specification of random parameters
                 ; Cor    (for correlated parameters – optional) $
```

The **; Fcn** list consists of a list of names of variables which appear in $\mathbf{x}_{2i}$, followed in parentheses by (n) for normally distributed, (u) for uniform, or (t) for triangular.

The following example refits the earlier model with three normally distributed coefficients

```
POISSON  ; Lhs = docvis
         ; Rhs = one,age,hhninc,educ,female,hhkids,married
         ; Rpm ; Fcn = one(n), hhninc(n), female(n) ; Correlated
         ; Pts = 125 ; Halton
         ; Partial Effects $
```

Other options for the Poisson and negative binomial models are generally supported, including predictions and residuals, restrictions, controls on the optimization, display of output, marginal effects, and so on. Output includes the standard displays, as shown above. The matrices saved are *b* and *varb* as usual, as are scalars *nreg*, *kreg*, *logl*, and *exitcode*. An additional matrix, *sdrpm* is created. This is a column vector which contains the implied standard deviations of the random coefficients.

E43: Two Part Models for Count Data

E43.1 Introduction

This chapter describes several extended models for count data. The basic formulation is the *Poisson regression model*. For a discrete random variable, Y observed over a period of length T_i, and observed frequencies, y_i, $i = 1,...,n$, where y_i is a nonnegative integer count, and regressors $\mathbf{x}_i$,

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\exp(-\lambda_i)\lambda_i^{y_i}}{y_i!}, \; y_i = 0,1,...; \;\; \log \lambda_i = \boldsymbol{\beta}'\mathbf{x}_i.$$

In this model, λ_i is both the mean and variance of y_i;

$$E[y_i|\mathbf{x}_i] = \lambda_i.$$

The partial effects in this nonlinear regression model are,

$$\frac{\partial E[y_i \,|\, \mathbf{x}_i]}{\partial \mathbf{x}_i} = \lambda_i\boldsymbol{\beta}\,.$$

The various extensions are also provided for the negative binomial model.

The two part models involve a behavioral specification of the count model generally involving a participation equation and an intensity equation. The hurdle model, for example, has been used in health care applications in which the individual decides whether or not to use the health care system (the first, binary outcome model equation) and then, given a decision to participation, how intensively to use the system (the second, count equation). The five models detailed in this chapter are

- sample selection
- endogenous treatment effects
- models for underreporting of counts
- zero inflation models (GPP allows this form **; Rh2)**
- hurdle models

These and other two part models are surveyed in Greene (2005a)

E43.2 Model for Sample Selection

The Poisson and negative binomial models can be fit with a Heckman style correction for sample selection. The method used here is maximum likelihood, however, not two step least squares. The formulation is similar to the linear selectivity model. The specification used here is as follows:

y_i = Poisson or negative binomial variable with conditional mean

$\log \lambda_i = \boldsymbol{\beta}' x_i + \varepsilon_i$;

z_i = a binary indicator of whether data on $[y_i, \mathbf{x}_i]$ are observed, with underlying latent structure, $z_i = 1(\boldsymbol{\gamma}' w_i + u_i) > 0$ (a probit model);

(ε_i, u_i) ~ bivariate standard normal with correlation ρ and $\text{Var}[\varepsilon_i] = \sigma^2$;

and $[y_i, \mathbf{x}_i]$ = observed only when $z_i = 1$.

Estimation of the selection model is by full information maximum likelihood.

The following is a counterpart to the sample selection model for linear regression. We present two approaches. The Poisson and negative binomial specifications are modified as follows: The selection indicator z_i is determined by

$$z_i^* = \boldsymbol{\gamma}'\mathbf{w}_i + u_i \text{ in which } u_i \sim N[0,1],$$

$$z_i = \mathbf{1}(z_i^* > 0).$$

Thus, a probit model applies to the indicator, z_i. For the observed count variable, in the population,

$$y_i \sim \text{Poisson } (\lambda_i) \text{ or negative binomial } (\lambda_i, \theta)$$

However, $y_i, \mathbf{x}_i$ are observed only when $z_i = 1$.

Then, $y_i | \mathbf{x}_i, (z_i = 1) \sim$ Poisson or negative binomial.

This leads to a Heckman style correction of the count data model. However, the last assumption is questionable. In the standard regression framework, the development proceeds by modeling the joint distribution of u_i and the disturbance in the regression model, which would correspond to

$$\varepsilon_i = y_i - E[y_i | \mathbf{x}_i].$$

The familiar Heckman model hinges on joint normality of $[u_i, \varepsilon_i]$, which is clearly untenable here – since y_i is discrete, its deviation from the conditional mean function would not be normally distributed. The approach taken is to join the selection approach with the heterogeneity model of the Section E42.4.1;

$$\lambda_i | \varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i)$$

Then, $[u_i, \varepsilon_i]$ ~ Bivariate normal with zero means, correlation ρ, and standard deviations 1 and σ.

Thus, $y|\varepsilon$ is distributed as Poisson with mean (and variance) $E[y|\varepsilon] = \exp(\boldsymbol{\beta}'\mathbf{x} + \varepsilon)$. The distribution in the selected population is nonPoisson, but this does preserve its discreteness. The force of the sample selection is exerted on the mean of the discrete variable (and its variance). The estimator is full information maximum likelihood. Discussion appears in Terza (1998, 2009) and Greene (2011).

E43.2.1 Full Information Maximum Likelihood Estimation

A full information maximum likelihood estimator for the sample selection model is requested for the **POISSON** or **NEGBIN** specifications with

PROBIT ; Lhs = ... ; Rhs = ... ; Hold $
POISSON ; Lhs = .. ; Rhs = ... ; Selection ; MLE $ (or NEGBIN)

The computations are based on the heterogeneity model. This must be preceded by the probit model in order to define the full set of variables in the model and to provide the starting values for the iterations. Partial effects are requested with

; Partial Effects.

All options, including

Optimization:	**; Maxit = n**	to set maximum restrictions
	; Alg = name	to select algorithm (you generally should not change this)
	; Tlf [= value]	to set tolerance for convergence criteria
	; Output = value	to control intermediate output
	; Hpt = n	to specify number of nodes for Hermite quadrature
Constraints:	**; Rst = list**	to specify fixed value and equality restrictions
	; CML: spec	to define a constrained maximum likelihood estimator
	; Test: spec	to define Wald tests
Output:	**; Covariance Matrix**	to display the estimated asymptotic covariance matrix, same as **; Printvc**.
	; List	to display predicted values
	; Keep = name	to retain fitted values
	; Res = name	to retain residuals
	; Parameters	to retain estimates of σ and ρ in *b* and *varb*

and so on for other program options are all supported. Output for this model will include the initial Poisson regression followed by the FIML results, then any optional output you have requested, such as a list of fitted values.

NOTE: This estimator reestimates the parameters of the probit model, and replaces the estimates that were initially retained with **; Hold** on the probit command. See the example below.

The results that are retained include

Matrices: *b* and *varb* include Poisson slopes followed by probit parameters σ then ρ with **; Parameters** option

Scalars:

logl = log likelihood
kreg = number of parameters in [β′, γ′, σ, ρ]′
nreg = number of observations, total, not just selected
s = estimate of σ
rho = estimate of ρ

Last Function: None

The elements of the partial effects are computed by quadrature with the model, during the estimation step. **PARTIALS** and **SIMULATE** are not enabled for this model.

This example bases the sample selection on the addon insurance variable in the health care data.

PROBIT ; Lhs = addon ; Rhs = one,age,hhninc,married,hhkids ; Hold $
POISSON ; Lhs = docvis ; Rhs = one,age,female,hsat
; Select ; MLE ; Partial Effects $

E43.2.2 Imposing Restrictions and Fixing ρ

The parameter vector is [β′, γ′, σ, ρ]′. Use this if you wish to impose constraints. For example, to fix the value of ρ at -.5, you could use the following:

```
NAMELIST  ; xp = Rhs variables in probit equation
          ; xr = Rhs variables in Poisson model $
CALC      ; kp = Col(xp) ; kr = Col(xr) $
PROBIT    ; Lhs = ...
          ; Rhs = xp
          ; Hold $
POISSON   ; Lhs = the dependent variable
          ; Rhs = xr
          ; Selection
          ; MLE
          ; Rst = kr_b, kp_c, sg, -.5 $
```

```

You can use this device to test for a selectivity effect as well. The simple t and likelihood ratio tests can be carried out based on the value of ρ that is estimated. But, the t test requires estimation of the full model while the LR test requires assembling estimates of the pair of models and collecting three terms:

```
PROBIT    ; ... ; Hold $
POISSON   ; ... estimate full model by FIML $
CALC      ; lfiml = logl $
CALC      ; lprobit = logl $
REJECT    ; the Lhs variable for probit model = 0 $
POISSON   ; ... Poisson model without selection, on selected observations $
CALC      ; lpois = logl
          ; List
          ; lm = 2*(lfiml - lprobit - lpois)
          ; 1 - Chi(lm,1)  $
```

The LM test should be the simplest to carry out. In the earlier example, just change our -.5 to 0, and add **; Maxit = 0** to the command. An example appears below.

E43.2.3 Technical Details

The central result in estimation of the two part models by FIML as done here is the connection of the participation equation to the intensity equation through the correlation of the two disturbances. The participation equation is

$$z_i^* = \boldsymbol{\gamma}'\mathbf{w}_i + u_i \text{ in which } u_i \sim N[0,1],$$

$$z_i = \mathbf{1}(z_i^* > 0).$$

The intensity equation is based on a conditional mean function

$$\lambda_i|\varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i), \text{ where } \varepsilon_i \sim N[0,\sigma^2] \text{ and } \mathrm{corr}(\varepsilon_i,u_i) = \rho.$$

To obtain the log likelihood, we first project u_i on ε_i so

$$u_i = (\rho/\sigma)\varepsilon_i + \tau v_i \text{ where } \tau = \sqrt{1-\rho^2}\ .$$

Combining terms, the density for the observed $y_i|\varepsilon_i$ when $z_i = 1$ is the Poisson probability

$$P(y_i|z_i{=}1, \varepsilon_i) = P_i(y_i|\varepsilon_i).$$

The contribution to the likelihood is the density of the observed outcome. Conditioned on ε_i, when $z_i = 0$, this is

$$\mathrm{Prob}(z_i = 0|\varepsilon_i) = \Phi\left(\frac{-[\gamma' z_i + (\rho/\sigma)\varepsilon_i]}{\sqrt{1-\rho^2}}\right) = \Phi_i^0(\varepsilon_i)$$

The contribution to the likelihood when $z_i = 1$ is the joint density of z_i and y_i.

$$\text{Prob}(y_i,z_i{=}1|\varepsilon_i) = \text{Prob}(y_i|z_i{=}1, \varepsilon_i)\text{Prob}(z_i{=}1|\varepsilon_i)$$

$$= P_i(y_i|\varepsilon_i)\,\Phi\left(\frac{[\gamma' z_i + (\rho/\sigma)\varepsilon_i]}{\sqrt{1-\rho^2}}\right) = \Phi_i^1(\varepsilon_i)P(y_i \mid \varepsilon_i)\,.$$

To form the log likelihood function, it is necessary to integrate e_i out of the density. The unconditional contribution to the likelihood of observation i is

$$f(y_i, z_i) = \int_{\varepsilon_i} f(y_i, z_i \mid \varepsilon_i) f(\varepsilon_i) d\varepsilon_i.$$

Collecting terms once again, this is

$$f(y_i, z_i) = \int_{\varepsilon_i} \left[(1-z_i)\Phi_i^0(\varepsilon_i) + z_i\Phi_i^1(\varepsilon_i)P(y_i \mid \varepsilon_i)\right]\frac{1}{\sigma}\phi\left(\frac{\varepsilon_i}{\sigma}\right)d\varepsilon_i.$$

The log likelihood function is then the sum of the logs of the terms. Parameters to be estimated are $\boldsymbol{\gamma}$ in the probit equation, $\boldsymbol{\beta}$ in the Poisson conditional mean function, ρ and σ. The integrals are computed using Gauss-Hermite quadrature. Further details on the method may be found in Section R26.7 and in Greene (2011). Partial effects are obtained as the derivatives of the expected conditional mean function,

$$E(y_i \mid \mathbf{x}_i) = \int_{\varepsilon_i} \left[\Phi_i^1(\varepsilon_i)\lambda(\varepsilon_i)\right]\frac{1}{\sigma}\phi\left(\frac{\varepsilon_i}{\sigma}\right)d\varepsilon_i.$$

This function and its derivatives are also computed using Hermite quadrature.

E43.3 An Incidental Truncation Model

Winkelmann (1997, pp. 112-113) describes a model (attributed to Crepon and Duguet (1995)) which is labeled the 'incidental truncation' model. This is a case in which the binary variable is correlated with the Poisson outcome, and directly affects it, in a form similar to the ZIP models discussed below. In this model, the data are observed when $z_i = 0$, but $z_i = 0$ implies that $y_i = 0$. The difference between this and the ZIP model is the correlation between the two latent disturbances. The structure is actually a small modification of the model we have considered above.

$$z_i^* = \boldsymbol{\gamma}'\mathbf{w}_i + u_i \text{ in which } u_i \sim N[0,1],$$

$$z_i = \mathbf{1}(z_i^* > 0).$$

Thus, a probit model applies to the indicator, z_i. The following applies to the observed y_i:

y_i^* ~ Poisson $(\lambda_i|\varepsilon_i)$ is a latent variable distributed as Poisson

$\lambda_i|\varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i)$

$y_i = y_i^*$ and $\mathbf{x}_i$ are observed when $z_i = 1$.

$y_i = 0$ when $z_i = 0$, $\mathbf{x}_i$ is still observed when $z_i = 0$.

For the sample selection model, the joint density of the observed response variables y_i and z_i is of the form

$$\mathbf{1}(z_i = 1)\times\{\text{Prob}(z_i = 1) \times \text{Poisson probability}\} + \mathbf{1}(z_i = 0)\times\text{Prob}(z_i = 0)$$

while for the incidental truncation model, the joint density is of the form

$$\text{Prob}(z_i = 1) \times \text{Poisson probability} + \mathbf{1}(z_i = 0)\times\text{Prob}(z_i = 0)$$

This model is requested by adding

; All

to the **POISSON** command given earlier. All other aspects are the same.

E43.4 Endogenous Treatment Effect

The endogenous treatment is a modification of the selection model in which the 'selection' equation is replaced with a treatment equation,

$$z_i^* = \boldsymbol{\gamma}'\mathbf{w}_i + u_i \text{ in which } u_i \sim N[0,1],$$
$$z_i = \mathbf{1}(z_i^* > 0).$$

A probit model applies to the treatment indicator, z_i. The following applies to the observed y_i:

$$y_i^* \sim P(\lambda_i|\varepsilon_i) \text{ is a latent variable distributed as Poisson or negative binomial}$$
$$\lambda_i|\varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \theta z_i + \varepsilon_i), \text{ where } \varepsilon_i \sim N[0,\sigma^2] \text{ and } \text{corr}(\varepsilon_i,u_i) = \rho.$$

The treatment dummy variable appears in the conditional mean function of the count variable. The endogeneity of the treatment effect is induced by the correlation of ε_i and u_i.

This model is requested with

```
PROBIT       ; Lhs = ... ; Rhs = ... ; Hold $
POISSON      ; Lhs = ..  ; Rhs = ... , z
or NEGBIN    ; Selection ; MLE
             ; Treatment $
```

The command differs from the selection model by the appearance of z in the Rhs of the count model and in the addition of **; Treatment** in the command.

The example below continues the application of the selection model in Section E43.2.1.

```
PROBIT       ; Lhs = addon
             ; Rhs = one,age,female,married,hhkids ; Hold $
POISSON      ; Lhs = docvis
             ; Rhs = one,age,female,hsat,addon
             ; Selection ; MLE ; Treatment $
```

E43.5 Poisson Models with Underreporting

We consider two models for underreporting in count data. The basic formulation is as follows: The observed count y_i is assumed to be the sum of J indicators of whether an event that occurred was reported or not. Thus, suppose that an event occurs at instant j, and c_j is an indicator, 0 or 1, that the event is counted in the total. Thus, $y_i = \Sigma_j c_j$. The probability distribution associated with y_i is induced by the underlying probability that c_i is 1. We consider several models of underreporting, based on probit and logit models, and based on exogenous or endogenous reporting.

The Poisson model with underreporting is developed in Winkelmann (1996) and Winkelmann and Zimmermann (1993). The underlying logic is that the Poisson count, Y, is the result of recording of Y individual events, y_j. In the standard model, if c_i is an indicator that the ith event that happens is actually recorded, then, the probability that c_i equals one is 1.0. But, suppose that c_i is a binary variable determined by a binary process, such that

$$c_i^* = \boldsymbol{\gamma}'\mathbf{z}_i + u_i$$

$$c_i = 1 \text{ iff } c_i^* > 0,$$

where $\boldsymbol{\gamma}$ is a parameter vector, $\mathbf{z}_i$ is a covariate vector, and u_i is a disturbance. If u_i is normally distributed, this is a probit model. The authors show that with this form of underreporting in the Poisson model,

$$\text{E}[y_i \,|c_i\,] = P_i^* \text{ E}[y_i\,]$$

where $P_i = \text{Prob}[c_i = 1]$

and $E[y_i]$ = the mean of the underlying Poisson variable.

In the probit case, $P_i = \Phi(\boldsymbol{\gamma}'\mathbf{z}_i)$ where $\Phi(.)$ is the standard normal CDF.

We also allow a logistic model, with $P_i = \Lambda(\boldsymbol{\gamma}'\mathbf{z}_i)$.

The basic underreporting model, is a Poisson regression model with

$$\text{E}[y_i \mid \mathbf{x}_i,\mathbf{z}_i\,] = \exp[\,\boldsymbol{\beta}'\mathbf{x}_i\,]F(\boldsymbol{\gamma}'\mathbf{z}_i)$$

where $F(.)$ may be specified as either a probit or logit equation. The model commands for this model are

POISSON ; Lhs = y ; Rhs = x ; Rh2 = z $

and **POISSON ; Lhs = y ; Rhs = x ; Rh2 = z ; Logit $**

The other options for this model are the same as for the standard Poisson model, including **; Partial Effects**, the output controls for fitted values and residuals, display of technical output, controls of the optimization method, and restrictions, which can be imposed with

; Rst = specification

or **; CML: specification**

In both cases, the parameter vector being estimated is $[\boldsymbol{\beta}, \boldsymbol{\gamma}]$.

E43.5.1 Heterogeneity and Exogenous Underreporting

The model of the previous section can be converted to one with exogenous underreporting by adding unobserved heterogeneity to the Poisson model. The full structure becomes

$$c_i^* = \boldsymbol{\gamma}'\mathbf{z}_i + u_i$$

$$c_i = 1 \text{ iff } c_i^* > 0,$$

$$E[y_i \mid c_i, \varepsilon_i] = P_i^* \, E[y_i \mid \varepsilon_i]$$

where $P_i = \text{Prob}[c_i = 1]$

$E[y_i \mid \varepsilon_i]$ = the mean of the underlying Poisson variable

$$E[y_i \mid \mathbf{x}_i, \mathbf{z}_i, \varepsilon_i] = \exp[\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i] \, F(\boldsymbol{\gamma}'\mathbf{z}_i)$$

At this point we assume that the correlation between ε_i and u_i equals zero. This model is requested by the command

POISSON ; Lhs = y ; Rhs = x ; Het ; Rh2 = z ; No Correlation $

(As before, **; Logit** may be specified.) The last specification is provided to restrict the model to the exogeneity case – the more general model is presented just below.

An alternative model with exogenous underreporting is Winkelmann's Poisson/Logit model, which replaces the probit reporting equation with a logit reporting equation. The resulting model is

$$E^{**}[Y_i \mid \varepsilon_i] = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i) \times 1 / \{1 + \exp[-\boldsymbol{\gamma}'\mathbf{z}_i]\}$$

This model is requested with

POISSON ; Lhs = y ; Rhs = x ; Heterogeneity ; Rh2 = z ; Logit $

This model is a modification of the heterogeneity model presented in Section E42.4. Estimation is done by the same quadrature method. This model merely changes the form of the conditional mean function.

E43.5.2 Endogenous Underreporting

The most general form of this class of models is the model with endogenous underreporting. This model is obtained by relaxing the restriction that the correlation between the heterogeneity and the latent effect in the binary choice model is zero. Winkelmann shows that the resulting distribution is a modification of our heterogeneity model in the previous section. We begin with the same specification:

$$c_i^* = \boldsymbol{\gamma}'\mathbf{z}_i + u_i.$$

Write $u_i = E[u_i \mid \varepsilon_i] + h_i = (\rho/\sigma)\varepsilon_i + h_i.$

Then, $\text{Var}[h_i] = (1 - \rho^2).$

The recording event is $c_i \quad = \; 1$ iff $c_i^* > 0$.

We require $\quad P_i|\varepsilon_i \; = \; \text{Prob}[c_i = 1 \mid \varepsilon_i]$

$$= \; \text{Prob}[\boldsymbol{\gamma}'\mathbf{z}_i/\sqrt{1-\rho^2} \;+\; \{(\rho\sigma)/\sqrt{1-\rho^2}\,\}\varepsilon_i \;+\; v_i \;>\; 0]$$

where $v_i = h_i \,/\, \sqrt{1-\rho^2}$ has standard normal distribution. Let $\theta = (\rho\sigma)/\sqrt{1-\rho^2}$ and $\boldsymbol{\delta} \;=\; \boldsymbol{\gamma}/\sqrt{1-\rho^2}$. The conditional probability is now the usual for a probit model,

$$P_i \mid \varepsilon_i \;=\; \Phi[\boldsymbol{\delta}'\mathbf{z}_i + \theta\varepsilon_i].$$

Returning to the Poisson model,

$$\text{E}[y_i \mid c_i, \varepsilon_i] \;=\; P_i|\varepsilon_\text{i} \times \text{E}[y_i \mid \varepsilon_i]$$

where we have denoted

$$\text{E}[y_i \mid \varepsilon_i] \;=\; \text{the mean of the underlying Poisson variable.}$$

Combining terms, we have

$$\text{Prob}[Y_i = j \mid \text{x}_i, \mathbf{z}_i, \varepsilon_i] \;=\; \exp(-E^*[Y_i \mid \varepsilon_i\,]) \times \{\text{E}^*[\,Y_i \mid \varepsilon_i]\}^j \,/\, j!,$$

where $\quad \text{E}^{**}[\,Y_i \mid \varepsilon_i] \;=\; \exp[\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i] \times \Phi[\boldsymbol{\delta}'\mathbf{z}_i + \theta\varepsilon_i],$

$$\boldsymbol{\delta} \;=\; \boldsymbol{\gamma} \,/\, (1 - \rho^2)^{\,1/2} \;\text{ and }\; \theta \;=\; \rho\sigma \,/\, \sqrt{1-\rho^2}\;.$$

and ρ is the correlation between ε_i and u_i. That is, the endogenous underreporting changes the mean of the Poisson distribution. As before, estimation is carried out by integrating u_i out of the conditional distribution. A nonzero value of ρ produces the endogeneity of the reporting.

This model is requested simply by adding

; Rh2 = variables in z(i) ; Het

to the Poisson model, so the full command is

POISSON ; Lhs = y ; Rhs = ... x ; Rh2 = ... z ; Het $

The additional parameters estimated are scalar coefficient ρ and coefficient vector $\boldsymbol{\gamma}$. For purposes of starting values and fixed value/equality restrictions, the coefficient vector in this model is $[\boldsymbol{\beta} \quad \boldsymbol{\gamma} \quad \rho \quad \sigma]$. Thus, you should use

; Start = list of values for $\boldsymbol{\beta}, \boldsymbol{\gamma}, \rho, \sigma$,
and/or **; Rst** = list of specifications for $\boldsymbol{\beta}, \boldsymbol{\gamma}, \rho, \sigma$

Other results for this model are the same as for the heterogeneity model, including parameter estimates, predicted values, marginal effects, etc. An application below illustrates.

E43.6 Zero Inflation Models for Counts

In some settings, the zero outcome of the count data model represents a sort of partial observability. Consider, for example, one's answer to a survey question about utilization of a sport fishing site within a recent period. The answer, 'zero' could arise from two underlying responses. If the individual is not a participant in this sport, they would always answer zero. If they are, however, then the zero may be just the number of times they used the site *in the particular period,* and the response might be some positive number in another period.

- $Y = 0$ happens to be the number of times the individual used that facility in the survey period. At some other time, the same individual might choose $Y = j > 0$.

- $Y = 0$ occurs because the individual would never use the facility, regardless of the characteristics that appear in the model.

If so, then fitting a simple Poisson model (or negative binomial) to these data would overstate ('inflate') the theoretical probability of zero in the Poisson model. The Poisson model may not accurately assign probability to the outcome $Y = 0$, if a separate process is simultaneously at work influencing this outcome. An alternative formulation for these data that might be more appropriate is the 'Zero Inflated Poisson' (ZIP) model:

$$z = 0 \text{ if the response would always be 0, 1 if a Poisson model applies,}$$

$$y = \text{the response from the Poisson model,}$$

$$zy = \text{the observed response.}$$

Then, the probabilities of the various outcomes are

$$\text{Prob}[y = 0] = \text{Prob}[z = 0] + \text{Prob}[z = 1]\times\text{Prob}[y = 0 \mid \text{Poisson}]$$

$$\text{Prob}[y = \text{j} > 0] = \text{Prob}[z = 1] \times \text{Prob}[y = j \mid \text{Poisson}].$$

Another clearly defined example is provided by Lambert (1992) in which the observed outcome is the number of defective items produced by a production process. If the process is 'in control,' the number will be zero, by definition. If the process is 'not in control,' the sampled count might be zero or some positive value, depending partly on sampling variability. As one more alternative, consider the number of children reported by a survey respondent. The response 0 *yet* is different from the response 0 *and none planned*.

The ZIP model is based on construction of a model for z, such as the probit model, which is then integrated into the count data settings (Poisson and negative binomial) discussed above. We allow several different formulations for the model. (See Lambert (1992) and Greene (1994).) The ZIP model is also extended to some of the other variants of the model, including the underreporting model and the semiparametric random effects model.

The ZIP model is, using our own notation (not Lambert's),

$$Y_i = 0 \text{ with probability } q_i$$

$$Y_i \sim \text{Poisson}(\lambda_i) \text{ with probability } 1 - q_i$$

so that

$$\text{Prob}[Y_i = 0] = q_i + [1 - q_i]R_i(0)$$

$$\text{Prob}[Y_i = j > 0] = [1 - q_i]R_i(j)$$

where

$$R_i(y) = \text{the Poisson probability} = e^{-\lambda i}\, \lambda_i^{\,yi} \;/\; y_i!$$

and

$$\lambda_i = e^{\boldsymbol{\beta}'\mathbf{x}i}.$$

We allow four formulations of the ancillary, state probability, q_i,

$$q_i \sim \text{Logistic}[v_i]$$

and

$$q_i \sim \text{Normal}[v_i].$$

Let $F[v_i]$ denote either the normal or logistic CDF. Then, v_i may be defined in two ways. First,

$$v_i = \tau\log[\lambda_i] = \tau\boldsymbol{\beta}'\mathbf{x}_i$$

which defines a single new parameter (which may be positive or negative). This is labeled the ZIP(τ) model in the following. The alternative model is

$$v_i = \boldsymbol{\gamma}'\mathbf{z}_i$$

for a parameter vector $\boldsymbol{\gamma}$ and set of variables $\mathbf{z}_i$ which may or may not share variables with $\mathbf{x}_i$. Note that if $\mathbf{z}_i$ equals $\mathbf{x}_i$, the two models are still not the same since even if so, the second allows a full set of new parameters. An excellent reference on this model, albeit with a somewhat narrower focus on the choice aspects of the model than we consider, is Lambert (1992). Another related source is Mullahy (1986). Finally, Greene (1994) presents the theory upon which the ZIP estimator and selectivity estimator described earlier are based.

The same formulations are provided for the negative binomial model, which has

$$R_i(j) = \Gamma(\theta+y_i)/[y_i!\Gamma(\theta)]\; u_i^{\theta}\; [1 - u_i]^{\,yi}$$

$$\theta = 1/\alpha, \text{ where } \alpha \text{ is the overdispersion parameter}$$

$$u_i = \theta / [\theta + \lambda_i].$$

and the gamma count model,

$$R_i(j) = G(\alpha j, \lambda_i) - G(\alpha j + \alpha, \lambda_i)$$

where

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i) \text{ (as usual)}$$

$$G(\alpha j, \lambda_i) = 1 \text{ if } j = 0, \text{ or } \frac{1}{\Gamma(\alpha j)}\int_0^{\lambda_i} u^{\alpha j-1}e^{-u}du \text{ if } j > 0,\ j = 0,1,...$$

The ZIP model extends the Poisson model in a few different directions. First, of course, the altering of the zero probability will be useful in some settings. In addition, the changed zero probability induces a divergence between the mean and variance of the distribution. For the Poisson model, define the indicator $d_i = 1$ if state 1, y_i always = 0 and $d_i = 0$ if state 2, y_i produced by the Poisson process. Thus, $q_i = \text{Prob}[d_i = 1]$. Then,

$$E[y_i] = q_i 0 + (1 - q_i)\lambda_i = (1 - q_i)\lambda_i$$

and

$$\begin{aligned}\text{Var}[y_i] &= E_{di}[\text{Var}[y_i \mid d_i]] + \text{Var}_{di}[E[y_i \mid d_i]] \\ &= [q_i 0 + (1 - q_i)\lambda_i] + [q_i(0 - (1 - q_i)\lambda_i)^2 + (1 - q_i)(\lambda_i - (1 - q_i)\lambda_i)^2] \\ &= \lambda_i(1 - q_i)[1 + \lambda_i q_i] > E[y_i].\end{aligned}$$

As such, the ZIP specification induces overdispersion, though it arises from a different source than is assumed in the familiar treatments in the literature.

It will be useful to test for the overdispersion. However, there will be a problem distinguishing the ZIP model from an underlying negative binomial specification as the source of the overdispersion. In particular, recall for the negative binomial model that

$$\text{Var}[y_i]/E[y_i] = 1 + \alpha E[y_i].$$

In the ZIP model, we have that

$$\text{Var}[y_i]/E[y_i] = 1 + [q_i/(1-q_i)]E[y_i],$$

which is quite similar. The testing procedure is complicated by the fact that the ZIP model is not nested within either the Poisson or the negative binomial models. That is, the restriction which produces the simpler model is $q_i = 0$, which is not a simple parametric restriction. In order to make $q_i \to 0$, it is necessary for some parameter to $\to +\infty$ or $-\infty$. Vuong (1989) has proposed a test statistic for nonnested models which appears to have some power to distinguish between non-Poissonness due to the overdispersion of the negative binomial model and the force of the splitting mechanism in the ZIP part of the model. The statistic is

$$V = \sqrt{n}\,\overline{m}/s_m$$

where

$$m_i = \log[f_1(y_i)/f_2(y_i)],$$

$f_1(\bullet)$ and $f_2(\bullet)$ are densities for the competing models, and $\overline{m}$ and s_m are the sample mean and standard deviation for the sample of m_is. Asymptotically, the statistic is distributed as standard normal, so its value may be compared to the critical value from the standard normal distribution, e.g., 1.96. The test is directional; large positive values favor f_1 while large negative values favor f_2. The Vuong test is included in the standard output for the ZIP models. (See the application below.)

E43.6.1 Commands for the ZIP Models

The basic model command for the Poisson/ZIP(τ) is

POISSON ; Lhs = ... ; Rhs = ...
or NEGBIN ; ZIP $

This uses the logistic splitting distribution. For the model, with normally distributed splitting rule, add

; ZIP = normal

to the command. Once again, this requests the τ form of the model, $z_i = \tau\boldsymbol{\beta}'\mathbf{x}_i$. To request the second form, with an independent model for the regime split, simply add to the command

; Rh2 = the variables in z

Note that the presence of **; ZIP** in the command is the essential switch. If this is omitted, the default Poisson model is estimated. The **NEGBIN ; ZIP ; …** combination is often called the ZINB or ZINB(τ) in the recent literature. Other model frameworks available for this model are

; Model = Gamma

for the gamma model and

; Model = GP1 or GP2 or GPP

for the generalized Poisson model. The generalized Poisson model does not provide the τ format. If you do not include **; Rh2 = list** for the generalized Poisson model, the program substitutes **; Rh2 = one**. The preceding provides 14 different specifications for the zero inflation model (four models, τ or not, logistic or normal, lead to the τ forms for the generalized Poisson).

NOTE: Censoring, truncation and sample selection are not supported in this model.

If you wish to give starting values and/or fixed value and equality constraints, specify them for the ZIP model with parameter vector [$\boldsymbol{\beta}$,τ] for the ZIP(τ) model or [$\boldsymbol{\beta},\boldsymbol{\gamma}$] for the ZIP model. For the ZINB(τ), ZINB, and the gamma models, the extra parameter, θ for the negative binomial model and P for the gamma model follows $\boldsymbol{\beta}$ in the list. The generalized Poisson has yet another parameter, the P = 1 or 2 or free. If you choose the ZIP form, $\boldsymbol{\gamma}$ will be the last set of parameters in the list (and in the displayed output). Note, once again, you provide θ, not α for the negative binomial model. The options

; Start = list of starting values
and **; Rst = constraints**
or **; CML: specification of constraints**

may be used freely with these models. Do note that because of a difference in the order of magnitude, equality constraints forcing elements of $\boldsymbol{\gamma}$ to equal elements of $\boldsymbol{\beta}$ will probably produce very poor results.

All other options for the Poisson and negative binomial models are available, including

; Keep = name

to save the conditional mean, $E[y_i] = (1 - q_i)\lambda_i$,

; Res = name

to save the residual, and

; Prob = name

to save the probability associated with the observed outcome,

$$\text{Prob}[Y_i = 0] = q_i + [1 - q_i]R_i(0)$$
$$\text{Prob}[Y_i = j > 0] = [1 - q_i]R_i(j).$$

All other options for nonlinear optimization listed earlier are also supported. You may also request

; Partial Effects

as usual. The computed marginal effects are the derivatives of the conditional mean function shown above, which are computed using

$$\frac{\partial E[y_i \mid \mathbf{x}_i, \mathbf{z}_i]}{\partial \mathbf{x}_i} = (1 - q_i)\lambda_i \boldsymbol{\beta} - \lambda_i \frac{\partial q_i}{\partial \mathbf{x}_i}$$

The second part of the marginal effect will vary depending on the model. There are four forms for the normal or logistic models and the linear form, $\boldsymbol{\gamma}'\mathbf{z}_i$ and the τ form $\tau\boldsymbol{\beta}'\mathbf{x}_i$. For convenience, assume that $\mathbf{z}_i = \mathbf{x}_i$. (Otherwise, this applies to any variables that $\mathbf{z}_i$ and $\mathbf{x}_i$ have in common.). The splitting probability is either the logistic CDF, $\Lambda(.)$, which has density $q_i'(.) = \Lambda(.)[1-\Lambda(.)]$, or the normal CDF, $\Phi(.)$ which has density $q_i'(.) = \phi(.)$. Assembling the parts gives

$$\frac{\partial q_i}{\partial \mathbf{x}_i} = q_i' \times \boldsymbol{\delta}$$

where $\boldsymbol{\delta} = \boldsymbol{\gamma}$ for the linear form or $\boldsymbol{\delta} = \tau\boldsymbol{\beta}$ for the τ form. The computation of the marginal effects accounts for the splitting effect and for any overlap between the variables in the splitting model and in the base Poisson or negative binomial model. An example appears below.

NOTE: Because the terms in the marginal effect enter with different signs, it is possible for the marginal effect of a variable to have the opposite sign from the corresponding coefficient in the Poisson regression. This is likely to occur in samples which have a very large proportion of zeros, since in this case, the q_i is likely to be quite large.

E43.6.2 ZIP Models with Latent Heterogeneity

The Zero Inflated Poisson model is extended to allow normal heterogeneity in the regression. Thus, in the model,

$$\text{Prob}[y_i = 0] = [1 - q_i]\text{R}[\,\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, 0\,] + q_i,$$

$$\text{Prob}[y_i = j] = [1 - q_i]\text{R}[\,\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, j\,],\ j > 0$$

where R[.] is the Poisson probability with mean function exp[$\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i$,] and q_i is the regime splitting model described above. The same four forms of the model for q_i are available, logistic and normal (probit) for the distribution and linear or τ for the argument of the regime probability.

The basic model command is

POISSON ; Lhs = y ; Rhs = ... ; ZIP ; Het ; ... $

The different forms of the splitting model are the ZIP(τ) form, in which

$$q_i = F[\,\tau\,\boldsymbol{\gamma}'\mathbf{z}_i\,]$$

and the ZIP form $q_i = F[\boldsymbol{\gamma}'\mathbf{z}_i\,]$

and F(.) may be either a probit or logit equation. The ZIP(τ) forms are requested with

POISSON ; Lhs = y ; Rhs = x ; Heterogeneity ; ZIP ; ...$
and **POISSON ; Lhs = y ; Rhs = x ; Heterogeneity ; ZIP ; Logit ; ...$**

The default form is the probit model, and **; Logit** requests the logit model instead. (Note that this reverses the default in the model without heterogeneity, where logit is the default.) The ZIP forms are requested with the **; Rh2 = ...** specification,

POISSON ; Lhs = y ; Rhs = x ; Rh2 = z ; Heterogeneity ; ZIP $
and **POISSON ; Lhs = y ; Rhs = x ; Rh2 = z ; Heterogeneity ; ZIP ; Logit $**

NOTE: This model does not extend to the negative binomial, gamma or GP models. Each of these already accounts for heterogeneity and overdispersion, so adding this feature to a model which already has heterogeneity and excess zeros greatly overspecifies the model. The estimation process will break down in these instances.

E43.6.3 A ZIP Model with Endogenous Zero Inflation

Finally, a model with an endogenously determined splitting model would be

$$q_i = \Phi[\,\boldsymbol{\gamma}'\mathbf{z}_i + u_i]$$

$$\text{Prob}[y_i = 0] = [1 - q_i]\text{R}[\,\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, 0\,] + q_i,$$

$$\text{Prob}[y_i = j] = [1 - q_i]\text{R}[\,\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, j\,],\ j > 0$$

and u_i is correlated with ε_i. This model is requested with

POISSON ; Lhs = y ; Rhs = x ; Rh2 = z
; Het ; ZIP ; Correlation $

There is only one form for this model, the **POISSON ; Zip = normal**, index model with latent heterogeneity correlated with the latent effect in the splitting equation.

E43.6.4 Output for the ZIP Models

The ZIP models begin with the full set of output for the underlying model, Poisson or negative binomial. If you request it with **; OLS**, this will include the initial OLS results, the Poisson regression model, if requested, the negative binomial model, then, finally, the results for the ZIP model. The initial Poisson and, if requested, negative binomial model(s) will be fit ignoring any constraints in order to obtain starting values. The final output presents the table of statistical results for the estimated coefficients. The Poisson or negative binomial parameters will be followed by the parameter(s) for the splitting model. The leading diagnostics table contains a number of related statistics. A table gives the following comparison of the original model and the zero altered model:

Estimates of prob[$Y = 0 \mid \mathbf{x}$ = sample means],
Number of zero observations, actual and predicted using $N\times$Prob[Y=0],
Log likelihood.

Note that although in most cases, the log likelihood function for the zero inflated model will exceed that for the unaltered model, the two values are not comparable because the base model is not obtainable from the ZIP model by restricting the coefficients in the latter. Finally, Vuong's statistic is presented.

The saved results from the ZIP model are:

Matrices:	*b* and *varb*	
	zaptau =	the parameters of the splitting model, τ or $\boldsymbol{\gamma}$
Scalars:	*ybar* and *sy*	for the Lhs variable
	nreg and *kreg*	for the estimated model
	exitcode	
	alpha and *varalpha*	for an estimated negative binomial model
	tau and *vartau*	if you fit the ZIP(τ) model
Last Model:	*b_variable*	for the Poisson or negative binomial model
	alpha	if you fit the negative binomial model
	c_variable	for the ZIP model, the coefficients on the Rh2 variables

Last Function: Conditional mean, $(1 - q_i)\lambda_i$.

E43.6.5 Application

To illustrate the model, we have fit the least elaborate Poisson specification, then the same model using the generalized Poisson (P) format.

E43.6.6 Technical Details

To formulate the log likelihood and gradient for the ZIP models, let

$$q_i = F(\boldsymbol{\gamma}'\mathbf{z}_i) \text{ for the ZIP models}$$

and

$$q_i = F(\tau\boldsymbol{\beta}'\mathbf{x}_i) \text{ for the ZIP}(\tau) \text{ model,}$$

where $F(t)$ is either the cumulative normal probability, $\Phi(t)$, for the probit model or the cumulative logistic probability, $\Lambda(t)$ for the logit model. Let $f(t)$ denote either the Poisson(λ_i), the negative binomial (λ_i,θ) or the gamma (λ_i,P) probability density function. (This produces 12 possible models.) Then, the probability density function for the observed random variable, y_i, is

$$p(y_i) = p_i = (1 - q_i)f(y_i) + \mathbf{1}(y_i = 0)q_i,$$

so, the log likelihood is simply

$$\log L = \Sigma_i \log p(y_i).$$

To obtain the gradient, let $\boldsymbol{\beta}^*$ equal either $\boldsymbol{\beta}$ for the Poisson model, ($\boldsymbol{\beta}$,θ) for the negative binomial model or ($\boldsymbol{\beta}$,P) for the gamma model. Then, each term in

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}*} = \Sigma_i (\partial \log p_i/\partial \boldsymbol{\beta}^*)$$

is

$$\frac{\partial \log p_i}{\partial \boldsymbol{\beta}*} = (1/p_i)[(1 - q_i)f(y_i)\{\partial \log f(y_i)/\partial \boldsymbol{\beta}^*\} + \{\mathbf{1}(y_i = 0) - f(y_i)\}\{\partial q_i/\partial \boldsymbol{\beta}^*\}].$$

The derivatives of log$f$(y_i) were given earlier.

NOTE: These derivatives are approximated numerically for the gamma model.

The cross derivatives, $\partial q_i/\partial \boldsymbol{\beta}^*$ will equal **0** in the ZIP model, or $\tau \mathbf{x}_i q_i'$ for the ZIP(τ) model with a trailing zero for θ or P if $f(y_i)$ is the negative binomial or gamma model, since these parameters do not enter q_i. (The inner derivative, q_i', is either the standard normal density, ϕ_i for the probit model, or $\Lambda_i(1-\Lambda_i)$ for the logit model.) Finally, the parameters of the ZIP model are either $\boldsymbol{\gamma}$, a vector, in the ZIP model or τ, a scalar, in the ZIP(τ) model. Denoting these generically as $\boldsymbol{\gamma}$, we have

$$\partial \log p_i/\partial \boldsymbol{\gamma} \;=\; [\mathbf{1}(y_i = 0)](q_i'/p_i)(\boldsymbol{\beta}'\mathbf{x}_i)$$

for the ZIP(τ) model. For the ZIP model, $\boldsymbol{\beta}'\mathbf{x}_i$ is replaced with $\mathbf{z}_i$, the vector of covariates. The second derivatives are fairly complicated, but in *LIMDEP*'s implementation, the BHHH estimator is used, instead, as a convenient expedient.

For the ZIP specification, a natural set of starting values for the parameters is provided by the probit or logit and independent Poisson or negative binomial estimates. (The Poisson values are used to start the gamma model.) In the ZIP(τ) case, the Poisson or negative binomial model can be used for the regression parameters. One could then choose a value for τ which would produce approximately the correct probability for zero. An alternative possibility would be to estimate τ by fitting a probit or logit model to the binary indicator $\mathbf{1}(y_i = 0)$ with the single covariate equal to the Poisson estimates of $\boldsymbol{\beta}'\boldsymbol{x}_i$ (only to get the right sign and approximately the right magnitude on τ; this is not a consistent estimator). Save for a few badly identified cases found by experimentation in which no solution could be found, convergence of the DFP or Broyden algorithms appears to be routine for these models.

E43.7 Hurdle Models

A case related to the ZIP model is known as the hurdle model. Hurdle models arise when the 'zero or positive' decision is different from the count decision. One can think in terms of two decisions – the health care utilization data examined in the previous chapter provides a good example. One decision is whether to 'be a participant.' This is equivalent to a decision as to whether the count will be zero or positive. The second decision is how many, given that the count will be positive. In the health care utilization case, we can consider two types of individuals, those who do not intend to visit a doctor or the hospital and those who do. For the latter, the observed count is the number of visits, given that the number of visits will be positive. The formal model is

z = 0 if the response will be zero, 1 if the response will be positive

y = the count of occurrences given that the count will be positive.

This model consists of two parts, which may be dependent or independent:

Prob[z = 0 or 1|$\mathbf{x}_i$] = a probit or logit model

Prob[y = j | y > 0|$\mathbf{x}_i$] = a count data model with truncation at zero.

An alternative approach to the excess zeros case is the hurdle model presented by Mullahy (1986) and Creel and Loomis (1990). (A complete description may be found in Winkelmann (2000).) Logically, the model arises from two simultaneous process. The first is a 'hurdle,' in which the individual 'decides' whether y will equal zero or some value greater than zero. The second is a conditional count model in which the number of occurrences is conditional on that number being positive. The hurdle model is very similar to the ZIP model:

$$\begin{aligned}\text{Prob}(Y_i = 0) &= f_i(0)\\ \text{Prob}[Y_i = j] &= \frac{1-f_i(0)}{1-P_i(0)}P_i(j),\ j = 1,2,...\\ &= A_i(0)P_i(j)\end{aligned}$$

where $f_i(0)$ is the probability of the zero outcome, $P_i(j)$ is the probability of the nonzero outcomes conditioned on the outcome being greater than zero, and the subscript i indicates dependence on covariates $\mathbf{z}_i$ for f_i and $\mathbf{x}_i$ for P_i. The combination of the two produces the unconditional distribution above. The hurdle model can be assembled from any desired binary choice model and count model.

Let d_i denote a binary indicator of whether the observed count is zero or positive. The log likelihood function separates the probabilities into two simple parts:

$$\begin{aligned}\log L &= \sum\nolimits_{d=0} \log f_i(0)\\ &+ \sum\nolimits_{d=1} \log[1 - f_i(0)] - \log[1 - P_i(0)] + \log P_i(j).\end{aligned}$$

The four terms of the log likelihood partition into two log likelihoods,

$$\begin{aligned}\log L &= \sum\nolimits_{d=0} \log f_i(0) + \sum\nolimits_{d=1} \log[1 - f_i(0)]\\ &+ \sum\nolimits_{d=1} \log P_i(j) - \log[1 - P_i(0)].\end{aligned}$$

The first term is the log likelihood for a binary choice model – probit, logit, complementary log log, etc. (See Chapter E27.) The second part is the log likelihood for a count distribution that is truncated at zero. We have already presented this model in Section E42.2.3. The end result is that the hurdle model can be fit in two simple parts using models already presented. A natural formulation would be the logit binary choice model coupled with the Poisson model for the positive counts. (Mullahy's original presentation of this model suggested an $f_i(0)$ that was a constant – no covariates. This could be obtained in our formulation simply by specifying **; Rhs = one** in the binary choice model.

The hurdle model induces over- or underdispersion in the distribution, but in a nonconstant fashion. Winkelmann presents the following convenient result:

$$\text{Var}_i[Y_i] = \text{E}_i[Y_i] + \frac{1-A_i(0)}{A_i(0)}\{\text{E}_i[Y_i]\}^2$$

where now, the subscript indicates dependence on both $\mathbf{z}_i$ and $\mathbf{x}_i$. Since $A_i(0)$ can exceed one, this model can induce underdispersion. (The mean function and $A_i(0)$ are functionally dependent in such a way that no combination of parameters produces a negative variance.) Underdispersion occurs if zeros are less frequent than the parent (Poisson or negative binomial) model would predict.

The conditional mean in this model can be obtained by making convenient use of the fact that the sums from one to infinity are the same if the zero outcome is included. This produces the conditional mean function

$$\mathrm{E}_i[Y_i] \quad = \quad \frac{1 - f_i(0)}{1 - P_i(0)}\lambda_i\,,$$

where $\lambda_i \quad = \quad \exp(\boldsymbol{\beta}'\mathbf{x}_i)$

and $P_i(0) \quad = \quad \exp(-\lambda_i)$ for the Poisson model and

$= \; [\theta/(\theta + \lambda_i)]^\theta$ for the negative binomial model.

The marginal effects obtained by differentiation, after a bit of algebra and collecting terms, are

$$\frac{\partial E_i[Y_i]}{\partial \mathbf{x}_i} \quad = \quad \frac{1 - f_i(0)}{1 - P_i(0)}\lambda_i\,\boldsymbol{\beta} \times \left(1 + \frac{\lambda_i}{1 - P_i(0)}\frac{\partial P_i(0)}{\partial \lambda_i}\right).$$

The latter derivatives are

$$\frac{\partial P_i(0)}{\partial \lambda_i} \quad = \quad -P_i(0) \;\text{ for the Poisson model and}$$

$$= \; -\,[P_i(0)]^{(\theta+1)/\theta}.$$

(The Poisson model results when $\theta \rightarrow \infty$ so the results are consistent.) Finally,

$$\frac{\partial E_i[Y_i]}{\partial \mathbf{z}_i} \quad = \quad \frac{-1}{1 - P_i(0)}\lambda_i \times \frac{\partial f_i(0)}{\partial \mathbf{z}_i}.$$

The three cases supported here are

logit: $f_i(0) \; = \; \Lambda(-\boldsymbol{\delta}'\mathbf{z}_i)$, $\quad \dfrac{\partial f_i(0)}{\partial \mathbf{z}_i} \; = \; -\Lambda(-\boldsymbol{\delta}'\mathbf{z}_i)[1 - \Lambda(-\boldsymbol{\delta}'\mathbf{z}_i)]\,\boldsymbol{\delta}$

probit: $f_i(0) \; = \; \Phi(-\boldsymbol{\delta}'\mathbf{z}_i)$, $\quad \dfrac{\partial f_i(0)}{\partial \mathbf{z}_i} \; = \; -\phi(-\boldsymbol{\delta}'\mathbf{z}_i)\,\boldsymbol{\delta}$

complementary log log: $f_i(0) \; = \; \exp(-\exp(\boldsymbol{\delta}'\mathbf{z}_i)) \; = \; \exp(-\gamma_i)$, $\quad \dfrac{\partial f_i(0)}{\partial \mathbf{z}_i} \; = \; -\gamma_i f_i(0)\,\boldsymbol{\delta}$

(The third of these, suggested by Mullahy (1986) is convenient as it allows a straightforward test of hurdle effects against the Poisson null, which is nested. In the other two models, the Poisson model is not nested, so the test is less convenient. See below for details) Finally, when the regime model and the count model have variables in common, the two effects are added.

Hurdle models can be fit with a single instruction rather by fitting the parts separately. The command is

POISSON ; Lhs = dependent variable
; Rhs = independent variables
; Hurdle $

In this base case

- the count model is assumed to be Poisson,
- the hurdle equation is assumed to be logistic,
- variables that enter the hurdle equation are the same as in the Poisson equation.

Several alternative specifications may be chosen: Use

; Model = Negbin

(or change the command to **NEGBIN**) for the negative binomial count model

Use **; Normal** for the probit model
; Cloglog for the complementary log log model. (See below.)

Use **; Rh2 = list of variables** to specify the variables in **z** explicitly.

Other specifications, including

; Keep = name	to retain fitted values (using conditional mean)
; Res = name	to retain residuals
; Prob = name	to retain predicted probabilities for observed outcomes
; List	to display predictions, residuals, etc.
; Output = value	to control technical output during iterations
; Partial Effects	
; Test: spec	to define Wald tests
; Rst = list	to specify fixed value and equality restrictions
; CML: spec	to define a constrained maximum likelihood estimator

and so on, are all available as in other count models already discussed.

The estimation results saved by this estimator are as usual:

Matrices: *b* = coefficient vector – this will be all parameters, including θ if the negative binomial model is fit
varb = asymptotic covariance matrix

Scalars: *logl* = scalar log likelihood
nreg = number of observations
kreg = number of variables in *x* - does not include *z*.

Last Function: hurdle conditional mean function

E43.7.1 Testing for Hurdle Effects

There are two ways to test for hurdle effects in this setting. Under the assumption of a Poisson count model, complementary log log hurdle model, and identical variables in the two equations, the probability which enters the log likelihood becomes

$$\text{Prob}(Y_i = 0) = \exp(-\gamma_i)$$

$$\text{Prob}[Y_i = j] = \frac{1-\exp(-\gamma_i)}{1-\exp(-\lambda_i)}\frac{\exp(-\lambda_i)\lambda_i^{yi}}{y_i!}, j = 1,2,...$$

where $\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$

and $\gamma_i = \exp(\boldsymbol{\delta}'\mathbf{x}_i)$.

In this case, the hurdle model becomes the Poisson model if $\boldsymbol{\delta} = \boldsymbol{\beta}$. Since this is a simple parametric restriction, and the models are nested, a Wald, likelihood ratio, or LM test could be used. Here is an approach:

```
NAMELIST    ; x = the Rhs variables $
CALC        ; k = Col(x) $
POISSON     ; Lhs = ... ; Rhs = x  $
MATRIX      ; bp = b $
CALC        ; lp = logl $
POISSON     ; Lhs = ... ; Rhs = x
            ; Hurdle ; Cloglog $
CALC        ; lh = logl $
MATRIX      ; bh = b ; vh = varb $
```

The next three commands carry out the LM, LR and Wald tests, respectively.

```
POISSON     ; Lhs = ... ; Rhs = x
            ; Hurdle ; Cloglog
            ; Start = bp,bp ; Maxit = 0 $
CALC        ; List ; lrtest = 2*(lh - lp) ; 1 - Chi(lrtest,k) ; Wald = 0 $
MATRIX      ; d = i2’ * bh ; ik = Iden(k) ; ikm = -ik ; i2 = [ik/ikm]
            ; Wald = d’*< i2’[vh]i2>*d $
CALC        ; List ; Wald ; 1 - Chi(Wald,k) $
```

When other forms are used, the models are nonnested. In these cases, the classical testing procedures no longer have the limiting chi squared distributions, and are no longer useable. One possibility is the Vuong statistic for testing the nonnested models that was suggested in the previous section. The statistic is

$$V = \sqrt{n}\,\overline{m} \,/\, s_m$$

where $m_i = \log[f_h(y_i)/fp(y_i)]$,

$f_h(\bullet)$ and $fp(\bullet)$ are densities for the hurdle and Poisson models, respectively, and $\overline{\mathrm{m}}$ and s_m are the sample mean and standard deviation for the sample of m_is. In principle, asymptotically, the statistic is distributed as standard normal, so its value may be compared to the critical value from the standard normal distribution, e.g., 1.96. The test is directional; large positive values favor *fh* while large negative values favor *fp*. We do note that the hurdle model involves an extension of the Poisson model with the addition of additional parameters. As such, intuition suggests that it is unlikely that the test would ever favor the Poisson model. If the intuition is right, then the asymptotic behavior of the statistic may not be as assumed here, and the validity of the test becomes questionable. With that caveat, the following procedure could be used for this test – it is not part of the standard output for the hurdle model:

```
NAMELIST    ; x = the Rhs variables $
POISSON     ; Lhs = ... ; Rhs = x
            ; Prob = fp $
POISSON     ; Lhs = ... ; Rhs = x
            ; Prob = fh
            ; Hurdle ; ... (whatever other specification) $
CREATE      ; mi = Log(fh/fp) $
CALC        ; List ; v = Sqr(n) * Xbr(mi) / Xdv(mi) $
```

E43.7.2 Heterogeneity and Endogeneity

Heterogeneity may be entered into the conditional mean of the count model in the same fashion as the ZIP models. With

; Heterogeneity

The mean function becomes

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i)$$

As before, the log likelihood is now maximized using Hermite quadrature. Results are essentially the same as before, with the additional results related to the distribution of ε_i. The hurdle effect becomes endogenous if ε_i is correlated with u_i in the hurdle equation. Once again, this model parallels the zero inflation model. The model with endogenous hurdle effects is requested with

; Heterogeneity ; Correlated.

E43.7.3 Applications

Like the zero inflation model, there are many different combinations of hurdle equation, count model, heterogeneity and endogeneity. Testing procedures for distinguishing some of them statistically were suggested earlier. The following illustrates two specifications, the base case Poisson with exogenous hurdle effect and the Poisson model with endogenous hurdle effect.

```
SAMPLE    ; All $

E43.7.4 Technical Details

Let d_i denote a binary indicator of whether the observed count is zero or positive. The log likelihood function separates the probabilities into two simple parts:

$$\log L = \sum_{d=0} \log f_i(0)$$

$$+ \sum_{d=1} \log[1 - f_i(0)] - \log[1 - P_i(0)] + \log P_i(j)$$

The four terms of the log likelihood partition into two log likelihoods,

$$\log L = \sum_{d=0} \log f_i(0) + \sum_{d=1} \log[1 - f_i(0)]$$

$$+ \sum_{d=1} \log P_i(j) - \log[1 - P_i(0)]$$

The derivatives for the hurdle model are quite simple. Six mixtures of models are supported. For the hurdle equation, let

$$w_i = \boldsymbol{\delta}'\mathbf{z}_i.$$

Then,

$$f_i(0) = \text{logit model} = \Lambda(-w_i)$$

$$= \text{probit model} = \Phi(-w_i)$$

$$= \text{complementary log log model} = \exp(-\exp(w_i))$$

For the count model,

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$$

$$P_i(j) = \text{Poisson model } (\lambda_i)$$

$$= \text{negative binomial model } (\lambda_i).$$

The necessary terms for differentiation of these functions appear elsewhere in this chapter. The BHHH estimator is used for the estimator of the asymptotic covariance matrix of the MLE. As noted, this model can be estimated in parts, by fitting a binary choice model to the dependent variable obtained as **1**(count > 0) and a truncated (at zero) count model to the observations with nonzero counts. The identical parameter estimates will be obtained if you do so. The advantage here, aside from the simplicity of the combined command, is the ability to impose various restrictions and use different procedures for testing hypotheses.

E44: Panel Data Models for Counts

E44.1 Introduction

This chapter describes estimators for models for counts based on panel data. The basic formulation, once again, is the Poisson regression model. For a discrete random variable, Y, observed frequencies, y_i, $i = 1,...,n$, where y_i is a nonnegative integer count, and regressors $\mathbf{x}_i$,

$$\text{Prob}(Y = y_i) = \frac{\exp(\lambda_i)\lambda_i^{y_i}}{y_i!},\ y_i = 0,1,...;\ \log \lambda_i = \boldsymbol{\beta}'\mathbf{x}_i.$$

In this model, λ_i is both the mean and variance of y_i that is $E[y_i|\mathbf{x}_i] = \text{Var}[y_i|\mathbf{x}_i] = \lambda_i$. The partial effects in this nonlinear regression model are

$$\frac{\partial E[y_i \mid \mathbf{x}_i]}{\partial \mathbf{x}_i} = \lambda_i \boldsymbol{\beta}.$$

The negative binomial regression model is an extension of the Poisson regression model that results from the introduction of a certain kind of unobserved individual heterogeneity into the Poisson model; the negative binomial model arises as a modification of the Poisson model in which the mean is μ_i, respecified so that

$$\log \mu_i = \log\lambda_i + \varepsilon_i = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,$$

where $\exp(\varepsilon_i)$ has a gamma distribution with mean 1.0 and variance α. The resulting unconditional distribution (derived in Section E41.4.5) is

$$\text{Prob}[Y = y_i] = \frac{\Gamma(\theta + y_i)}{\Gamma(\theta)\Gamma(y_i + 1)} u_i^{\theta}(1-u_i)^{y_i},\ u_i = \theta / (\theta + \lambda_i).$$

This model has an additional parameter, $\alpha = 1/\theta$, such that $\text{Var}[y_i] = E[y_i]\{1 + \alpha E[y_i]\}$.

This chapter presents *LIMDEP*'s implementation of panel data models for Poisson and negative binomial regressions. The topics described in this chapter are

- Panel data models
- Commands for estimating panel data models
- Fixed effects models
- Random effects models
- Random parameters models
- Latent class models
- GMM estimators for count models with panel data

E44.2 Panel Data Models for Count Data

The full range of *LIMDEP*'s panel data estimation routines are provided for the Poisson, and negative binomial regression models and for some of the formulations of the zero inflation models.

NOTE: Save for the exceptions explicitly noted below, the panel data treatments are not supported for the gamma model or for the extensions of the count data models, including the sample selection models, and the underreporting models. Limited cases for the heterogeneity models are noted below. The ZIP/Logit and ZINB/Logit models are supported, but the (τ) forms are not.

E44.2.1 Fixed Effects

For the fixed effects case,

$$\log\lambda_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} \;\; (+ \varepsilon_{it} \text{ for the negative binomial model }).$$

The difference here is that the model cannot be fit by least squares using deviations from group means. Two approaches are used instead. One possibility is to use a conditional maximum likelihood approach – the model conditioned on the sum of the observations is free of the fixed effects and has a closed form. This is provided for both Poisson and negative binomial models. A second approach is direct, brute force estimation of the full model including the fixed effects. Neglecting the latent log gamma heterogeneity in the negative binomial model, write the fixed effects model as

$$\log\lambda_{it} = \alpha_i d_{it} + \boldsymbol{\beta}'\mathbf{x}_{it},\; i = 1,...,N,\; t = 1,...,T_i,$$

where α_i is the coefficient on a binary variable, d_i, which indicates membership in the ith group. The panel is assumed to consist of N groups with T_i observations in the ith group. The panel need not be balanced; T_i may vary across groups. This model is estimated in two ways. The *conditional* estimators are obtained by using the conditional joint distribution, $f(y_{i1},y_{i2},...,y_{iT}|\Sigma_t y_{it})$. (See Griliches, Hall, and Hausman (1984).) The resulting density is a function of $\boldsymbol{\beta}$ alone, which is then estimated by (conditional) maximum likelihood. The *unconditional* estimator is obtained by a direct maximization of the full log likelihood function and estimating all parameters including the group specific constants.

E44.2.2 Random Effects

The random effects model is

$$\log \lambda_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + u_i.$$

Once again, the approach used for the linear model, in this case, FGLS, is not useable. The approach is to integrate out the random effect and estimate by maximum likelihood the parameters of the resulting distribution (which, it turns out, is the negative binomial model when the kernel is Poisson). Both fixed and random effects models are provided for the Poisson and negative binomial (gamma mixture) formulations. The bulk of the received literature on random effects is in the Poisson model. We also present models for random effects based on the normal distribution.

The random effects model for the count data framework is

$$\log\lambda_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + u_i,\ i = 1,...,N,\ t = 1,...,T_i,$$

where u_i is a random effect for the ith group such that $\exp(u_i)$ has a gamma distribution with parameters(θ,θ). Thus, $E[\exp(u_i)]$ has mean 1 and variance $1/\theta = \alpha$. This is the framework which gave rise to the negative binomial model earlier, so that, with minor modifications, this is the estimating framework for the Poisson model with random effects. For the negative binomial model, Hausman, et al. proposed the following approach: We begin with the Poisson model with the random effects specification shown above. The random term, u_i is distributed as gamma with parameters(θ_i,θ_i), which produces the negative binomial model with a parameter that varies across groups. Then, it is assumed that $\theta_i/(1+\theta_i)$ is distributed as beta(a_n,b_n), which layers the random group effect onto the negative binomial model. The random effect is added to the negative binomial model by assuming that the overdispersion parameter is randomly distributed across groups.

The two random effects models discussed above may be modified to use the normal distribution for the random effect instead of the gamma, with $u_i \sim N[0,\sigma^2]$. For the Poisson model, this is an alternative to the log-gamma model which gives rise to the negative binomial model. It is also essentially the same as the model of latent heterogeneity discussed in Section E42.4.1. The negative binomial model is much more involved than this, and the normal model is a considerably simpler alternative.

E44.2.3 Random Parameters

We provide a full random parameters formulation for both Poisson and negative binomial models,

$$\log \lambda_{it} = \boldsymbol{\beta}_i'\mathbf{x}_{it} + u_i \text{ (} + \varepsilon_{it} \text{ for the negative binomial model),}$$

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i,\ \mathbf{z}_i = \text{ a set of observed covariates,}$$

$$\mathbf{v}_i \sim \text{ joint standard normal, uniform, or triangular.}$$

The random parameters models are described in detail below and in Chapter R24.

E44.2.4 Latent Class Models

The Poisson model for a panel of data, $i = 1,...,N$, $t = 1,...,T_i$ is

$$\text{Prob}[Y_{it} = y_{it}|\ \lambda_{it}] \;=\; \exp[-\lambda_{it}] \times \lambda_{it}^{yit} \;/\; y_{it}! \;=\; P(i,t)$$

where $\lambda_{it} = \exp(\boldsymbol{\beta}'\mathbf{x}_{\text{it}})$

is the conditional [on $\mathbf{x}_{it}$] mean, as usual. Henceforth, we use the term ‘group’ to indicate the T_i observations on respondent i in periods $t = 1,...,T_i$. The following extends to the negative binomial model as well, but for the moment, we focus on the Poisson model.

Unobserved heterogeneity in the distribution of Y_{it} is assumed to impact the mean (and variance) λ_{it}. The continuous distribution of the heterogeneity is approximated by using a finite number of ‘points of support.’ The distribution is approximated by estimating the location of the support points and the mass (probability) in each interval. In implementation, it is convenient and useful to interpret this discrete approximation as producing a sorting of individuals (by heterogeneity) into J classes, $j = 1,...,J$. (Since this is an approximation, J is chosen by the analyst.)

Thus, we modify the model for a latent sorting of y_{it} into J ‘classes’ with a model which allows for heterogeneity as follows: The probability of observing y_{it} given that regime j applies is

$$P(i,t|j) \;=\; \text{Prob}[Y_{it} = y_{it}|\lambda_{it},j]$$

where the mean $\lambda_{it}|j$ is specific to the group. The analyst does not observe directly which class, $j = 1,...,J$ generated observation $y_{it}|j$, and class membership must be estimated. Heckman and Singer (1984) suggest a simple form of the class variation in which only the constant term varies across the classes. This would produce the model

$$\lambda_{it}|j \;=\; \exp[\,\boldsymbol{\beta}'\mathbf{x}_{it} \;+\; \delta_j].$$

We formulate this approximation more generally as,

$$\lambda_{it}|j \;=\; \exp[\,\boldsymbol{\beta}'\mathbf{x}_{it} \;+\; \boldsymbol{\delta}_j'\mathbf{x}_{it}].$$

In this formulation, each group has its own parameter vector, $\boldsymbol{\beta}'_j = \boldsymbol{\beta} + \boldsymbol{\delta}_j$, though the variables that enter the mean are assumed to be the same. (This could be changed by imposing restrictions on the full parameter vector, as described below.) This allows the Heckman and Singer formulation as a special case by imposing restrictions on the parameters. We denote the mass, or probability of membership in class j as F_j, $j = 1,...,J$, such that $F_1 + F_2 + ... + F_J = 1$. Then, the posterior probability of an observed sequence of observations is

$$P(i) \;=\; \sum\nolimits_{j=1}^{J} F_j P(i|j)$$

where $$F_j \;=\; \frac{\exp(\theta_j)}{\sum\nolimits_{m=1}^{J}\exp(\theta_m)},\; \theta_J \;=\; 0,\; \Sigma_j\, F_j = 1.$$

The model is fit by maximizing the likelihood for the observed data with respect to all parameters including θ_j, $j = 1,...,J$.

E44.3 Commands for Panel Data Models

The command structure for the panel data models is built by adding specifications to the common command. The panel data set is declared first.

SETPANEL ; Group = id variable ; Pds = group count variable $

Then, **POISSON ; Lhs = dependent variable ; Rhs = regressors**
or NEGBIN ; ... any model specific specifications ...
; Panel $

As always, panels may be unbalanced. The **; Panel** may be replaced with**; Pds** specification which gives either the fixed number of periods or the variable which gives the group count. The zero inflation models must be of the form

; ZIP [; Rh2 = list of variables in zero inflation probability]

Only the logit splitting form is supported for this model. If you omit the **; Rh2** list, then this probability will be a constant. Otherwise, it will be of the form

$$\text{Prob[regime 0]} = \frac{\exp(\delta'\mathbf{z}_{it})}{1+\exp(\delta'\mathbf{z}_{it})}$$

(The (τ) form is not supported.) The variables in $\mathbf{z}_{it}$ may vary across time, or, for the random parameters model and latent class model, may be the same in every period.

NOTE: The panel data estimators automatically bypass missing values, and keep all valid observations in a group. Thus, you should not use **SKIP** or **REJECT** to bypass missing values with these estimators. An important implication of this is that in the actual data set used to fit the model, the actual group sizes may be smaller than specified by the **SETPANEL** command or the**; Pds** variable.

Other options for these models are the same as in other settings, including

; Start = list	to give starting values
; Keep = name	to retain fitted values
; Res = name	to retain residuals
; Prob = name	to retain fitted probabilities for observed outcome
; List	to display predicted values
; Partial Effects	
; Rst = list	to specify fixed value and equality restrictions
; CML: spec	to define a constrained maximum likelihood estimator

and the various options for output and control during the iterations.

E44.4 Fixed Effects Models

The fixed effects Poisson and negative binomial models may be estimated two ways. The conditional estimator is the one presented in Hausman, Hall, and Griliches (1984). The unconditional estimator is computed by maximizing the log likelihood directly for all parameters, including the dummy variable coefficients, as described in Chapter R23. We consider them in turn. Only the second method is available for the zero inflation models.

E44.4.1 Conditional Estimation of Poisson and Negative Binomial Models

The conditional estimators for the Poisson and negative binomial models are based on the conditional log likelihood,

$$\log L_c = \sum_{i=1}^{n} \log P\left(y_{i,1}, y_{i,2}, \ldots, y_{i,T_i} \mid \sum_{t=1}^{T_i} y_{i,t}\right).$$

For the negative binomial, this is a different log likelihood and produces different results from the unconditional estimator given in the next section. For the Poisson model, it turns out to be algebraically and numerically identical. The command structure for the conditional fixed effects estimator is

```
POISSON      ; Lhs = y
or NEGBIN    ; Rhs = independent variables
             ; Panel $
```

That is, these are the default panel data estimators for these models. Other options such as marginal effects, fitted values, controls on output, starting values, constraints, and so on are all available. The model in this framework has

$$E[y_{it} \mid \mathbf{x}_{it}] = \exp(\alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it}) = \lambda_{it}$$

so the marginal effects would be

$$\partial E[y_{it} \mid \mathbf{x}_{it}]/\partial \mathbf{x}_{it} = \lambda_{it}\boldsymbol{\beta}.$$

In order to compute this quantity, it would be necessary to have an estimate of α_i in hand. But, the estimator is conditioned on the sum, so α_i is conditioned out of the log likelihood, and not estimated. In order to provide information about scaling in the model, we compute marginal effects by using $\bar{y}$ as an estimate of the scale factor at the means. This is an approximation that will estimate the marginal effects reasonably well. The standard errors are questionable, as the variance of the mean is ignored – as a consequence, the t ratios for the marginal effects will be the same as for the corresponding coefficients.

NOTE: The fixed effects model for the Poisson distribution does not allow an overall constant. Surprisingly, an overall constant term is identified in the conditional distribution of the negative binomial model. Your Rhs list may include one in the negative binomial model (but not the Poisson model.) Allison (2001) shows that the reason this occurs is that HHG did not formulate a true fixed effects model in the mean of the random variable. Their formulation layers the fixed effect into the heterogeneity model, not the conditional mean. This is then conditioned out of the distribution to produce the model that is estimated. Thus, in the HHG formulation for the negative binomial model, we do not have $\log\lambda_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it}$. The conditional mean is still $\exp(\alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it})$, however. The unconditional estimator below (also advocated by Allison) produces this formulation for $\log\lambda_{it}$. A fuller discussion of the two different treatments appears in the technical details in Section E44.4.5.

E44.4.2 Unconditional Estimation of Count Data Models

The unconditional estimator for the Poisson model is obtained by direct maximization of the log likelihood

$$\log L = \sum_{i=1}^{n} \log\left[\prod_{t=1}^{T_i} \frac{\exp(-\exp(\alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it}))[\exp(\alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it})]^{y_{it}}}{y_{it}!}\right]$$

with respect to all K+N parameters, where N may be up to 100,000. (Details on the mechanics of estimating 100,000+K parameters are given below and in Chapter R23.) This estimator is also available for the negative binomial model, which has a similar log likelihood with the Poisson density replaced by the negative binomial counterpart;

$$p(y_{it}|\mathbf{x}_{it}) = \text{Prob}[Y = y_{it}] = \frac{\Gamma(\theta + y_{it})}{\Gamma(\theta)\Gamma(y_{it}+1)} u_{it}^{\theta}(1-u_{it})^{y_{it}}, \; u_{it} = \theta / (\theta + \lambda_{it}).$$

NOTE: Full estimation of the fixed effects negative binomial model in this fashion generally encounters the 'incidental parameters' problem. This does not affect the Poisson model, however. The incidental parameters problem is discussed in detail in Chapter R23. The specific relationship to the Poisson model is discussed in Section E44.4.5 below.

This estimator is obtained by adding

; FEM

to the **POISSON** or **NEGBIN** command. (The default estimator is the conditional one. The optional estimator is the unconditional one.)

The unconditional estimator allows for truncation (not censoring) at zero. The model specification is

; TPM

with no other specifications. This is for the conditional distribution $y_i | y_i > 0$, as appears in hurdle models.

You may also estimate the zero inflation models with fixed effects. The full specification of the zero inflation model with this modification is

$$Y_{it} = 0 \text{ with probability } q_{it}$$

$$Y_{it} \sim \text{Poisson}(\lambda_{it}) \text{ or negative binomial with probability } 1 - q_{it}$$

so that

$$\text{Prob}[Y_{it} = 0] = q_{it} + [1 - q_{it}]R_{it}(0)$$

$$\text{Prob}[Y_{it} = j > 0] = [1 - q_{it}]R_{it}(j)$$

where

$$R_{it}(y) = \text{the Poisson probability} = e^{-\lambda it}\lambda_{it}^{yit} / y_{it}!$$

and

$$\lambda_{it} = e^{\alpha i + \boldsymbol{\beta}'\mathbf{x}it}$$

or the negative binomial probability with overdispersion parameter $\alpha = 1/\theta$,

$$R_{it}(y_{it}) = \Gamma(\theta + y_{it})/[y_{it}!\Gamma(\theta)]\, u_{it}^{\theta}\, [1 - u_{it}]^{yit},\ u_i = \theta / [\theta + \lambda_{it}].$$

The state probability, q_i has

$$\text{Prob}[q_{it} = 1] = \Lambda(\boldsymbol{\gamma}'\mathbf{z}_{it}).$$

You must provide a set of starting values for this model (unlike the other two). Do this simply by fitting the model without fixed effects before fitting the model with the fixed effects. The command structure would be as follows:

```
POISSON      ; Lhs   = dependent variable
or NEGBIN    ; Rhs   = independent variables
             ; Zip   ; Rh2 = variables in z (optional) $
POISSON      ; Lhs   = dependent variable
or NEGBIN    ; Rhs   = independent variables
             ; ZIP   ; Rh2 = variables in z (optional)
             ; FEM   ; Pds = panel specification $
```

Note the Rh2 list is optional. If you do not include it, then the regime model will contain only a constant term; i.e., q_{it} will be a constant.

NOTE: In specifying the ZIP model, include *one* in both the Rhs and Rh2 lists in both model commands, even if the splitting probability is constant. That is, in the first command above, you should have **; Rh2 = one**. If you do not have this, then the first model fit will be the ZIP(τ) or ZINB(τ), which will provide inappropriate starting values for the second model. The starting values are very important for this model.

NOTE: In the zero inflation model, the individual effect enters the mean of the probability model, not the splitting probability.

In this setting, a few of the optional estimation features are restricted. The options generally available are

; Keep = name	to retain the fitted value, λ_{it}
; Res = name	to retain residuals
; Prob = name	to retain p_{it}
; Cprob = name	to retain the group probability, $\Pi_t\, p_{it}$
; List	to produce a list of actual and predicted outcomes and probabilities
; Covariance Matrix	to display the covariance matrix for the slopes only, same as **; Printvc**
; Partial Effects	to produce the marginal effects computed at the data means

The restrictions specifications, **; Rst** and **; CML:** are unavailable, but you may use

; Test: spec	to specify a Wald test based on the coefficient vector not including α_i
; Start = list	to give starting values for $\boldsymbol{\beta}$(and θ for **NEGBIN**).

You may also provide one common value for the α_is, but not a full set, regardless of N, and **; Maxit = value**, for example **; Maxit = 0** to carry out LM tests. Estimation is only by Newton's method, so **; Alg = method** is not available. But, you may set the convergence rules as usual.

NOTE: Though the fixed effects estimators are computed, the asymptotic covariance matrix is not. As such, the only hypotheses related to the fixed effects which may be tested will rely on the likelihood function, not the individual coefficients.

E44.4.3 Two Way Unconditional Fixed Effects Estimator

The unconditional estimator can also produce a two way fixed effects model,

$$E[y_{it}\,|\mathbf{x}_{it}] = \exp(\alpha_i + \delta_t + \boldsymbol{\beta}'\mathbf{x}_{it}) = \lambda_{it}$$

There will now be MaxT_i-1 additional coefficients in the model. You can request this estimator by adding

; Time = ti

where the variable *ti* tells, for each observation, in which period the observation occurred. This variable must take the values 1,2,...,MaxT_i. That is, it must be coded with 't,' the index number of the period. A date will not work – it will be flagged as identifying too many coefficients. Observations may be made at different periods in the different groups. For example, if you have a panel with three observations in the first group and seven in the second, the first three observations could have been made at t = 2, t = 4, and t = 7. The program assumes that MaxT_i is equal to the largest group size in the model. (That way, it is assured that there are no holes in the sequence of observations.) Thus, the largest group in the sample must have this variable coded with the complete set of integers, 1,2,...,*Tmax*.

NOTE: If you have a balanced panel with **; Pds = T** where *T* is a fixed value, then you can specify the time effects with **; Time = one** as there can be no variation in the coding of the period in a balanced panel.

NOTE: Our experience has been that the fixed effects model produces considerable instability in the negative binomial, though it works nicely in the Poisson model. The reason may be that as in the normal heterogeneity case, there is heterogeneity already embodied in the model.

The fixed effects model with time effects is estimated by actually creating the time specific dummy variables. You will see a complete set of time effects in the output. As such, however, if you have a large group size in your panel, this extension may create an extremely large model.

E44.4.4 Applications

To illustrate the panel data estimators, we will return to the German health care data used in the preceding chapters. This is an unbalanced panel with 7,293 individuals observed from one to seven times. The following fits a few of the basic fixed effects models. For these data, the ZIP model with fixed effects appears to be badly specified. The unconditional fixed effects estimator for the negative binomial model is also inestimable with these data.

```
SETPANEL    ; Group = id ; Pds = ti $
NAMELIST    ; x = age,educ,hhninc,newhsat $
CREATE      ; date = year - 1983 $
CREATE      ; If(date = 8)date = 6 $
CREATE      ; If(date = 11)date = 7 $
```

The base case is the Poisson model with no fixed effects.

```
POISSON     ; Lhs = docvis ; Rhs = x,one ; Partial Effects $
```

This is the Poisson conditional fixed effects estimator.

```
POISSON     ; Lhs = docvis ; Rhs = x,one
            ; Panel ; Partial Effects $
```

This is the Poisson unconditional fixed effects estimator. The coefficient estimates are identical, but the marginal effects are computed differently.

```
POISSON     ; Lhs = docvis ; Rhs = x
            ; Panel ; Partial Effects ; FEM $
```

This is the Hausman et al. negative binomial conditional fixed effects estimator. The unconditional fixed effects is computed as well. As expected, since they are different models, the estimates are noticeably different.

```
NEGBIN      ; Lhs = docvis ; Rhs = x
            ; Panel ; Partial Effects $
NEGBIN      ; Lhs = docvis ; Rhs = x,one $
NEGBIN      ; Lhs = docvis ; Rhs = x,one ; Panel ; FEM $
```

These are two different fixed effects estimators. The first is the conditional estimator; the second is the unconditional estimator. The parameter estimates and standard errors are identical. The log likelihood values are not because the conditional and unconditional log likelihoods are different functions.

E44.4.5 Technical Details for Fixed Effects Models

For the conditional approaches, the fixed effects models are transformed to an estimable form by obtaining the conditional density, $p(y_{i1},y_{i2},...,y_{i,Ti}|\Sigma_t y_{it})$. This removes the fixed effect from the resulting distribution. (Derivations may be found in Hausman, Hall, and Griliches (1984).) For the Poisson distribution,

$$p(y_{i1},y_{i2},...y_{iT}|\Sigma_t y_{it}) = \left[\frac{\left(\sum_t y_{it}\right)!}{\prod_t y_{it}!}\right]\prod_t p_{it}{}^{y_{it}}$$

where $$p_{it} = \frac{\lambda_{it}}{\sum_t \lambda_{it}} = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_{it})}{\sum_{t=1}^{T_i} \exp(\boldsymbol{\beta}'\mathbf{x}_{it})}.$$

Note that $p_{it} = \lambda_{it}/\Sigma_t\lambda_{it}$, where $\lambda_{it} = e^{\alpha_i}e^{\boldsymbol{\beta}'\mathbf{x}_{it}}$, but the fixed effects fall out of the result. The contribution to the log likelihood, gradient and Hessian for the ith group is

$$\log L_i = \log p\big(y_{i1},y_{i2},...,y_{i,Ti}|\Sigma_t y_{it}\big)$$

$$\partial \log p\big(y_{i1},y_{i2},...,y_{i,Ti}|\Sigma_t y_{it}\big)/\partial\boldsymbol{\beta} = \Sigma_t y_{it}(\mathbf{x}_{it} - \bar{\mathbf{x}}_i)$$

$$\bar{\mathbf{x}}_i = \Sigma_t p_{it}\mathbf{x}_{it}.$$

$$\partial^2 \log p\big(y_{i1},y_{i2},...,y_{i,Ti}|\Sigma_t y_{it}\big)/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' = -(\Sigma_t y_{it})\,[\Sigma_t p_{it}(\mathbf{x}_{it} - \bar{\mathbf{x}}_i)(\mathbf{x}_{it} - \bar{\mathbf{x}}_i)'].$$

The negative inverse of the Hessian is used to estimate the asymptotic covariance of the estimator for the Poisson model. Though it might not be obvious from the preceding, this result is algebraically identical to the solution that is obtained by using the unconditional, brute force approach described below.

The contribution of the ith group to the conditional log likelihood function in the Poisson fixed effects model is of the form

$$\log L_i = \sum_{t=1}^{T_i} y_{it} \log p_{it}.$$

Suppose for the moment that β were known. The likelihood equation for the ith fixed effect coefficient provides the implicit solution

$$\alpha_i = \log\left[\left(\sum_{t=1}^{T_i} y_{it}\right)/\left(\sum_{t=1}^{T_i}\exp(\boldsymbol{\beta}'\mathbf{x}_{it})\right)\right].$$

If the dependent variable takes value zero for every observation in group i, then the sum equals zero, and group i does not contribute to the log likelihood. Such observation groups are dropped from the analysis. The results from conditional estimation of the Poisson model will contain a statement such as the following which appears in our application:

```
Skipped 1153 groups with inestimable ai
```

Note that unlike the binary choice models, it is not necessary for the y_{it} to vary within the group, so long as it is nonzero. In essence, the estimator of α_i is based on log $\overline{y}_i$, so any nonzero value will suffice, whether or not there is within group variation. The same consideration arises in the unconditional estimator described below, in this case for the negative binomial model as well. (This would be expected, since for the Poisson model, the conditional and unconditional estimators are expected.)

For the negative binomial model, the treatment is quite different in the conditional and unconditional formulations. Winkelmann (2008) provides a useful summary: We begin with the NB2 assumption,

$$\text{Prob}(Y = y_{it}) = \frac{\Gamma(\theta + y_{it})}{\Gamma(\theta)\Gamma(y_{it}+1)}\left(\frac{\theta}{\theta+\lambda_{it}}\right)^{\theta}\left(\frac{\lambda_{it}}{\theta+\lambda_{it}}\right)^{y_{it}},$$

where $\Gamma(.)$ is the gamma function. In order to obtain the contagion result needed to derive the distribution of the sum of negative binomials, it is necessary to assume that the NB1 form applies to the individual observation. The NB1 form can obtained by replacing θ with $\theta\lambda_{it}$ in each appearance in the NB2 form. To avoid a step, we suppose as well that the overdispersion parameter plays the role of the fixed effect, θ_i. We now also absorb the effect in λ_{it}, and write $\phi_{it} = \theta_i\lambda_{it}$. The density for NB1 becomes

$$\text{Prob}(Y = y_{it}) = \frac{\Gamma(\phi_{it} + y_{it})}{\Gamma(\phi_{it})\Gamma(y_{it}+1)}\left(\frac{\theta}{\theta+1}\right)^{\phi_{it}}\left(\frac{1}{\theta+1}\right)^{y_{it}}.$$

In this form, $E[y_{it}] = \theta_i\lambda_{it} = \phi_{it}$

and $\text{Var}[y_{it}] = \phi_{it}(1 + \theta_i)$.

This is a fixed effects model of a sort, since

$$E[y_i] = \exp(\beta'x_{it} + \log\theta_i) = \exp(\beta'x_{it} + \alpha_i)$$

but note that θ_i(or α_i) is playing more than just the role of a fixed effect here. It is also changing the variance. It cannot be interpreted the way that we are accustomed to interpreting fixed effects. We do note, this makes clear the source of a frequently observed peculiarity of the model. No problem is caused by the presence of an overall constant, or, indeed, other time invariant variables in $\mathbf{x}_{it}$. Notwithstanding this ambiguity of the model, this is the formulation that was devised by Hausman, Hall and Griliches (1984) and that has been widely used since then. The conditional distribution that corresponds to the NB1 model with that type of fixed effect is

$$p\big(y_{i1},y_{i2},...,y_{i,Ti}|\Sigma_t y_{it}\big) = \prod_t\left(\frac{\Gamma(\lambda_{it}+y_{it})}{\Gamma(\lambda_{it})y_{it}!}\right)\frac{\Gamma(\Sigma_t\lambda_{it})[(\Sigma_t y_{it}!)]}{\Gamma(\Sigma_t\lambda_{it} + \Sigma_t y_{it}]}.$$

The log likelihood is, again,

$$\text{Log } L = \Sigma_i \log p\big(y_{i1},y_{i2},...,y_{i,Ti}|\Sigma_t y_{it}\big).$$

The gradient for the *i*th observation group is

$$\partial\, p\big(y_{i1},y_{i2},\ldots,y_{i,Ti}|\Sigma_t y_{it}\big)/\partial\boldsymbol{\beta} \;=\; \Sigma_t\lambda_{it}e_{it}\mathbf{x}_{it},$$

$$e_{it} \;=\; [\Psi(\lambda_{it}+y_{it}) - \Psi(\lambda_{it})] - [\Psi(\Sigma_t\,\lambda_{it}+\Sigma_t\,y_{it}) - \Psi(\Sigma_t\,\lambda_{it})],$$

$$\Psi(t) \;=\; \Gamma'(t)/\Gamma(t) \;=\; \text{the digamma function.}$$

The asymptotic covariance matrix for the negative binomial estimator is computed with the BHHH estimator. We do note an aspect of the negative binomial model. The Hausman et al. conditional estimator is numerically quite stable, in spite of its questionable theoretical pedigree. (The model is overspecified – it essentially is a Poisson model with two heterogeneity effects and in spite of this, it is not really an ‘effects’ model.) In contrast, the true fixed effects model fit with the unconditional estimator, while more theoretically orthodox is, in our experience, quite numerically unstable. We have frequently observed serious numerical problems such as overflows.

The unconditional log likelihood for both models is maximized by using Newton’s method. A full discussion of the method is given in Chapter R23; for convenience, only a short sketch of the result is given here, for the Poisson model. (The results for the negative binomial (NB2) model are similar.) The log likelihood is

$$\log L \;=\; \sum_{i=1}^{n}\;\log\left[\prod_{t=1}^{T_i}\;\frac{\exp(-\exp(\alpha_i+\boldsymbol{\beta}'\mathbf{x}_{it}))[\exp(\alpha_i+\boldsymbol{\beta}'\mathbf{x}_{it})]^{y_{it}}}{y_{it}\,!}\right]$$

Let p_{it}, y_{it}, $\mathbf{x}_{it}$ and λ_{it} denote the obvious components of this function. Then,

$$\frac{\partial\log L}{\partial\boldsymbol{\beta}} \;=\; \sum_{i=1}^{N}\sum_{t=1}^{T_i}(y_{it}-\lambda_{it})\mathbf{x}_{it} \;=\; \mathbf{g}_{\beta}$$

$$\frac{\partial\log L}{\partial\alpha_\iota} \;=\; \sum_{t=1}^{T_i}(y_{it}-\lambda_{it}) \;=\; g_i$$

$$\frac{\partial^2\log L}{\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}'} \;=\; -\sum_{i=1}^{N}\sum_{t=1}^{T_i}\lambda_{it}\mathbf{x}_{it}\mathbf{x}_{it}' \;=\; \mathbf{H}_{\beta\beta'}$$

$$\frac{\partial^2\log L}{\partial\alpha_i^{\,2}} \;=\; -\sum_{t=1}^{T_i}\lambda_{it} \;=\; h_{ii}$$

$$\frac{\partial^2\log L}{\partial\boldsymbol{\beta}\partial\alpha_i} \;=\; -\sum_{t=1}^{T_i}\lambda_{it}\mathbf{x}_{it} \;=\; \mathbf{h}_{\beta i}$$

The results for the Poisson model (not the negative binomial model) are identical to the conditional estimator. This has an important implication: Unlike most other models, the incidental parameters issue does not apply to the Poisson model. The unconditional fixed effects estimator is consistent.

E44.5 Random Effects Models

The random effects model for the Poisson framework is

$$\begin{aligned}\log\lambda_{it}^* &= \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_i,\ i = 1,...,N,\ t = 1,...,T_i,\\ &= \log[\lambda_{it}\exp(\varepsilon_i)]\end{aligned}$$

where ε_i is a random effect for the *i*th group, the same in every period, such that $\exp(\varepsilon_i)$ has a gamma distribution with parameters(θ,θ). Thus, $E[\exp(\varepsilon_i)]$ has mean 1 and variance $1/\theta = \alpha$. This is the framework which gave rise to the negative binomial model earlier, so that, with the minor modifications, this is the estimating framework for the Poisson model with random effects. For the negative binomial model, Hausman, et al. proposed the following approach: We begin with the Poisson model with the random effects specification shown above. The random term, ε_i is distributed as gamma with parameters(θ_i,θ_i), which produces the negative binomial model with a parameter that varies across groups. Then, it is assumed that $\theta_i/(1+\theta_i)$ is distributed as beta(a_n,b_n), which layers the random group effect onto the negative binomial model. Details on the resulting distribution are given below. In sum, then, the random effect is added to the negative binomial model by assuming that the overdispersion parameter is randomly distributed across groups. Use

; Random

to request the random effects model.

There is another useful interpretation of the random effects model. Rewrite the model as

$$\log\lambda_{it}^* = \alpha_i + \boldsymbol{\beta}_1'\mathbf{x}_{it},\ i = 1,...,N,\ t = 1,...,T_i,$$

where $$\alpha_i = \alpha + \varepsilon_i$$

This is a trivial modification of the essential structure of the model. However, as written, we can reinterpret the model as an ordinary count model with a random constant term. This suggests an alternative approach to estimation. The random parameters models discussed in Section R24.3 gives further details, including this special case. The two random effects models discussed above may be modified to use the normal distribution for the random effect instead of the gamma, $\varepsilon_i \sim N[0,\sigma^2]$. For the Poisson model, this is an alternative to the log-gamma model which gives rise to the negative binomial. The negative binomial model is much more involved than this, and the normal model is a considerably simpler alternative. To request the random effects models with normally distributed heterogeneity, use

```
POISSON      ; Lhs = ... ; Rhs = ... ; Pds = ...
or NEGBIN    ; Random Effects
             ; Normal distribution $
```

The parameters estimated by these models are as follows:

	Log-gamma	Lognormal
Poisson	$\boldsymbol{\beta},\alpha$	$\boldsymbol{\beta},\sigma^2$
Negative Binomial	$\boldsymbol{\beta},a_n,b_n$	$\boldsymbol{\beta},\alpha,\sigma^2$

NOTE: The negative binomial model might be somewhat overparameterized by this extension. The random effect essentially adds a heterogeneity term to a model that is obtained by adding a heterogeneity term to a lower level (the Poisson) model. As such, it will be common that attempts to fit the negative binomial model with random effects will be unsuccessful.

You may use

	; Start = list	to give starting values
and	**; Rst = list**	to impose restrictions

for any of the four models. The default algorithm is BFGS, which you should use unless there is some definite reason to use some other. Other controls, such as **; Maxit [= 0]** are available as usual.

The random effects models are computed using the Butler and Moffitt method, with Gauss-Hermite integration. They can also be fit as random parameters, i.e., random constant models, using the RP estimator described in Section E44.6.

The panel data models produce a full set of results for the base model before estimation of the random effects model. Thus, the Poisson models produce three sets of estimates while the negative binomial model will produce four sets of results:

- OLS results (if requested with **; OLS**)
- Poisson regression, ignoring the group effects
- negative binomial model ignoring the group effects
- negative binomial model including the fixed or random effects.

The retrievable results are

Matrices: *b* and *varb*

Scalars: *kreg*, *nreg*, *logl*, *s* (when σ is estimated)

Last Model: *b_variable*, *a* (if you fit a negative binomial model)

E44.5.1 Application

To illustrate the random effects estimators, we will reestimate two of the models fit earlier with fixed effects. Several variants of the random effects models are suggested. We first fit the Poisson model with no effects, then with log gamma then normally distributed random effects. The random parameters model is an alternative estimator for the model with normally distributed effects fit by the Butler and Moffitt method. The three random effects Poisson models can also be fig using the negative binomial specification.

E44.5.2 Technical Details for Random Effects Models

The random effects models are obtained by integrating $\exp(\varepsilon_i)$ out of

$$p(y_{i1},y_{i2},\ldots,y_{iT},\exp(\varepsilon_i)) \;=\; p(y_{i1},y_{i2},\ldots,y_{iT}|\exp(\varepsilon_i))g(\exp(\varepsilon_i)).$$

For the Poisson model, the random effect is assumed to enter multiplicatively through λ_{it}, the same as in the earlier derivation of the negative binomial model. Conditioned on the heterogeneity, the T_i observations $y_{it}|\exp(\varepsilon_i)$ are distributed as independent Poisson variates each with parameter $\exp(\varepsilon_i)\lambda_{it}$. Then,

$$p(y_{i1},y_{i2},\ldots,y_{iT}|\exp(\varepsilon_i)) \;=\; \Pi_t p(y_{it}|\exp(\varepsilon_i)).$$

We assume that $g(\exp(\varepsilon_i))$ is the gamma distribution with parameters (θ,θ) with $\theta = 1/\alpha$, so that $E[\exp(\varepsilon_i)]$ equals 1. The density that results when u_i is integrated out is

$$p(y_{i1},y_{i2},\ldots,y_{iT},) \;=\; \frac{\left(\prod_t \lambda_{it}^{\,y_{it}}\right)\Gamma\left(\theta+\sum_t y_{it}\right)}{\left(\prod_t y_{it}!\right)\Gamma(\theta)\left(\sum_t y_{it}\right)!\left(\sum_t \lambda_{it}\right)^{\sum_t y_{it}}}u_i^{\theta}(1-u_i)^{\sum_t y_{it}}$$

where $u_i = \theta / (\theta + \Sigma_t y_{it})$. As usual, $\log L = \Sigma_i \log p(\ldots)$. The gradient for the ith term is

$$\partial \log L_i/\partial \boldsymbol{\beta} \;=\; \Sigma_t w_{it}\mathbf{x}_{it}$$

where $$w_{it} \;=\; \lambda_{it}u_i(A_i - 1) \;+\; \lambda_{it}(y_{it} - A_i)$$

$$A_i \;=\; \Sigma_t y_{it} / \Sigma_t \lambda_{it}$$

and $$\partial \log L_i/\partial \theta \;=\; \Psi(\theta + \Sigma_t y_{it}) - \Psi(\theta) + \log u_i + (1 - u_i) - (u_i/\theta)\Sigma_t y_{it}.$$

Construction of the density for the random effects negative binomial model is described above. We first build the heterogeneity in to the distribution of ε_i by letting θ_i carry the random effect. (Note this is similar to the handling of the fixed effects negative binomial earlier.) It is assumed that $\theta_i/(1+\theta_i)$ is distributed as beta(a_n,b_n), which layers the random group effect onto the negative binomial model. The resulting model is

$$p(y_{i1},y_{i2},\ldots,y_{iT},) = \frac{\Gamma(a_n+b_n)\Gamma\left(a_n+\sum_{t=1}^{T_i}\lambda_{it}\right)\Gamma\left(b_n+\sum_{t=1}^{T_i}y_{it}\right)}{\Gamma(a_n)\Gamma(b_n)\Gamma\left(a_n+b_n+\sum_{t=1}^{T_i}\lambda_{it}+\sum_{t=1}^{T_i}y_{it}\right)}\prod_{t=1}^{T_i}\frac{\Gamma(\lambda_{it}+y_{it})}{\Gamma(\lambda_{it})\Gamma(y_{it}+1)}$$

The derivatives are

$$\begin{aligned}
\partial\log L_i/\partial\boldsymbol{\beta} &= \Sigma_t\lambda_{it}e_{it}\mathbf{x}_{it}\\
\partial\log L_i/\partial a_n &= \Sigma_t\lambda_{it}e_{it} - \Psi(a_n) + \Psi(a_n + \Sigma_t\lambda_{it})\\
\partial\log L_i/\partial b_n &= \Sigma_t\lambda_{it}e_{it} - \Psi(b_n) + \Psi(b_n + \Sigma_t y_{it})\\
e_{it} &= \Psi(a_n + \Sigma_t\lambda_{it}) - \Psi(a_n + b_n + \Sigma_t\lambda_{it} + \Sigma_t y_{it}) + \Psi(\lambda_{it} + y_{it}) - \Psi(\lambda_{it})\\
\Psi(z) &= d\log\Gamma(z)/dz \ \text{ (the `digamma' function).}
\end{aligned}$$

For the random effects model with normally distributed group effects, we form the likelihood function in the same fashion as in Section E44.5.2 for the cross section case – the derivation is identical with a small change in the notation. For group *i*, conditioned on ε_i, the T_i observations are independent. The unconditional density for the observed data is formed by integrating ε_i out of the joint density. Thus,

$$p(y_1,y_2,\ldots,y_{T_i}) = \int_{-\infty}^{\infty}\prod_{t=1}^{T_i}\frac{\exp(-\lambda_{it}\,|\,\varepsilon_i)(\lambda_{it}\,|\,\varepsilon_i)^{y_{it}}}{y_{it}!}\left(\frac{1}{\sigma}\right)\phi\left(\frac{\varepsilon_i}{\sigma}\right)d\varepsilon_i$$

where $\lambda_{it}|\varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_i)$ is the mean of y_{it} conditioned on the group effect. The log likelihood, its derivatives with respect to $\boldsymbol{\beta}$ and σ, and the estimate of the Hessian are computed as discussed in Section E44.5.2. In all cases, the estimator of the covariance matrix for the estimated coefficients is the BHHH estimator obtained by summing the outer products of the gradients for the *N* observations.

As before, there are two ways to handle the normally distributed effect, with quadrature using the Butler and Moffitt method, or as a random constant model, using maximum simulated likelihood, as considered in the next section.

E44.6 Random Parameters Models

The random parameters model is described in detail in Chapter R24. The general form of the model for the Poisson and negative binomial regressions is

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_{it}$$

where $\boldsymbol{\beta}$ = the fixed means of the distributions for the random parameters.

$\mathbf{z}_i$ = a set of M observed variables which do not vary over time and which enter the means (optional).

$\boldsymbol{\Delta}$ = coefficient matrix, $K \times M$, which forms the observation specific term in the mean.

$\mathbf{v}_{it}$ = unobservable $K\times1$ latent random term in the ith observation in $\boldsymbol{\beta}_i$. Each element of $\mathbf{v}_{it}$ has zero mean and variance one. Each element of $\mathbf{v}_{it}$ may be distributed as normal, uniform, or triangular. They need not be the same.

$$\lambda|\mathbf{v}_{it} = \exp(\boldsymbol{\beta}_i'\mathbf{x}_{it})$$

$$P(y_i|\mathbf{x}_{it},\mathbf{v}_{it}) = \text{Poisson or negative binomial probability given } \lambda_i.$$

Several extensions and narrower details for the model are given in Section R24.3. The Poisson and negative binomial models are standard applications of the results given there.

The command for the random parameters model is structured as follows:

	POISSON	**; Lhs**	**= dependent variable**
	or NEGBIN	**; Rhs**	**= list of all variables in $\mathbf{x}_i$, including one if the model contains a constant**
		; Panel	
		; RPM	**(random parameters model)**
or		**; RPM**	**= list of variables in $\mathbf{z}_i$**
		; Fcn	**= specification of random parameters**
		; Pts	**= r (number of replications)**
		; Cor	**(for correlated parameters) $**

The last two specifications are optional. The remainder are mandatory parts of the command. The **; Fcn** list consists of a list of names of variables which appear in $\mathbf{x}_i$, followed in parentheses by (n) for normally distributed, (u) for uniform, or (t) for triangular. Other options for the Poisson and negative binomial model are specified as usual. These include:

; Par	to keep individual specific parameter estimates.
; Keep = name	to retain fitted values
; Res = name	to retain residuals
; Prob = name	to retain fitted probabilities for observed outcome
; Partial Effects	
; List	to display predicted values (only available if T_i is $\leq$ 10 for all i)
; Maxit= n	to set maximum iterations

and so on. The optional specifications are described in the technical details below.

Here is an example command for the model estimated in the previous section:

```
POISSON      ; Lhs = docvis ; Rhs = x,one ; Pds = ti
             ; RPM ; Fcn = one(n),income(n) ; Correlation ; Pts = 50
             ; Partial Effects $
```

This command specifies two correlated random and three fixed parameters, and 50 replications for the simulations.

The random parameters estimator allows for truncation (not censoring) at zero. The model specification is

```
             ; TPM
```

with no other specifications. This is for the conditional distribution $y_i|y_i > 0$, as appears in hurdle models.

The random parameters model with only a random constant term is equivalent to the random effects model in the previous section. However, the estimates obtained will be different for two reasons. First, the model is estimated by simulation, not by analytical maximum likelihood. Second, the distribution of the random term is assumed to be normal here, whereas in the previous models it is assumed to be log-gamma (though you can specify a normally distributed term as well). A comparison appears below. The random parameters model is also extended to the Poisson and negative binomial ZIP models. This estimator is described at the end of this section.

E44.6.1 Application

In order to replicate results with this estimator, you must either reset the seed for the random number generator to the same value every time, or use Halton sequences as we have below. Otherwise, results produced by identical commands will differ slightly. The command **CALC ; Ran(your value)** placed before each command will remove this source of variation. We have continued the illustrations in the previous sections with a slightly different specification. For this illustration, we have also restricted the sample to those 886 individuals observed in all seven periods of the panel. The commands are as follows:

```
REJECT       ; ti < 7 $
NAMELIST     ; x = one,female,hhninc,educ $
POISSON      ; Lhs  = docvis ; Rhs = x ; Partial Effects $
POISSON      ; Lhs  = docvis ; Rhs = x ; Partial Effects
             ; RPM  ; Fcn = female(n),hhninc(n),educ(n)
             ; Panel ; Pts = 25 ; Halton ; Correlated
             ; Partial Effects $
POISSON      ; Lhs  = docvis ; Rhs = x ; Partial Effects
             ; RPM  ; Fcn = female(n),hhninc(n),educ(n)
             ; Panel ; Pts = 25 ; Halton ; Correlated ; AR1 $
NEGBIN       ; Lhs  = docvis ; Rhs = x ; Partial Effects $
NEGBIN       ; Lhs  = docvis ; Rhs = x ; Partial Effects
             ; RPM  ; Fcn = female(n),hhninc(n),educ(n)
             ; Panel ; Pts = 25 ; Halton; Correlated $
```

E44.6.2 ZIP Models with Random Parameters

The random parameters model may be extended to the zero inflated Poisson and negative binomials models. The random parameters specification applies to the parameters in the regression model, not the regime splitting model. The model is

$$Y_{it} = 0 \text{ with probability } q_{it},$$

$$Y_{it} \sim \text{Poisson}(\lambda_{it}) \text{ or NegBin}(\lambda_{it},\theta) \text{ with probability } 1 - q_{it}$$

$$\text{Prob}[Y_{it} = 0] = q_{it} + [1 - q_{it}]R_{it}(0), \quad \text{Prob}[Y_{it} = j > 0] = [1 - q_{it}]R_{it}(j)$$

where $$R_{it}(y) = \text{Poisson probability} = e^{-\lambda it}\lambda_{it}^{yit} / y_{it}!, \quad \lambda_{it} = \exp(\boldsymbol{\beta}_i{}'\mathbf{x}_{it})$$

(the random parameters appear in λ_{it}) or,

$$R_{it}(j) = \text{negative binomial probability} = \Gamma(\theta+y_{it})/[y_{it}!\Gamma(\theta)]\, u_{it}^{\theta}\, [1 - u_{it}]^{yit}$$

$$\theta = 1/\alpha, \text{ where } \alpha \text{ is the overdispersion parameter}$$

$$u_{it} = \theta / [\theta + \lambda_{it}],$$

$$q_{it} \sim \text{Logistic}[v_{it}], \quad v_{it} = \boldsymbol{\gamma}'\mathbf{z}_{it}.$$

The command form is

POISSON	**; Lhs**	**= dependent variable**
or NEGBIN	**; Rhs**	**= list of all variables in $\mathbf{x}_i$, including one**
	; ZIP	**; Rh2 = list of variables for regime split, including one**
	; Panel	
	; RPM	**(for random parameters model)**
or	**; RPM**	**= list of variables in $\mathbf{z}_i$**
	; Fcn	**= specification of random parameters**
	; Pts	**= r (number of replications – this is optional)**
	; Cor	**(for correlated parameters – optional) $**

The ***; Fcn = list*** *specification is applied only to the Rhs variables.*

E44.7 Latent Class Models

The count model for a panel of data, $i = 1,...,N$, $t = 1,...,T_i$ is the Poisson

$$\text{Prob}[Y_{it} = y_{it}|\ \lambda_{it}] \ = \ \exp[-\lambda_{it}] \times\lambda_{it}^{yit} \ / \ y_{it}! \ \text{ where } \lambda_{it} \ = \ \exp[\boldsymbol{\beta}'\mathbf{x}_{it}]$$

or negative binomial probability,

$$\text{Prob}[Y_{it} = y_{it}|\ \lambda_{it}, \tau] \ = \ \Gamma(\tau + y_{it})/[y_{it}!\Gamma(\tau)]\ u_{it}^{\tau}\ [1 - u_{it}]^{\,yit} \ \text{ where } \ u_i \ = \tau / [\tau + \lambda_{it}].$$

(We have changed the symbol for the dispersion parameter to avoid a conflict with our generic notation for the latent class probabilities.) Henceforth, we use the term 'group' to indicate the T_i observations on respondent i in periods t=1,...,T_i. The following extends to the negative binomial model as well, but for the moment, we focus on the Poisson model.

Unobserved heterogeneity in the distribution of Y_{it} is assumed to impact the mean (and variance) λ_{it}. The continuous distribution of the heterogeneity is approximated by using a finite number of 'points of support.' The distribution is approximated by estimating the location of the support points and the mass (probability) in each interval. In implementation, it is convenient and useful to interpret this discrete approximation as producing a sorting of individuals (by heterogeneity) into J classes, $j = 1,...,J$ where J is chosen by the analyst.)

The probability of observing y_{it} given that the individual is in class j is

$$P(i,t|j) \ = \ \text{Prob}[Y_{it} = y_{it}|\lambda_{it},j]$$

where the mean $\lambda_{it}|j$ is specific to the group. The analyst does not observe directly which class, $j = 1,...,J$ generated observation $y_{it}|j$, and class membership must be estimated. Heckman and Singer (1984) suggest a simple form of the class variation in which only the constant term varies across the classes. This would produce the model $\lambda_{it}|j \ = \ \exp[\ \boldsymbol{\beta}'\mathbf{x}_{it} \ + \ \delta_j]$. We formulate this more generally as,

$$\lambda_{it}|j \ = \ \exp[\boldsymbol{\beta}_j'\mathbf{x}_{it}] \text{ and, for the negative binomial model, } \theta|j \ = \ \theta_j.$$

In this formulation, each class has its own parameter vector, $(\boldsymbol{\beta}_j,\theta_j)$though the variables that enter the mean are assumed to be the same. The negative binomial model has a separate dispersion parameter in each class as well. This allows the Heckman and Singer formulation as a special case by imposing restrictions on the parameters. The prior probabilities for the latent classes are formulated as constants.

$$F_j \ = \ \frac{\exp(\theta_j)}{\sum_{m=1}^{J}\exp(\theta_m)}, \ \theta_J \ = \ 0, \ \Sigma_j\, F_j = 1.$$

The class probabilities may also be functions of a set of covariates, in which case

$$F_{ij} \ = \ \frac{\exp(\boldsymbol{\theta}_j'\mathbf{z}_i)}{\sum_{m=1}^{J}\exp(\boldsymbol{\theta}_m'\mathbf{z}_i)}.$$

An extension to the zero inflation models and a further generalization are presented in Section E44.7.

The estimation command for this model is

```
POISSON      ; Lhs  = ... ; Rhs = independent variables
or NEGBIN    ; LCM (for latent class model)
             ; Pts   = the desired number of classes, 2, 3, ..., 9
             ; Pds  = panel data specification $
```

(The model must be fit with panel data.) The default number of support points is five. But, this is fairly high. You may set J to 2, 3, 4, or 5. To specify that the class probabilities are functions of covariates, use

; LCM = the set of variables

(The default is **; LCM** = **one**. You may omit the '**= one**' if your class probabilities are constant.)

NOTE: For the case in which class probabilities have covariates, it is assumed that these are the same in every period. You should repeat these variables for each observation within the group. The program uses the first row, so, in fact, any data, including zeros, will suffice. However, do not mark observations 2 - T_i for these variables as missing. This will flag the observation as bad data to be bypassed.

Other options are the standard ones for Poisson and negative binomial models, including

; Par	to keep individual specific parameter estimates.
; Keep = name	to retain fitted values
; Res = name	to retain residuals
; Prob = name	to retain estimated probabilities for observed outcome

Some particular values computed for the latent class model are

; Group = the index of the most likely latent class
; Cprob = estimated probability for the most likely latent class

(Computation of these values is described in the technical details.) Other options include

; Maxit = n	to set maximum iterations
; Rst = list	to specify fixed value and equality restrictions
; CML: spec	to define linear constraints
; Test: spec	to define Wald tests

and so on. You can use the **; Rst = list** option to structure the latent class model so that different variables appear in different classes. Alternatively, you can use this to force the Heckman and Singer form of the model as follows, where we use a three class model as an example:

```
NAMELIST    ; x = ... one, list of variables $
CALC        ; k1 =  Col(x) - 1 $
POISSON     ; Lhs = ... ; Rhs = x ; LCM ; Pts = 3
            ; Rst = d1,k1_b, d2,k1_0, d3,k1_0, t1,t2,t3 $
```

Estimates retained by this model include

Matrices:	*b*	=	full parameter vector, $[\beta_1', \beta_2', \ldots F_1, \ldots, F_J]$
	varb	=	full covariance matrix
	beta_i	=	individual specific parameters, if **; Par** is requested.

Note that *b* and *varb* involve $J \times (K+1)$ estimates. Two additional matrices are created

b_class	=	a $J \times K$ matrix with each row equal to the corresponding β_j
class_pr	=	a $J \times 1$ vector containing the estimated class probabilities

Scalars:	*kreg*	=	number of variables in Rhs list
	nreg	=	total number of observations used for estimation
	logl	=	maximized value of the log likelihood function
	exitcode	=	exit status of the estimation procedure

The latent class estimator allows for truncation (not censoring) at zero. The model specification is

; TPM

with no other specifications. This is for the conditional distribution $y_i|y_i > 0$, as appears in hurdle models.

E44.7.1 Testing for Latent Heterogeneity

In order to test for latent class effects, you must compare a model with the effects to one without. This is not a parametric restriction on the latent class model. Note, thus, if θ_j is set equal to zero, this just produces $F_j = 1/J$. Alternatively, forcing all coefficient vectors to equal zero destroys the identifiability of the latent class probabilities – their standard errors will go to $+\infty$. (Try it.) Therefore, in order to test for class effects, the restricted and unrestricted models must be fit separately. One can use a likelihood ratio test, based on the following computations: For the latent class model the unrestricted log likelihood is,

$$\log L_U = \sum\nolimits_{i=1}^{N} \log \sum\nolimits_{j=1}^{J} F_j \prod\nolimits_{t=1}^{T_i} P(i,t|j).$$

For the Poisson or negative binomial model with no latent class sorting, the log likelihood is

$$\log L_R = \sum\nolimits_{i=1}^{N} \log \prod\nolimits_{t=1}^{T_i} P(i,t).$$

In both models, observations within the groups are assumed to be independent. Taking logs in the second expression produces the conventional log likelihood function for the count model,

$$\log L_R = \sum\nolimits_{i=1}^{N} \sum\nolimits_{t=1}^{T_i} P(i,t).$$

Therefore, it appears that a conventional likelihood ratio statistic can be computed. The degrees of freedom would be (J-1)(1+K). The first J-1 would be for the free latent class probabilities while the latter K(J-1) would be for the additional slope parameters in the last J-1 latent classes. The problem with this approach is that the model is not identified under the restrictions, so this is not a conventional LR test. That is, without the latent class sorting, the extra slope parameters cannot be estimated, and without variation across classes in the slope parameters, the class parameters cannot be estimated. The upshot is that if this is a valid LR statistic, then surely the degrees of freedom is fewer than (J-1)(1+K). But, whether it is appears not to be conclusively determined in the literature. (See Heckman and Singer for discussion.)

E44.7.2 Application

To illustrate the technique, we have applied the technique to the German health care data once again. A three class model for *docvis* is fit without restrictions, then restricted so as to produce the Heckman and Singer form of the model in which only the constant terms differ.

```
POISSON     ; Lhs  = docvis ; Rhs = one,female,hhninc,educ
            ; Panel ; Pts = 3 ; LCM ; Partial Effects $
POISSON     ; Lhs  = docvis ; Rhs = one,female,hhninc,educ
            ; Panel ; Pts = 3 ; LCM ; Partials Effects
            ; Rst  = b01,3_b,b02,3_b,b03,3_b,t1,t2,t3 $
```

```

E44.7.3 Latent Class Model with Zero Inflation

You can extend the latent class model to the zero inflation models as well. The extended model departs from the basic probabilities as usual, the Poisson

$$R(i,t|j) = \exp[-\lambda_{it\,|\,j}] \times \lambda_{it\,|\,j}^{\;yit} \;/\; y_{it}!$$

where $\lambda_{it|j} = \exp[\boldsymbol{\beta}_j'\mathbf{x}_{it}]$

or negative binomial probability,

$$R(i,t|j) = \Gamma(\tau_j + y_{it})/[y_{it}!\Gamma(\tau_j)]\; u_{it\,|\,j}^{\;\tau j}\,[1 - u_{it\,|\,j}]^{\;yit}$$

$$\tau_j = 1/\alpha_j, \text{ where } \alpha_j \text{ is the overdispersion parameter}$$

$$u_{it|j} = \tau_j / [\tau_j + \lambda_{it|j}].$$

The mean $\lambda_{it} \mid j$ and, if negative binomial, overdispersion, τ_j, are specific to the group. The zero inflation model then adds

$$Y_{it}|\, j = 0 \text{ with probability } q_{it|j},$$

$$Y_{it}|\, j \sim \text{Poisson}(\lambda_{it\,|\,j}) \text{ or NegBin}(\lambda_{it\,|\,j},\theta_j) \text{ with probability } 1 - q_{it\,|\,j}$$

where $q_{it\,|\,j} = \text{Logit probability } (\boldsymbol{\gamma}_j'\mathbf{z}_{it}) = \dfrac{\exp(\boldsymbol{\delta}_j'\mathbf{z}_{it})}{1+\exp(\boldsymbol{\delta}_j'\mathbf{z}_{it})}.$

Thus, $\text{Prob}[Y_{it} = 0 \mid j] = q_{it|j} + [1 - q_{it|j}]R_{it}(0 \mid j),$

$$\text{Prob}[Y_{it} = m > 0 \mid j] = [1 - q_{it|j}]R_{it}(m \mid j).$$

Combining terms, the preceding define

$$P(i,t \mid j) = \text{Prob}[Y_{it} = y_{it} \mid j]$$

and the rest of the analysis is the same as in the previous section.

The command for this model just adds the ZIP specification to the earlier latent class specification:

POISSON	**; Lhs**	**= ...**
or NEGBIN	**; Rhs**	**= independent variables**
	; ZIP	**; Rh2 = variables in regime probability**
	; LCM	**(for latent class model)**
	; Pts	**= the desired number of classes, 2, 3, 4, or 5**
	; Pds	**= panel data specification $**

All other options and parts of the command are the same as before.

E44.7.4 Technical Details on Estimating Latent Class Models

The sequence of T_i observations for individual i, given group j is $\mathbf{y}(i|j) = [y(i,1|j),y(i,2|j),...,y(i,T_i|j)]$. Observations for individual i in different periods are assumed to be independent. Thus, the joint probability of the sequence of observations $[\mathbf{y}(i|j)]$ is

$$P(i|j) \quad = \quad \prod_{t=1}^{T_i} P(i,t|j).$$

We denote the mass, or probability in interval (group) j as F_j, $j = 1,...,J$, such that $F_1 + F_2 + ... + F_J = 1$. Then, the posterior probability of an observed sequence of observations is

$$P(i) \quad = \quad \sum_{j=1}^{J} F_j P(i|j)$$

where F_j is the prior probability of membership in the jth class. We parameterize the group probabilities with

$$F_j \quad = \quad \frac{\exp(\theta_j)}{\sum_{m=1}^{J}\exp(\theta_m)}, \ \theta_J \ = \ 0, \ \Sigma_j F_j = 1.$$

where $\theta_J = 0$, since $\Sigma_j F_j = 1$. The class probabilities may also be functions of a set of covariates, in which case

$$F_{ij} \quad = \quad \frac{\exp(\boldsymbol{\theta}'_j \mathbf{z}_i)}{\sum_{m=1}^{J}\exp(\boldsymbol{\theta}'_m \mathbf{z}_i)}, \ \boldsymbol{\theta}_J \ = \ \mathbf{0}, \ \Sigma_j F_j = 1.$$

NOTE: In this formulation, the covariates are assumed to be the same in every period. Data on $\mathbf{z}_i$ must be present in every period, but the first observation in each group is used to compute the prior probabilities.

The log likelihood function for the observed sample is

$$\log L = \sum_{i=1}^{N} \log[P(i)]$$

$$= \sum_{i=1}^{N} \log \sum_{j=1}^{J} F_{ij} \prod_{t=1}^{T_i} P(i,t|j).$$

This function is maximized with respect to the vector of parameters

$$\boldsymbol{\beta} = (\boldsymbol{\beta}_1,...,\boldsymbol{\beta}_J),\ \boldsymbol{\theta}_1,...,\boldsymbol{\theta}_J.$$

subject to the restriction that $\boldsymbol{\theta}_J = \mathbf{0}$. (Other restrictions may be imposed as well.)

Among the useful results of this formulation is a posterior estimate of the probabilities of particular group membership; using Bayes theorem,

$$P(j \mid i) = P(i, j) / P(i)$$

$$= \frac{P(i \mid j)F_{ij}}{\sum_{j=1}^{J} P(i \mid j)F_{ij}}$$

Using this result, we compute j^* = the index of the group with the highest posterior probability. The predicted values, residuals, and predicted probabilities for the observed outcomes are then computed as those associated with group j^*. That is, for example,

$$\text{Fitted value}_{it} = \lambda_{it|j^*} = \exp(\boldsymbol{\beta}_{j^*}'\mathbf{x}_{it})$$

and so on.

Maximization of the log likelihood does not require any unusual techniques or approaches. (Some authors, e.g., Cockburn (1999) have used the EM algorithm for a Poisson model of this sort, but this is a means to an end, not a necessity. We have found that the conventional approach used here works without problems, and is much simpler.) The gradient of the log likelihood function is

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}_j} = \sum_{i=1}^{N} \frac{1}{P_i} F_j P_{i|j} \sum_{t=1}^{T_i} \frac{\partial \log P_{it|j}}{\partial \boldsymbol{\beta}_j}$$

$$\frac{\partial \log L}{\partial \boldsymbol{\theta}_j} = \sum_{i=1}^{N} \frac{1}{P_i} \sum_{m=1}^{J} P_{i|m} F_{im} [1(m=j) - F_j]\mathbf{z}_i$$

The gradients in the first term are $(y_{it} - \lambda_{it|j})\mathbf{x}_{it}$ for the Poisson model and $[\tau_j(y_{it} + q_{it|j}) - \tau_j]\,\mathbf{x}_{it}$ where θ_j is the overdispersion parameter and $q_{it|j} = \tau_j/(\tau_j + \lambda_{it|j})$ for the negative binomial model. The BHHH estimator is used for estimating the asymptotic covariance matrix of the maximum likelihood estimates.

E44.8 GMM Estimators for Count Models with Panel Data

This section develops *LIMDEP* commands to compute GMM estimators for panel data count data models See Blundell, Griffith, and Windmeijer (2002) and also Romeu (2004) for a review of Windmeijer's software that does this. These are not hard coded in *LIMDEP*, but can be directly implemented with trivial changes to the programs listed below. The reader is referred to the articles for theoretical development of the models. The remainder of this section presents the *LIMDEP* code for estimation.

Step 1. Set up the data. The Rhs variables in the model are assumed to be *xa*,*xb*,*xc*,... We assume for the illustration below that this is *xa*,*xb*,*xc*,*xd*,*xe*. The Lhs variable is *y*.

Step 2. Create lagged values of all variables. Use namelists *x* for the current Rhs values and *x*1 for the lagged values. Variables *y* and *y*1 are the current lagged values of the dependent variable.

Step 3. Set up panel data indicators such that variable *t* is the period number. The panel need not be balanced. Also set up the usual group count variable, called, say, *ti*. We also need the group identifier. This would normally be *_stratum* created by the panel estimator. We'll call it *group* where needed below.

The data setup commands for our constructed example are as follows:

```
NAMELIST ; x = xa,xb,xc,xd,xe $
CREATE   ; xa1 = xa[-1] ; xb1 = xb[-1] ; xc1 = xc[-1]
         ; xd1 = xd[-1] ; xe1 = xe[-1]$
CREATE   ; y1= y[-1]$
NAMELIST ; x1 = xa1,xb1,xc1,xd1,xe1 $
```

The sample must also be set to eliminate the lost observation due to the lagging.

```
SAMPLE   ; 2 - n $
```

Step 4. If the models are being estimated using instrumental variables, define namelists for these as well.

```
NAMELIST ; z = za,zb,zc,zd,ze,zf $ ... the list of instrumental variables $
```

Estimators are shown for four model groups: cross sections, panel data, presample means and linear feedback models, respectively. Throughout, the nomenclature used is based on Romeu's Table 1. The table has two columns of model definitions, which we label A and B. In the A column, there are six models, which we label 1A,...,6A. In the second column, we, use 1B, 2B, 3B1, 3B2, 4B1, 4B2, 5B and 6B.

E44.8.1 Cross Section Estimators

For a model with exogenous or predetermined regressors, we use the whole sample. With additive errors, treat it as a cross section, Poisson regression – Models 1A and 3A.

```
SAMPLE     ; All $
POISSON    ; Lhs = y ; Rhs = x $
```

This is for exogenous or predetermined regressors and multiplicative errors, Models 2A and 4A.

```
POISSON    ; Lhs = y ; Rhs = x $
GMME       ; Start = b ; Labels = b1,b2,b3,b4,b5
           ; Fn1 = (y-exp(x'b1))/exp(x'b1) * xa
           ; Fn2 = (y-exp(x'b1))/exp(x'b1) * xb
           ; Fn3 = (y-exp(x'b1))/exp(x'b1) * xc
           ; Fn4 = (y-exp(x'b1))/exp(x'b1) * xd
           ; Fn5 = (y-exp(x'b1))/exp(x'b1) * xe $
```

With endogenous regressors, the number of equations changes to the number of instrumental variables. Assumed here to be *za,zb,zc,zd,ze,zf*. These are overidentified so we use a two step estimator. The two routines are for additive (Model 5A) and multiplicative errors (Model 6A), respectively.

```
POISSON    ; Lhs = y ; Rhs = x $
GMME       ; Start = b ; Labels = b1,b2,b3,b4,b5
           ; Fn1 = (y-exp(x'b1)) * za ; Fn2 = (y-exp(x'b1)) * zb
           ; Fn3 = (y-exp(x'b1)) * zc ; Fn4 = (y-exp(x'b1)) * zd
           ; Fn5 = (y-exp(x'b1)) * ze ; Fn6 = (y-exp(x'b1)) * zf $
MATRIX     ; optimal w = <sigma> $
GMME       ; Start = b ; Labels = b1,b2,b3,b4,b5 ; sigma = optimal w
           ; Fn1 = (y-exp(x'b1)) * za ; Fn2 = (y-exp(x'b1)) * zb
           ; Fn3 = (y-exp(x'b1)) * zc ; Fn4 = (y-exp(x'b1)) * zd
           ; Fn5 = (y-exp(x'b1)) * ze ; Fn6 = (y-exp(x'b1)) * zf $
```

This is for the multiplicative errors model.

```
POISSON    ; Lhs = y ; Rhs = x $
GMME       ; Start = b ; Labels = b1,b2,b3,b4,b5
           ; Fn1 = (y-exp(x'b1))/exp(x'b1) * za
           ; Fn2 = (y-exp(x'b1))/exp(x'b1) * zb
           ; Fn3 = (y-exp(x'b1))/exp(x'b1) * zc
           ; Fn4 = (y-exp(x'b1))/exp(x'b1) * zd
           ; Fn5 = (y-exp(x'b1))/exp(x'b1) * ze
           ; Fn6 = (y-exp(x'b1))/exp(x'b1) * zf $
MATRIX     ; optimal w = <sigma> $
GMME       ; Start = b ; Labels = b1,b2,b3,b4,b5 ; sigma = optimal w
           ; Fn1 = (y-exp(x'b1))/exp(x'b1) * xa
           ; Fn2 = (y-exp(x'b1))/exp(x'b1) * xb
           ; Fn3 = (y-exp(x'b1))/exp(x'b1) * xc
           ; Fn4 = (y-exp(x'b1))/exp(x'b1) * xd
           ; Fn5 = (y-exp(x'b1))/exp(x'b1) * xe $
```

E44.8.2 Panel Data Estimators

The panel data estimators for exogenous regressors are not valid with multiplicative errors. (This is cell 2B (no model) in Romeu’s table.) With additive errors, the estimator is the familiar fixed effects estimator, Model 1B.

```
POISSON    ; Lhs = y ; Rhs = x  ; Panel  ; FEM $
```

For additive errors with predetermined and endogenous regressors and also for multiplicative errors, create the instrumental variables from the current and lagged values of z. Collect these in namelist *z*. For the examples, *z* = *z*1,*z*2,*z*3,*z*4,*z*5,*z*6,*z*7. There are some differences across cases in the specific instrumental variables used. Lose an observation in each group because of the lagging.

```
REJECT     ; t = 1 $
```

These are the Chamberlain forms, 3B1 and 4B1 and corresponding dynamic forms

```
POISSON    ; Lhs = y ; Rhs = x $
GMME       ; Start = b ; Labels = b1,b2,b3,b4,b5
           ; Fn1 = (y*exp(x1'b1)/exp(x'b1) - y1) * z1
           ; Fn2 = (y*exp(x1'b1)/exp(x'b1) - y1) * z2
           ; Fn3 = (y*exp(x1'b1)/exp(x'b1) - y1) * z3
           ; Fn4 = (y*exp(x1'b1)/exp(x'b1) - y1) * z4
           ; Fn5 = (y*exp(x1'b1)/exp(x'b1) - y1) * z5
           ; Fn6 = (y*exp(x1'b1)/exp(x'b1) - y1) * z6
           ; Fn7 = (y*exp(x1'b1)/exp(x'b1) - y1) * z7 $
MATRIX     ; optimal w = <sigma> $
GMME       ; Start = b ; Labels = b1,b2,b3,b4,b5 ; sigma = optimal w
           ; Fn1 = (y*exp(x1'b1)/exp(x'b1) - y1) * z1
           ; Fn2 = (y*exp(x1'b1)/exp(x'b1) - y1) * z2
           ; Fn3 = (y*exp(x1'b1)/exp(x'b1) - y1) * z3
           ; Fn4 = (y*exp(x1'b1)/exp(x'b1) - y1) * z4
           ; Fn5 = (y*exp(x1'b1)/exp(x'b1) - y1) * z5
           ; Fn6 = (y*exp(x1'b1)/exp(x'b1) - y1) * z6
           ; Fn7 = (y*exp(x1'b1)/exp(x'b1) - y1) * z7 $
```

The Wooldridge forms 3B2, 4B2 and 5B, differ in the choices of instruments and the dynamic form of the model.

```
POISSON     ; Lhs = y ; Rhs = x $
GMME        ; Start = b ; Labels = b1,b2,b3,b4,b5
            ; Fn1 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z1
            ; Fn2 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z2
            ; Fn3 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z3
            ; Fn4 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z4
            ; Fn5 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z5
            ; Fn6 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z6
            ; Fn7 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z7 $
MATRIX      ; optimal w = <sigma> $
GMME        ; Start = b ; labels = b1,b2,b3,b4,b5 ; sigma = optimal w
            ; Fn1 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z1
            ; Fn2 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z2
            ; Fn3 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z3
            ; Fn4 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z4
            ; Fn5 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z5
            ; Fn6 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z6
            ; Fn7 = (y/exp(x'b1) - y1/exp(x1'b1) ) * z7 $
```

E44.8.3 Presample Means Estimators

The presample is defined as observations 1 to t_0. The sample is $t_1 = t_0+1$ to t.

```
SAMPLE      ; All $
REJECT      ; t  >  t0  $
MATRIX      ; pmeans = Gxbr(y,group) $
SAMPLE      ; All $
CREATE      ; logpmi = Log(pmeans(group)) $
REJECT      ; t < t1 $
POISSON     ; Lhs = y ; Rhs = x,logpmi $
GMME        ; Start = b ; Labels = b1,b2,b3,b4,b5,f
            ; Fn1 = (y-exp(x'b1-f*logpmi)) * xa
            ; Fn2 = (y-exp(x'b1-f*logpmi)) * xb
            ; Fn3 = (y-exp(x'b1-f*logpmi)) * xc
            ; Fn4 = (y-exp(x'b1-f*logpmi)) * xd
            ; Fn5 = (y-exp(x'b1-f*logpmi)) * xe
            ; Fn6 = (y-exp(x'b1-f*logpmi)) * logpmi $
MATRIX      ; optimal w = <sigma> $
GMME        ; Start = b ; Labels = b1,b2,b3,b4,b5 ; sigma = optimal w
            ; Fn1 = (y-exp(x'b1-f*logpmi)) * xa
            ; Fn2 = (y-exp(x'b1-f*logpmi)) * xb
            ; Fn3 = (y-exp(x'b1-f*logpmi)) * xc
            ; Fn4 = (y-exp(x'b1-f*logpmi)) * xd
            ; Fn5 = (y-exp(x'b1-f*logpmi)) * xe
            ; Fn6 = (y-exp(x'b1-f*logpmi)) * logpmi $
```

E44.8.4 Panel Data Linear Feedback Model Estimators

The linear feedback forms use the second lag of y. The lagged value is created, then the sample is restricted to the useable observations.

```
SAMPLE    ; All $
CREATE    ; y2 = y[-2] $
REJECT    ; t <= 2 $
```

This is the Chamberlain form, 3B1 and 4B1, and the dynamic form

```
POISSON   ; Lhs = y ; Rhs = x,y1 $
GMME      ; Start = b,0 ; Labels = b1,b2,b3,b4,b5,c
          ; Fn1 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z1
          ; Fn2 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z2
          ; Fn3 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z3
          ; Fn4 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z4
          ; Fn5 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z5
          ; Fn6 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z6
          ; Fn7 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z7 $
MATRIX    ; optimal w = <sigma> $
GMME      ; Start = b ; Labels = b1,b2,b3,b4,b5,c ; sigma = optimal w
          ; Fn1 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z1
          ; Fn2 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z2
          ; Fn3 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z3
          ; Fn4 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z4
          ; Fn5 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z5
          ; Fn6 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z6
          ; Fn7 = ((y-c*y1)*exp(x1'b1)/exp(x'b1) - (y1-c*y2)) * z7 $
```

This is the Wooldridge form for 3B2, 4B2 and 5B.

```
POISSON   ; Lhs = y ; Rhs = x $
GMME      ; Start = b,0 ; Labels = b1,b2,b3,b4,b5,c
          ; Fn1 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z1
          ; Fn2 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z2
          ; Fn3 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z3
          ; Fn4 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z4
          ; Fn5 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z5
          ; Fn6 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z6
          ; Fn7 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z7 $
MATRIX    ; optimal w = <sigma> $
GMME      ; Start = b ; Labels = b1,b2,b3,b4,b5,c ; sigma = optimal w
          ; Fn1 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z1
          ; Fn2 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z2
          ; Fn3 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z3
          ; Fn4 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z4
          ; Fn5 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z5
          ; Fn6 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z6
          ; Fn7 = ((y-c*y1)/exp(x'b1) - (y1-c*y2)/exp(x1'b1) ) * z7 $
```

E45: The Tobit Model for Censored Data

E45.1 Introduction

The model and estimators described in this chapter is based on the following general structure:

Latent Underlying Regression: $y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ \varepsilon_i \sim N[0,\sigma^2]$.

Observed Dependent Variable: if $y_i^* \leq L_i$, then $y_i = L_i$ (lower tail censoring)

if $y_i^* \geq U_i$, then $y_i = U_i$ (upper tail censoring)

if $L_i < y_i^* < U_i$, then $y_i = y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i$.

Various modifications of the model are considered in the sections to follow. Within this framework, the most familiar form is the lower censoring only, at zero variant. Truncation, in which only data in the third group are observed, is a related case which is discussed in Chapter E47. In practice, most of the received applications involve censoring, rather than truncation. The thresholds, L_i and U_i, may be constants or variables. We accommodate censoring in the upper or lower (or both) tails of the distribution. The most familiar case of this model in the literature is the 'tobit' model, in which $U_i = +\infty$ and $L_i = 0$, i.e., the case in which the observed data contain a cluster of zeros. In the standard 'censored regression,' or tobit model, the censored range of y_i^* is the half of the line below zero. (For convenience, we will drop the observation subscript at this point.) If y^* is not positive, a zero is observed for y, otherwise the observation is y^*. Models of expenditure are typical. We also allow censoring of the upper tail ('on the right'). A model of the demand for tickets to sporting events might be an application, since the actual demand is only observed if it is not more than the capacity of the facility (stadium, etc.). A somewhat more elaborate specification is obtained when the range of y^* is censored in both tails. This is the 'two limit probit' model. An application might be a model of weekly hours worked, in which less than half time is reported as 20 and more than 40 is reported as 'full time,' i.e., 40 or more.

The preceding gives the basic model. We also allow for several variations, including a model with heteroscedasticity, models for panel data, two different models of sample selection, and models with nonnormally distributed disturbances. Numerous variants and features of this model are gathered in Chapter E47. The basic model is developed in this chapter.

NOTE: The mere presence of a clump of zeros in the data set does not, by itself, adequately motivate the tobit model. The specification of the model also implies that the nonlimit observations will have a continuous distribution with observations near the limit points. In general, if you try to fit a tobit model, e.g., to financial data in which there is a clump of zeros, and the nonzero observations are ordinary financial variables far from zero, the model is as likely as not to break down during estimation. In such a case, the model of sample selection is probably a more appropriate specification.

The current theoretical literature contains a large amount of material devoted to semiparametric and nonparametric estimation of censored data models. See, e.g., the work of Bo Honoré. (www.princeton.edu/~honore). Section E45.10 provides an estimator for Powell's symmetrically censored least squares estimator at the end of this chapter.

E45.2 Commands

The basic command for estimation of the censored regression, or tobit model is

TOBIT ; Lhs = y ; Rhs = ... $

The default value for the censoring limit is zero, at the left (i.e., the familiar case). Censoring limits can be varied in two fashions. To specify upper, rather than lower tail censoring, add

; Upper

to the model. With no other changes, this would specify a model in which the observed values of the dependent variable would be either zero or negative rather than zero or positive. The specific limit point to use can be changed by using

; Limit = limit value

where '**limit value**' is either a fixed value (number or scalar) or the name of a variable. For example, the model of the demand for sporting events at stadiums with fixed capacities which sell out a significant proportion of the time might be

TOBIT ; Lhs = tickets
; Rhs = one, price, ...
; Upper censoring
; Limit = capacity $

Models with censoring in both tails of the distribution are requested by changing the **; Limit** specification to

; Limits = lower limit, upper limit

where '**lower limit**' and '**upper limit**' are either numbers, scalars, or the names of variables (or one of each). For example, in a labor supply model, we might have

; Limits = 20,40

NOTE: A few of the variants of the tobit model discussed below do not allow variation in the specification of the censoring limits. In particular, in the *nested and bivariate tobit*, and the *sample selection models*, only the default case of censoring from below (at the left) at zero is supported. In these cases, a **; Limit = value** specification will be ignored. For these models, if your censoring is *upper*, instead, multiply the dependent variable by -1, then reverse the signs of the coefficients after estimation. If censoring is at a nonzero value, subtract this value from the Lhs variable before estimation and before the sign switch above.

Starting values for estimation are obtained by ordinary least squares regression of the dependent variable on the regressors. A full set of OLS results is given before any other output is displayed if you request it with **; OLS**. As has been widely documented, these OLS estimates are inconsistent in this setting (usually biased toward zero). The results are presented for comparison purposes only; the actual OLS coefficients are not used for any other purposes by this program. If you do not provide other starting values, the OLS estimates, [$\mathbf{b}$,s] of [$\boldsymbol{\beta}$,σ], are used to begin the iterations.

You may provide your own starting values with

; Start = values for β then σ

The least squares estimates are followed by the iterations.

You may impose fixed value and within equation equality constraints on the coefficients by using the

; Rst = specification

Other restrictions may be imposed with

; CML: specification of linear restrictions

These are discussed in Chapter R13. Note, once again, the parameters that enter this model are $[\beta_1,\beta_2,...,\beta_K,\sigma]$. If you use these options, you must provide exactly K+1 identifiers for the parameters. As in all models, the option will allow you to constrain the variance to equal one of the slopes, but this is likely to impede convergence, and is unlikely to produce a satisfactory model specification.

During the iterations, the parameters are transformed using Olsen's (1978) transformation,

$$[\boldsymbol{\gamma}, \theta] = [\boldsymbol{\beta}/\sigma, 1/\sigma].$$

If you are generating technical output from the iterations in your output file, the reported parameter vector will be scaled. It is unscaled when the iterations are complete. Maximum likelihood estimates are displayed at exit from the iterations. This will include a table of diagnostic statistics and some notation about the specific model along with the standard output. The MLE of σ will appear with the other parameter estimates. The display includes the log likelihood, the values or identity of the lower and upper bounds, and the estimates of $[\boldsymbol{\beta},\sigma]$. As usual, the ancillary parameter, σ, is included with the rest of the estimated parameter vector in the output table.

Other options for the tobit model are the standard ones for nonlinear models, including

; Covariance Matrix	to display the estimated asymptotic covariance matrix, same as **; Printvc**.
; List	to display predicted values
; Parameters	to include the estimate of σ in the retained parameter vector
; Maxit = n	to set maximum iterations
; Alg = name	to select algorithm
; Tlf, ; Tlb, ; Tlg	to set the convergence criteria (use **; Set** to keep these settings)
; Output = value	to control the technical output during iterations
; Keep = name	to retain fitted values
; Res = name	to retain residuals
; Partial Effects	

and so on. Sample clustering for the estimated asymptotic covariance matrix may be requested with

; Cluster = specification.

E45.3 Results for the Tobit Model

You may request the display of ordinary least squares results by adding

; OLS

to the command. These will be suppressed if you do not include this request. The OLS values will be used as the starting values for the iterations. Maximum likelihood estimates are presented, as in the example below. Note that unlike most of the discrete choice models, there is no restricted log likelihood presented. The maximum likelihood estimates for a model that contains only a constant term are no less complicated than one with covariates, and there is no closed form solution for the (β,σ) parameter pair for this model. For a general test of the joint significance of all the variables in the model, we suggest the standard trio of tests, which can be carried out as follows: First set up the Rhs variables in the model.

```
NAMELIST    ; xvars = the x variables in the model, without the constant term $
CALC        ; kx  = Col(xvars) $
TOBIT       ; Lhs = y ; Rhs = one $
CALC        ; l0 = logl $
```

This command will produce the Lagrange multiplier statistic.

```
TOBIT       ; Lhs = y ; Rhs = xvars,one ; Start = kx_0,b,s ; Maxit = 0 $
TOBIT       ; Lhs = y ; Rhs = xvars,one $
```

Compute the likelihood ratio statistic.

```
CALC        ; List ; lr = 2*(logl - l0) ; 1 - Chi(lr,kx) $
```

This computes a Wald statistic.

```
MATRIX      ; beta = b(1:kx) ; vb = varb(1:kx,1:kx)
            ; List ; Wald = beta'<vb>beta $
CALC        ; List ; 1 - Chi(wald,kx) $
```

The application below demonstrates use of the commands. Retained output from the model includes

Matrices: *b*, *varb*

Scalars:

s	= estimated σ
ybar, *sy*, *kreg*	= number of coefficients,
nreg	= number of observations
nonlimts	= number of nonlimit observations in estimating sample

Variables: *logl_obs*, *genres_1*, *genres_2*

Last Model: *b_variable names*, *sigma*

Last Function: E[y|$\mathbf{x}$] – see the development in the next section.

The diagnostic information for the model also includes Fin and Schmidt's LM test for the model specification against the alternative suggested by Cragg as well as a test for nonnormality. The tests are described in Sections E45.9.2 and E45.9.3.

E45.4 Partial Effects

The partial effects in the tobit model when censoring is at the left, at zero, are computed using

$$E[y|\mathbf{x}] = \Phi(\boldsymbol{\beta}'\mathbf{x}/\sigma)[\boldsymbol{\beta}'\mathbf{x} + \sigma\phi(\boldsymbol{\beta}'\mathbf{x}/\sigma)/\Phi(\boldsymbol{\beta}'\mathbf{x}/\sigma)].$$

After some algebra, we find

$$\partial E[y|\mathbf{x}]/\partial\mathbf{x} = \Phi(\boldsymbol{\beta}'\mathbf{x}/\sigma)\boldsymbol{\beta}.$$

The preceding is a broad result which carries over to more general models. That is,

$$\partial E[y|\mathbf{x}]/\partial\mathbf{x} = \text{Prob(nonlimit)}\boldsymbol{\beta}$$

for all specifications of the censoring limits, whether in one tail or both. To obtain a display of the marginal effects for the tobit model, add

; Partial Effects

to the **TOBIT** command. A full listing of the marginal effects computed at the sample means, including standard errors, the estimated conditional mean, and the scale factor, will be included in the model output. An example appears below. The partial effects for the tobit model can be obtained with

```
NAMELIST    ; x = the Rhs of the model $
PARTIALS    ; Effects: x ; Means ; Summary $
```

By using the average partial effects instead – omit the **; Means** – you can use the full range of options with the **PARTIALS** and **SIMULATE** commands.

E45.4.1 Notes About Partial Effects in the Tobit Model

The conditional mean function for the latent variable is the latent regression,

$$E[y_i^* \mid \mathbf{x}_i] = \mathbf{x}_i'\boldsymbol{\beta}.$$

In analysis of this regression for prediction purposes or for analysis of partial effects,

$$m_k^* = \partial E[y_i^* \mid \mathbf{x}_i]/\partial x_{ik} = \beta_k$$

is treated as is normally done in conventional linear regression analysis. Standard errors and confidence intervals for predictions of the conditional mean,

$$\hat{E}[y_i^* \mid \mathbf{x}_i] = \mathbf{x}_i'\hat{\boldsymbol{\beta}}$$

and estimates of marginal effects,

$$\hat{m}_k{}^* = \hat{\beta}_k$$

are computable using conventional forms and the estimated asymptotic covariance matrix for the maximum likelihood estimators.

The more difficult computation involves the conditional mean function for the observed random variable, y_i. This is

$$E[y_i \mid \mathbf{x}_i] = [1\text{-}\Phi(\alpha_i)]L_i + \Phi(\alpha_i)\times [\mathbf{x}_i'\boldsymbol{\beta} + \sigma\, \lambda(\alpha_i)].$$

For this conditional mean, the marginal effects are surprisingly simple,

$$m_k = \partial E[y_i \mid \mathbf{x}_i] / \partial x_{ik} = \beta_k \times [1 - \Phi(\alpha_i)].$$

We note at this point a general result that we will use later. It is shown in Greene (1999) that the simple result

marginal effect = coefficient × probability of noncensored observation

is general for censoring in either or both tails of the distribution, *and extends beyond the normal distribution to any continuous distribution for* ε.

E45.4.2 Partial Effect for a Dummy Variable

Typical applications of the censored regression model involve discrete independent variables, often binary variables indicating presence or absence of a condition or whether or not some treatment was experienced. In our application below, we include a dummy variable for whether there are children in the home and whether or not the individual lives in a city. Whether differentiation of the conditional mean provides an accurate measure of the marginal impact of presence or absence of a treatment, or for some other dummy variable, depends on the variables in the model and other factors. Generally, the result will only be approximate, and the correct computation would be

$$\begin{aligned}\text{Impact} &= E[y_i \mid \mathbf{x}_i^1] - E[y_i \mid \mathbf{x}_i^0] \\ &= [1\text{-}\Phi(\alpha_i^1)]L_i + \Phi(\alpha_i^1) \times [\mathbf{x}_i^{1\prime}\boldsymbol{\beta} + \sigma\, \lambda(\alpha_i^1)] - \\ &\quad [1\text{-}\Phi(\alpha_i^0)]L_i + \Phi(\alpha_i^0) \times [\mathbf{x}_i^{0\prime}\boldsymbol{\beta} + \sigma\, \lambda(\alpha_i^0)],\end{aligned}$$

where the superscripts ‘1’ and ‘0’ indicate that in the computation, the dummy variable in the vector $\mathbf{x}_i$ takes values 1 and 0, respectively. Because it uses the means of the data, the internal calculation of partial effects does not accommodate this feature of the data. You should use **PARTIALS** to obtain the partial effects for the tobit model. The example below demonstrates.

E45.5 Predictions and Fit Measures

A listing of predictions is requested with

; List

The predictions and residuals are retained with

; Keep = name to retain predicted values
and **; Res = name** to retain residuals

There is a possible ambiguity in the computation of predictions in this model. Consider, first, the classical normal regression model with standard deviation σ_i. (We do this to avoid having to treat separately the tobit model with heteroscedasticity.) The conditional mean function is

$$E[y_i \mid \mathbf{x}_i] = \boldsymbol{\beta}'\mathbf{x}_i.$$

But, if y_i is restricted to the range $[L_i,U_i]$, the conditional mean becomes

$$E[y_i|\mathbf{x}_i , L_i < y_i < U_i] = \boldsymbol{\beta}'\mathbf{x}_i + \sigma_i \frac{\phi_L - \phi_U}{\Phi_U - \Phi_L}$$

where $\phi_j = \phi[(j - \boldsymbol{\beta}'\mathbf{x}_i) / \sigma_i], j = L_i,U_i$

and $\Phi_j = \Phi[(j - \boldsymbol{\beta}'\mathbf{x}_i) / \sigma_i], j = L_i,U_i$.

(This is the conditional mean function for the truncated regression model in Section E47.4.) With censoring in only one tail, either L_i will be $-\infty$ or U_i will be $+\infty$, in which case, ϕ_j will equal zero and Φ_j will be zero (for L_i) or one (for U_i). For the tobit model, then,

$$E[y_i{*}\mathbf{x}_i] = L_i\text{Prob}[y_i = L_i] + U_i\text{Prob}[y_i = \text{U}_i] + \text{Prob}[L_i < y_i < U_i]\text{E}[y_i \mid L_i < y_i < U_i].$$

This is $L_i\Phi_L + U_i(1 - \Phi_U) + (\Phi_U - \Phi_L)\boldsymbol{\beta}'\mathbf{x}_i + \sigma_i(\phi_L - \phi_U)$.

LIMDEP reports this as the prediction for the tobit model. Once again, in the case of censoring in only one tail, one of the densities is zero, and one of the tail probabilities is either zero or one.

The prediction displayed by **; List** and retained with **; Keep = name** is the conditional mean function listed above. We emphasize, *the prediction is not* $\boldsymbol{\beta}'\mathbf{x}$. The residual that is kept with **; Res** is the difference between actual and predicted values. If you require the linear index, you can obtain it with

```
NAMELIST   ; x = ... the Rhs for your tobit model $
TOBIT      ; Lhs = ... ; Rhs = x $
CREATE     ; xb = x ' b $
```

With **; List** the two additional variables displayed are the estimate of $\boldsymbol{\beta}'\mathbf{x}$ and the estimate of $[\Phi_U - \Phi_L]$. The latter is the estimated probability that the observation is a nonlimit observation. A different kind of residual, Chesher and Irish's (1987) 'generalized residual,' is discussed in Section E45.9.4.

You may use **SIMULATE** to analyze the predictions in the tobit model. The function analyzed by **SIMULATE** is the conditional mean function given earlier.

As in any nonlinear model, there is no obvious, well behaved counterpart to the R^2 in a linear regression (with a constant term) which is fit by ordinary least squares. Many surrogates have been suggested. A lengthy catalog appears in Veall and Zimmermann (1992). These are largely of three types:

1. Correlations between actual and predicted values for the nonlimit observations: Variations on two themes are suggested, one based on the squared correlation of the actual values of y_i and the predictions of y^*, $\hat{E}[y_i^*|\mathbf{x}_i] = \mathbf{x}_i'\hat{\boldsymbol{\beta}}$ and one based on the squared correlation of the actual values of y_i and the predictions of $y_i^*|(y_i^* > L_i)$, $\hat{E}[y_i^*|\mathbf{x}_i, y_i^* > L_i] = \mathbf{x}_i'\hat{\boldsymbol{\beta}} + \hat{\sigma}\lambda(\hat{\alpha}_i)$. The obvious defect here is that the limit observations are not included in the computation. But, this presents a bit of a dilemma. Simply including the limit observations in the computation would not solve the problem, because the 'fit' aspect in the limit range of the distribution is the model's ability to predict that an observation will be a limit observation, not its ability to predict the limit value, itself.

2. Mixtures of the correlations in type 1 above and the predicted probabilities for the limit observations: These represent an attempt to cover the defect in type 1. Ultimately, these measures end up mixing residuals in the nonlimit observations, which are of the scale of the observed continuous responses with residuals in the limit observations, which are

   $$e_i^0 = (1-d_i) - \Phi(\hat{\alpha}_i) = -\Phi(\hat{\alpha}_i).$$

   The authors of the survey appear skeptical of these measures, perhaps appropriately so.

3. Transformations of the log likelihood function which are bounded by zero and one: The primary virtue of these measures is that they are bounded and usually improve as the model improves. The most widely used is McFadden's

   pseudo-R2' = 1 - logL/logL0,

   where the latter is for a model with only a constant term. Since this mimics behavior of the log likelihood function, itself, the value added of the normalization seems modest. *The measures do not relate to a proportion of variation explained*, and they only range from zero to one because of the normalization. On the other hand, for purposes of comparing two models, one of which is nested within the other, the difference in the pseudo-R^2s will be a simple function of the likelihood ratio statistic that could be used to test the hypothesis of the restrictions. Of course, since this is the case, one might want to proceed directly to the likelihood ratio statistic and not bother with the 'fit measures.'

The authors of the survey suggest two criteria for fit measures: They should, at least roughly, mimic the OLS-R^2, and they should converge to the OLS-R^2 as the censoring probability goes to zero (since, in this case, the model converges to a linear regression model). The fit measures suggested earlier are based on the continuous data. However, prediction of the limit values is part of the purpose of the model. With that in mind, *LIMDEP* presents two alternatives which appear to satisfy the first criterion, and do meet the second:

$$R^2_{ANOVA} = \frac{\frac{1}{n}\sum_{i=1}^{n}\left(\hat{y}_i - \overline{\hat{y}}\right)^2}{\frac{1}{n}\sum_{i=1}^{n}\left(y_i - \overline{y}\right)^2} = \frac{\text{Var[predicted conditional mean]}}{\text{Var[dependent variable]}}$$

and

$$R^2_{DECOMPOSITION} = \frac{\frac{1}{n}\sum_{i=1}^{n}\left(\hat{y}_i - \overline{y}\right)^2}{\frac{1}{n}\sum_{i=1}^{n}\left(\hat{y}_i - \overline{y}\right)^2 + \frac{1}{n}\sum_{i=1}^{n}\left(y_i - \hat{y}_i\right)^2}$$

$$= \frac{\text{Variation of predicted mean}}{\text{Variation of predicted mean} + \text{Residual variation}}$$

Both measures use the full sample of observations. In both cases, the conditional mean function, or prediction is $E[y_i \mid \mathbf{x}_i] = [1-\Phi(\alpha_i)]L_i + \Phi(\alpha_i)\times[\mathbf{x}_i'\boldsymbol{\beta} + \sigma\,\lambda(\alpha_i)]$. The first fit measure takes the variance of the estimated conditional mean divided by the variance of the observed variable. In the population, for any $\mathbf{x}_i$, the total variance equals the variance of the conditional mean plus the residual variance. The numerator estimates a sample average of the first of these while the denominator averages the sum of the two. The second measure takes the variance of the conditional mean function around the overall mean of the data in the numerator. The denominator contains the sum of the numerator and a residual variance, the true value minus the conditional mean function. In a linear regression, both measures equal R^2 by construction. (*Note that the second does not equal zero in a model with only a constant*.)

E45.6 Robust and Cluster Corrected Covariance Matrix

Generally, the objective of a robust covariance matrix estimator is to use an estimator of the asymptotic covariance matrix of the MLE that is robust to certain misspecifications of the model. The estimator typically used is the 'sandwich' estimator, $\mathbf{V} = \mathbf{H}^{-1} \times \mathbf{BHHH} \times \mathbf{H}^{-1}$, where **H** is the negative of the second derivatives matrix of the log likelihood function and **BHHH** is the Berndt et al. outer products of first derivatives estimator. Under certain circumstances (see Greene (2011)), the MLE is consistent in the presence of certain misspecifications of the model, though the standard estimators of the asymptotic covariance matrix is inappropriate. The sandwich estimator provides the needed correction. However, the maximum likelihood estimators of the coefficients in the censored regression models are inconsistent in the presence of

- heteroscedasticity
- omitted variables, even if they are orthogonal to the included ones,
- incorrect assumption of the normal distribution,
- incorrect functional form,
- measurement error,
- fixed effects in panel data (omitted variables),
- random effects in a panel data (autocorrelation).

That leaves very little for the robust estimator to be robust to. One possibility is unobserved heterogeneity in a cross section, but only if it is orthogonal to the included variables. It is difficult to construct a case for the estimator – for example, this model is quite far removed from the linear exponential families analyzed by Gourieroux, Monfort, and Trognon (1984). In the end, for better or worse, the specification of the censored normal regression model is fairly fragile, and robust estimation of the asymptotic covariance is essentially a moot point.

The preceding notwithstanding, there are two robust covariance matrices obtainable with the tobit estimator. The **; Cluster** specification provides both. The ordinary sandwich estimator can be obtained with

; Cluster = 1

while if you have clustered data, use

; Cluster = fixed number of observations or stratification variable

The estimator for stratified and clustered data that uses

; Stratum = specification

is also supported. Details appear in Section R10.2.

E45.7 Application of the Tobit Model

We will demonstrate a few of the tobit estimators and carry out some specification tests and secondary analyses of the models. The data used are the Mroz (1987) data on female labor supply. This data set contains 753 observations on women's labor market experience. (The data are provided in data file Mroz.dat.)

The data file is taken from the 1976 panel study of income dynamics, and is based on data for the previous year, 1975. Of the 753 observations, the first 428 are for women with positive hours worked in 1975, while the remaining 345 observations are for women who did not work for pay in 1975. The listing below lists a few observations to illustrate. There are 19 variables in the data set and one which is to be constructed from the data read in:

lfp = a dummy variable = 1 if woman worked in 1975, else 0
whrs = wife's hours of work in 1975
kl6 = number of children less than 6 years old in household
k618 = number of children between ages 6 and 18 in household
wa = wife's age
we = wife's educational attainment, in years
ww = wife's average hourly earnings, in 1975 dollars
rpwg = wife's wage reported at the time of the 1976 interview
hhrs = husband's hours worked in 1975
ha = husband's age
he = husband's educational attainment, in years
hw = husband's wage, in 1975 dollars
faminc = family income, in 1975 dollars
mtr = marginal tax rate facing the wife
wmed = wife's mother's educational attainment, in years
wfed = wife's father's educational attainment, in years
un = unemployment rate in county of residence, in percentage points
cit = dummy variable = 1 if live in large city (SMSA), else 0
ax = actual years of wife's previous labor market experience
prin = *faminc* - (*whrs***ww*) = wife's property income (computed)

The likelihood ratio statistic is computed using the log likelihood from the full model and the log likelihood from the model with only a constant term. The statistic equals 102.1957013.

```
 [CALC] LR      =    102.1957013
```

E45.8 Technical Details

Estimation of the censored regression model is quite routine. For fully parametric specifications – that is, in which the full distribution is specified, maximum likelihood is the accepted method. The likelihood is formulated as follows: For observations which are censored, terms in the log likelihood are the probability of observing the discrete value. For uncensored observations, the term is the usual one, the density for the continuous random variable. Thus, for the censored normal regression model with censoring only in the lower tail,

$$\log L = \sum_{Observations\ with\ y_i = L_i} \log\Phi\left(\frac{L_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) + \sum_{Observations\ with\ y_i = y_i*} \log\left[\frac{1}{\sigma}\phi\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)\right].$$

The model is estimated using Olsen's (1978) transformation of the parameters, $\theta = 1/\sigma$ and $\boldsymbol{\gamma} = (1/\sigma)\boldsymbol{\beta}$. Let $d_i = 1$ for the noncensored observations and 0 otherwise. Then, the log likelihood simplifies to

$$\log L = \sum_{d_i=0} \log\Phi\left(\theta L_i - \mathbf{x}_i'\boldsymbol{\gamma}\right) + \sum_{d_i=1}(-1/2)\left(\log(2\pi) - \log\theta^2 + (\theta y_i - \mathbf{x}_i'\boldsymbol{\gamma})^2\right)$$

$$\frac{\partial \log - L}{\partial\begin{pmatrix}\boldsymbol{\gamma}\\ \theta\end{pmatrix}} = \begin{pmatrix} \sum_{d_i=0} -\dfrac{\phi(a_i)}{\boldsymbol{\Phi}(a_i)}\mathbf{x}_i + \sum_{d_i=1} e_i\mathbf{x}_i \\ \sum_{d_i=0}\dfrac{\phi(a_i)}{\boldsymbol{\Phi}(a_i)}L_i - \sum_{d_i=1}\left(e_i y_i - \dfrac{2}{\theta}\right)\end{pmatrix}$$

$$= \sum_{i=1}^{n}(1-d_i)\lambda_i^0\begin{pmatrix}\mathbf{x}_i\\ -L_i\end{pmatrix} + d_i\left[e_i\begin{pmatrix}\mathbf{x}_i\\ -y_i\end{pmatrix} + \begin{pmatrix}\mathbf{0}\\ 1/\theta\end{pmatrix}\right]$$

$$= \sum_{i=1}^{n}\mathbf{g}_i,$$

in which $a_i = \theta L_i$ - $\mathbf{x}_i'\boldsymbol{\gamma}$, $\lambda_i^0 = -\phi(a_i)/\Phi(a_i)$, and $e_i = \theta y_i$ - $\mathbf{x}_i'\boldsymbol{\gamma}$. The Hessian is

$$\frac{\partial^2 \log L}{\partial\begin{pmatrix}\boldsymbol{\gamma}\\ \theta\end{pmatrix}\partial\begin{pmatrix}\boldsymbol{\gamma}\\ \theta\end{pmatrix}'} = -\sum_{i=1}^{n}(1-d_i)\delta_i^0\begin{pmatrix}\mathbf{x}_i\\ -L_i\end{pmatrix}\begin{pmatrix}\mathbf{x}_i\\ -L_i\end{pmatrix}' + d_i\begin{pmatrix}\mathbf{x}_i\\ -y_i\end{pmatrix}\begin{pmatrix}\mathbf{x}_i\\ -y_i\end{pmatrix}' + d_i\begin{pmatrix}\mathbf{0}\\ 1/\theta\end{pmatrix}\begin{pmatrix}\mathbf{0}\\ 1/\theta\end{pmatrix}'.$$

The asymptotic covariance matrix for the maximum likelihood estimator is usually estimated by inserting the MLEs of $\boldsymbol{\gamma}$ and θ into the Hessian, then inverting. But, the BHHH estimator (sum of outer products of gradients)

$$\textbf{BHHH} = \left[\sum_{i=1}^{n}\hat{\mathbf{g}}_i\hat{\mathbf{g}}_i'\right]^{-1}$$

is used occasionally instead.

The preceding obtains the estimated asymptotic covariance matrix for the MLEs of $\boldsymbol{\gamma}$ and θ. To recover the counterpart for the original parameters, $\boldsymbol{\beta}$ and σ, we use the delta method. Let $\hat{\mathbf{V}}$ be the estimated covariance, and let

$$\mathbf{G} = \begin{bmatrix} \partial\boldsymbol{\beta}/\partial\boldsymbol{\gamma}' & \partial\boldsymbol{\beta}/\partial\theta \\ \partial\sigma/\partial\boldsymbol{\gamma}' & \partial\sigma/\partial\theta \end{bmatrix} = \begin{bmatrix} \frac{1}{\theta}\mathbf{I} & \frac{-1}{\theta^2}\boldsymbol{\gamma} \\ \mathbf{0}' & \frac{-1}{\theta^2} \end{bmatrix}.$$

Then, the estimated asymptotic covariance matrix for the MLEs of $\boldsymbol{\beta}$ and σ is

$$\hat{\mathbf{S}}\left(\hat{\boldsymbol{\beta}},\hat{\sigma}\right) = \hat{\mathbf{G}}\hat{\mathbf{V}}\hat{\mathbf{G}}''.$$

The Hessian for this model is negative definite for all values of the parameters. As such, estimation by Newton's method is the standard approach. (See, e.g., Fair (1978), Pratt (1981), Olsen (1978), and Amemiya (1984) on various aspects of computation of the maximum likelihood estimator.) Convergence to a maximum of the log likelihood is usually routine, the more so when Olsen's transformation is used.

NOTE: If convergence is not achieved in a relatively small number of Newton iterations, this is usually indicative of a problem with the data. Widely disparate scaling of the variables or near collinearity is likely to cause this situation.

The maximum likelihood estimator is consistent, efficient, and asymptotically normally distributed, in the fashion of other familiar estimators, such as in the probit model. The fact that the density function for the observed random variable, y_i, is a mixture of discrete and continuous underlying distributions is a complication of some magnitude that was addressed in Amemiya's (1973) seminal paper on the subject. The end result is that maximum likelihood estimation can proceed as usual in spite of the complication.

The full specification with censoring in both tails adds some complication. The full model is

$$y_i^* = \mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i, \text{ where } \varepsilon_i|\mathbf{x} \sim N[0,\sigma^2].$$

$$y_i = \begin{cases} L_i \ \textit{if} \ \ y_i^* \le L_i \\ y_i^* \ \textit{if} \ \ L_i < y_i^* < U_i \\ U_i \ \textit{if} \ \ y_i^* \ge U_i \end{cases}$$

The algebraic results for this formulation are essentially the same. The log likelihood now has three terms:

$$\log L = \sum\nolimits_{y_i=L_i} \log \boldsymbol{\Phi}\left(\theta L_i - \mathbf{x}_i'\boldsymbol{\gamma}\right) + \sum\nolimits_{y_i=U_i} \log\left[1-\boldsymbol{\Phi}\left(\theta U_i - \mathbf{x}_i'\boldsymbol{\gamma}\right)\right] + \sum\nolimits_{y_i=y_i^*} (-1/2)\left(\log(2\pi) - \log\theta^2 + (\theta y_i - \mathbf{x}_i\boldsymbol{\gamma})^2\right)$$

Let $\boldsymbol{\gamma} = (1/\sigma)\boldsymbol{\beta}$, and $\theta = (1/\sigma)$,

L_i, U_i = lower, upper censoring limits (may be $-\infty$, $+\infty$, a number, or variable)

and $\varepsilon_i = \theta y_i - \boldsymbol{\gamma}'\mathbf{x}_i$.

Individual terms in the log likelihood function and derivatives are as follows. To avoid a possible source of confusion, we will now use P_i to denote a term in the log likelihood, rather than L_i which to this point has stood both for the lower limit value and the term now denoted P_i. For nonlimit observations:

$$\log P_i = -(1/2)\varepsilon_i^2 + \log\theta - ½\log 2\pi,$$

$$\partial\log P_i/\partial\boldsymbol{\gamma} = \varepsilon_i\mathbf{x}_i,$$

$$\partial\log P_i/\partial\theta = -\varepsilon_i y_i + 1/\theta,$$

$$\partial^2\log P_i/\partial\boldsymbol{\gamma}\partial\boldsymbol{\gamma}' = -\mathbf{x}_i\mathbf{x}_i',$$

$$\partial^2\log P_i/\partial\boldsymbol{\gamma}\partial\theta = \mathbf{x}_i y_i,$$

$$\partial^2\log P_i/\partial\theta^2 = -y_i^2 - 1/\theta^2.$$

For limit observations:

$$z_i = \boldsymbol{\gamma}'\mathbf{x}_i - \theta U_i \text{ if } y_i \geq U_i \text{ or } z_i = \theta L_i - \boldsymbol{\gamma}'\mathbf{x}_i \text{ if } y_i \leq L_i,$$

$$\log P_i = \log\Phi(z_i),$$

$$\partial\log P_i/\partial\boldsymbol{\gamma} = [\phi(z_i)/\Phi(z_i)]\mathbf{x}_i \text{ if } y_i \geq U_i\text{, reverse sign if } y_i \leq L_i,$$

$$\partial\log P_i/\partial\theta = -[\phi(z_i)/\Phi(z_i)]U_i \text{ or } +[...]L_i \text{ if } y_i \leq L_i.$$

Let $\delta_i = (\phi/\Phi)[z_i + \phi/\Phi].$

Then,

$$\partial^2\log P_i/\partial\boldsymbol{\gamma}\partial\boldsymbol{\gamma}' = -\delta_i\mathbf{x}_i\mathbf{x}_i',$$

$$\partial^2\log P_i/\partial\boldsymbol{\gamma}\partial\theta = \delta_i U_i \text{ or } \delta_i L_i,$$

$$\partial^2\log P_i/\partial\theta^2 = -\delta U_i^2 \text{ or } -\delta L_i^2.$$

Actual Hessians are used to estimate the asymptotic covariance matrices.

Remaining results are based on

$$\begin{aligned}\text{Prob(noncensored)} &= 1 - \text{Prob(censored in lower tail)} – \text{Prob(censored upper tail)}\\ &= 1 - \Phi(\alpha_i^L) - [1-\Phi(\alpha_i^U)]\\ &= \Phi(\alpha_i^U) - \Phi(\alpha_i^L)\end{aligned}$$

where $\alpha_i^L = (L_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma$ and $\alpha_i^U = (U_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma$. This produces the conditional mean function

$$E[y_i|\mathbf{x}_i] = \Phi(\alpha_i^L)L_i + [1-\Phi(\alpha_i^U)]U_i + [\Phi(\alpha_i^U) - \Phi(\alpha_i^L)]\left[\mathbf{x}_i'\boldsymbol{\beta} + \sigma\frac{\phi(\alpha_i^L) - \phi(\alpha_i^U)}{\Phi(\alpha_i^U) - \Phi(\alpha_i^L)}\right].$$

The conditional mean function for the uncensored (truncated) variable appears in the brackets on the first line above. Other characteristics of the model are essentially as before. The marginal effects are once again a fraction of the underlying regression slopes

$$m_k = \beta_k[\Phi(\alpha_i^U) - \Phi(\alpha_i^L)].$$

The computation for dummy variables would proceed as before, by evaluating the conditional mean at the two points and computing the difference. A standard error would be computed by the delta method. The formidable algebra implied by the now quite complicated functional form suggests that the payoff to numerical differentiation using **WALD** will be considerable. (A general program for censoring using *LIMDEP* is given above.)

The McDonald and Moffitt decomposition described below is still obtainable in two parts based on the truncated variance, but the split is now more complicated;

$$\delta_i = \left[\frac{\phi(\alpha_i^L) - \phi(\alpha_i^U)}{\Phi(\alpha_i^U) - \Phi(\alpha_i^L)}\right]^2 - \frac{\alpha_i^L\phi(\alpha_i^L) - \alpha_i^U\phi(\alpha_i^U)}{\Phi(\alpha_i^U) - \Phi(\alpha_i^L)}.$$

E45.9 Specification Analysis

The tobit model in the form given above has provided a workhorse for a wealth of empirical research. In view of its widespread application, it is natural to expect there to be a variety of specification tests and analyses of the model. Several of the more common of these are described in this section. Some, such as the LM test for Cragg's model are built into the program, while others are implemented using sets of *LIMDEP* commands.

E45.9.1 McDonald and Moffitt's Decomposition of the Conditional Mean

A frequently cited result due to McDonald and Moffitt (1980) decomposes changes in the conditional mean into two parts. The conditional mean for the tobit model with simple zero lower tail censoring is

$$\mathrm{E}[y|\mathbf{x}] = 0 \times \mathrm{Prob}(y = 0) + \mathrm{Prob}(y > 0) \times E(y|\mathbf{x}, y > 0).$$

It follows that,

$$\partial E[y|\mathbf{x}]/\partial\mathbf{x} = \mathrm{Prob}(y > 0) \times \partial E[y|\mathbf{x}, y > 0]/\partial\mathbf{x} + E[y|\mathbf{x}, y > 0] \times \partial\mathrm{Prob}(y > 0)/\partial\mathbf{x}.$$

This breaks the slope into two parts:

- the change in *y* given nonlimit times the probability of being above the limit value,
- the change in the probability of being above the limit times the conditional mean.

(See their paper for discussion.) The formal counterparts to these expressions are:

$$\partial E[\mathrm{y}|\mathbf{x}]/\partial\mathbf{x} = [\Phi(1 - (\phi/\Phi)(\boldsymbol{\beta}'\mathbf{x}/\sigma + \phi/\Phi)) + \phi(\boldsymbol{\beta}'\mathbf{x}/\boldsymbol{\sigma} + \phi/\Phi)]\boldsymbol{\beta}.$$

The routines below do this computation twice. The first time, for illustration, it is done with **CALC** just to get the value of the expressions. Second, we use **WALD** to estimate a standard error for each part.

A small application based on a specific model that one might have fit could be as follows. This computes the decomposition.

```
NAMELIST    ; x = the set of variables $
TOBIT       ; Lhs = y ; Rhs = x ; Parameters $
CALC        ; kx = Col(x) $
MATRIX      ; xb = Mean(x) ; beta = b(1:kx) $
CALC        ; bxs = beta'xb/s ; mu = N01(bxs)/Phi(bxs)
            ; p = Phi(bxs)
            ; p1 = p*(1-bxs*mu-mu^2)
            ; p2 = N01(bxs)*(bxs + mu) $
WALD        ; Labels = kx_b,v ; Start = b  ; Var = varb
            ; Fn1 = b1'xb/v
            ; Fn2 = Phi(Fn1)
            ; Fn3 = N01(Fn1)/Fn2
            ; Fn4 = Fn2*(1-Fn3*(Fn1+Fn3))
            ; Fn5 = Fn2*Fn3*(Fn1+Fn3) $
```

As an alternative, the following is a general procedure that you can use with any model. First, set the model up with these three commands. The rest is standard. The routine computes the full set of marginal effects for the estimated model, decomposed by the formula given above.

```
NAMELIST    ; x = the list of Rhs variables $
CREATE      ; y = the dependent variable $
CALC        ; li = the lower limit value (usually zero) $
```

The remaining computations can use a standard procedure.

```
PROC  = mcdnm(y,x, li) $
TOBIT       ; Lhs = y ; Rhs = x ; Par ; Limit = li ; Partial Effects $
MATRIX      ; xb = Mean(x) $
CALC        ; k = Col(x) $
WALD        ; Labels = k_b,v
            ; Start = b ; Var = varb
            ; Fn1 = alpha = (li - b1'xb)/v
            ; Fn2 = p_censrd = 1-Phi(Fn1)
            ; Fn3 = lambda = N01(Fn1) / Fn1
            ; Fn4 = delta = Fn3*Fn3 - Fn1*Fn3
            ; Fn5 = firtsprt = Fn2*Fn4
            ; Fn6 = secndprt = Fn2*(1-Fn4)
            ; Fn7 = effect = Fn5 + Fn6 $
CALC        ; Part1 = Waldfns(5)
            ; Part2 = Waldfns(6) $
MATRIX      ; beta= b(1:k)
            ; me1= part1 * beta
            ; me2= part2 * beta
            ; me = me1 + me2
            ; List ; me12 = [me1,me2,me] $
ENDPROC $
EXEC        ; Proc  =  mcdnm(y,x,0)$
```

There is a modification that might be useful. The routine does not actually compute the standard error for the marginal effects. It computes the standard errors for the scale factors used to compute the marginal effects (Fn5, Fn6 and Fn7). The actual scaled coefficient vector, in parts, is given by the **MATRIX** command. If you want to compute the decomposition with standard errors for a particular coefficient, you can do so by simply adding these lines to the routine. We suppose that *b*3 is the coefficient of interest. You could add

; Fn8 = b3*Fn5 ; Fn9 = b3*Fn6 ; Fn10 = b3*Fn7

to the **WALD** command to accomplish this.

The following applies the procedure to the labor supply data. The model is set up with

```
NAMELIST   ; x = one,kl6,k618,wa,we,cit $ the list of Rhs variables
CREATE     ; y = whrs $  the dependent variable
CALC       ; li = 0 $ the lower limit value (usually zero)
EXECUTE    ; Proc = mcdnm(y,x,li) $
```

```

E45.9.2 Testing Cragg's Specification of the Tobit Model

A variant of the tobit model which has been used in some studies is that of Cragg (1971), in which the tobit model above applies, but the probability of a nonlimit outcome is determined apart from the level of the nonlimit outcome. Fin and Schmidt (1984) suggest, for example, that the probability of a fire in a building and the amount of the damage when a fire occurs might both depend on the age of the building, but in opposite directions. The tobit model precludes this. The model reduces to the following:

$$\text{Prob}(y^* > 0) = \Phi(\boldsymbol{\gamma}'\mathbf{z}),$$

$$\text{Prob}(y^* \leq 0) = 1 - \Phi(\boldsymbol{\gamma}'\mathbf{z}),$$

if $y^* > 0$, a truncated regression in $\boldsymbol{\beta}'\mathbf{x}$ applies.

This is a combination of the probit model and the truncated regression model. As it stands, the model can be estimated in two parts simply by using a probit model for the indicator of whether y^* is positive or not and a truncated regression model for the nonlimit observations. The tobit model results if it is assumed that $\mathbf{z} = \mathbf{x}$ and $\boldsymbol{\gamma} = \boldsymbol{\beta}$. Given the first, the second is a testable restriction. The log likelihood of the unrestricted model is simply the sum of those of the probit and truncated regressions. This can be compared to the log likelihood for the tobit model, which will be smaller than this sum. An unresolved side issue is that if the first equation does give the probability of a positive observation, then the relationship of the disturbance in the latent regression underlying the probit model to that in the truncated regression is unclear. It is unlikely that they could be independent. In the tobit model, the probit disturbance is $1/\sigma$ times that in the truncated regression. In Cragg's model, the relationship is ambiguous.

The tobit log likelihood function may be written

$$\begin{aligned}\log L &= \Sigma_i\,(1-I_i)\log\text{Prob}(y_i = 0) + I_i\log\text{Prob}(y_i > 0)\\ &\quad + \Sigma_i \log[f(y_i \mid y_i > 0) / \text{Prob}(y_i > 0)],\end{aligned}$$

where $I_i = 1$ if $y_i > 0$, and 0 otherwise.

The first part is the log likelihood function for a probit model. The second line is the log likelihood function for the truncated regression. The reformulation simply adds, then subtracts the second term in the first line. In the tobit model,

$$\text{Prob}(y > 0) = \Phi(\boldsymbol{\beta}'\mathbf{x}/\sigma) = \Phi(\boldsymbol{\gamma}'\mathbf{x})$$

and $$f(y \mid y > 0) = (1/\sigma)\phi(\boldsymbol{\beta}'\mathbf{x}/\sigma).$$

To obtain Cragg's formulation, it is necessary only to release the restriction that $\boldsymbol{\gamma} = \boldsymbol{\beta}/\sigma$. This is testable with a likelihood ratio test just by estimating the three implied models and computing

$$\lambda = 2(\log L_{probit} + \log L_{truncation} - \log L_{tobit}).$$

The following commands carry out the test for the small example in the preceding section. We omit the model results as they are only of secondary interest. Note, in the original data set, *lfp* is the variable corresponding to I_i. The test statistic is 60.77. The critical value with five degrees of freedom is 12.59, so the hypothesis of the tobit model is rejected. The 'p value' is zero.

```

```
[CALC] CHISQ   =     60.7665209
[CALC] *Result*=       .0000000
Calculator: Computed   3 scalar results
```

There is a disadvantage to the preceding method. The approach requires estimation of all three models. Another approach which in the end may be simpler to use is the LM test devised by Fin and Schmidt (1984). This requires estimation only of the tobit (i.e., restricted) model. To set this up, we reparameterize the model as follows, incorporating Olsen's transformation at the outset:

Limit probability = Prob($y^* \leq 0$) = $1 - \Phi(\boldsymbol{\delta}'\mathbf{x})$

Density for the nonlimit observation = $\eta\phi(\eta y - \boldsymbol{\gamma}'\mathbf{x}) / \Phi(\boldsymbol{\gamma}'\mathbf{x})$

This is Cragg's model as it stands. Now, let $\boldsymbol{\theta}$ be a free parameter vector and let

$$\boldsymbol{\delta} = \boldsymbol{\gamma} + \boldsymbol{\theta}.$$

Insert this in the definition above, to obtain the same model:

Limit probability = Prob($y^* \leq 0$) = $1 - \Phi[(\boldsymbol{\gamma} + \boldsymbol{\theta})'\mathbf{x}]$

Truncated normal density for the nonlimit observation = $\eta\phi(\eta y - \boldsymbol{\gamma}'\mathbf{x}) / \Phi(\boldsymbol{\gamma}'\mathbf{x})$

As before, let $I_i = 1$ indicate a nonlimit observation, and let $I_i = 0$ indicate a limit observation. Then the log likelihood for this model is that for a tobit model;

$$\log L = \Sigma_i (1-I_i)\log\{1 - \Phi[(\boldsymbol{\gamma} + \boldsymbol{\theta})'\mathbf{x}_i]\} + I_i\log\{\eta\phi(\eta y_i - \boldsymbol{\gamma}'\mathbf{x}_i) / \Phi(\boldsymbol{\gamma}'\mathbf{x}_i)\}$$

Cragg's model results if $\boldsymbol{\theta}$ is a free parameter vector while the tobit model is obtained by the restriction $\boldsymbol{\theta} = \mathbf{0}$. Given this simple formulation, Fin and Schmidt devised a Lagrange multiplier statistic to test the restriction. Let the function $\lambda(z) = \phi(z)/\Phi(z) = \lambda_1$. Let $\lambda(-z) = \lambda_0$. In the following, z will equal $\boldsymbol{\gamma}'\mathbf{x}$, and for convenience, let Φ denote the CDF, $\Phi(z)$. Then, Fin and Schmidt's LM statistic is computed as follows: Let

$$a_i = \lambda_{0i}\lambda_{1i}$$

$$b_i = \Phi_i \times (1 - z_i\lambda_{1i} - \lambda_1^{\,2})$$

$$c_i = \Phi_i \times (z_i + \lambda_{1i})/\eta$$

$$d_i = \Phi_i \times (2 + z_i^{\,2} + z_i\lambda_{1i})$$

$$e_i = \eta y_i - \boldsymbol{\gamma}'\mathbf{x}_i$$

Let $\mathbf{A}$ and $\mathbf{B}$, denote $n \times n$ diagonal matrices formed from these quantities and let $\mathbf{c}$ and $\mathbf{d}$ denote $n \times 1$ vectors formed from c_i and d_i. Now, denote the full $n \times K$ data matrix as $\mathbf{X}$. Then,

$$\mathbf{g} = \Sigma_{nonlimit\ observations}\ (\lambda_{1i} - e_i)\mathbf{x}_i$$

$$\mathbf{H} = (\mathbf{X}'\mathbf{A}\mathbf{X})^{-1} - [\mathbf{X}'\mathbf{B}\mathbf{X} - (\mathbf{X}'\mathbf{c})(\mathbf{c}'\mathbf{X})/\mathbf{d}'\mathbf{d}]^{-1}$$

and

$$\text{LM} = \mathbf{g}'\mathbf{H}\mathbf{g}.$$

This LM statistic is computed automatically by *LIMDEP* when it fits a tobit model, and is reported with the standard output. Here is the diagnostic table from the model estimated in the example above:

```
-----------------------------------------------------------------------------
Limited Dependent Variable Model - CENSORED
Dependent variable                      Y
Estimation criterion          -3903.79391
Estimation based on N =    753, K =    7
Inf.Cr.AIC  =    7821.6 AIC/N =   10.387
Threshold values for the model:
Lower=      .0000     Upper=+infinity
LM test [df] for tobit=      32.508[  6]
Normality Test, LM    =      10.378[  2]
ANOVA  based fit measure =    .048112
DECOMP based fit measure =    .164940
--------+--------------------------------------------------------------------
```

The LM statistic is shown above the fit measures – for this model and data set, the value is 32.508, with six degrees of freedom. The critical value, as noted earlier is 12.59, so the hypothesis of the model would be rejected.

E45.9.3 Testing for Nonnormality

Tests of the normality assumption in the censored regression model have been developed by many authors. Generally, they are based on the same approach as is used in the linear regression model; the skewness (third moment) and kurtosis (fourth moment) of the 'residuals' are compared to what would be expected if the underlying distribution were normal (zero and three, respectively). The obstacle in this setting is that it is difficult to obtain a 'clean' set of residuals. For the censored regression model, the obvious choice, $y_i - \mathbf{x}_i'\hat{\boldsymbol{\beta}}$ has an equally obvious defect. The residuals for the limit observations are clearly not going to conform to a normal distribution even if the model is correct, by construction.

Pagan and Vella's Conditional Moment Test

Pagan and Vella (1989) devised a conditional moment test for normality in the censored regression model. The test is based on the moment restrictions:

$$y_i^* = \mathbf{x}_i'\boldsymbol{\beta} + \varepsilon_i$$

$$E_y[E[\varepsilon_i^3 \mid y_i]] = 0$$

$$E_y[E[\varepsilon_i^4 \mid y_i] - 3\sigma^4] = 0.$$

Note that these are not the moments only of the truncated distribution, since they are averaged over the distribution of the observed y. For observations for which $y_i > L_i$, we observe y_i^*, so the moments are the familiar ones. For the limit observations, we require the moments of the truncated distribution. Pagan and Vella provide the following useful result (adapted for current purposes): Denoting $E[\varepsilon_i^j \mid y_i = L_i]$ as μ_j, their result is

$$\mu_j = (j\text{-}1)\sigma^2\mu_{j-2} + \alpha_i^{j-1}\sigma^j\lambda_i(\alpha_i)$$

where, as usual, $\alpha_i = (L_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma$, $\lambda_i(\alpha_i) = -\phi(\alpha_i)/\Phi(\alpha_i) = \lambda_i$, and, the initial values for the recursion are $\mu_{-1} = 0$ and $\mu_0 = 1$. Collecting terms, we have

	$y = L_i$	$y > L_i$
$E[\varepsilon_i \mid y_i]$	$\sigma[\lambda_i]$	0
$E[\varepsilon_i^2 \mid y_i]$	$\sigma^2[1 + \lambda_i\alpha_i]$	σ^2
$E[\varepsilon_i^3 \mid y_i]$	$\sigma^3[\lambda_i(2 + \alpha_i^2)]$	0
$E[\varepsilon_i^4 \mid y_i]$	$\sigma^4[3 + \lambda_i(3\alpha_i + \alpha_i^3)]$	$3\sigma^4$

To carry out the conditional moment test, we first compute

$$m_{i1} = E[\varepsilon_i^3 \mid y_i] \text{ and } m_{i2} = E[\varepsilon_i^4 \mid y_i] - 3\sigma^4$$

using the appropriate form from above, the sample data, and the maximum likelihood estimates of the parameters. Let the $n\times 2$ matrix, **M**, be constructed from these two columns of functions. Let the $n\times(K+1)$ matrix, **G**, contain the derivatives of the log likelihood function for the K elements in $\boldsymbol{\beta}'$ followed by that for σ. The transpose of the ith row of **G** is

$$\mathbf{g}_i = \frac{1}{\sigma}\left\{ d_i \begin{bmatrix} \left(\dfrac{\varepsilon_i}{\sigma}\right)\mathbf{x}_i \\ \left(\dfrac{\varepsilon_i}{\sigma}\right)^2 - 1 \end{bmatrix} + (1-d_i)\begin{bmatrix} \lambda_i \mathbf{x}_i \\ \lambda_i \alpha_i \end{bmatrix} \right\}$$

Then, **G** is computed with the sample data and the maximum likelihood estimates of the parameters. Finally, let **i** denote an $n\times 1$ column vector of ones. Then, the conditional moment statistic for this test is

$$\chi^2[2] = \mathbf{i}'\mathbf{M}[\mathbf{M}'\mathbf{M} - \mathbf{M}'\mathbf{G}(\mathbf{G}'\mathbf{G})^{-1}\mathbf{G}'\mathbf{M}]^{-1}\mathbf{M}'\mathbf{i}.$$

Under the hypothesis of normality, the statistic has a limiting chi squared distribution with two degrees of freedom.

The program below gives a general set of computations. For a particular application, it is necessary to provide the definitions of *x*, *y*, and *li*.

```
NAMELIST   ; x = the Rhs variables in the regression $
CALC       ; li = the lower censoring value (usually zero) $
CREATE     ; y = the Lhs variable in the model $
TOBIT      ; Lhs = y ; Rhs = x ; Limit = li $
CREATE     ; d = y > li ; d0 = 1 - d ; xb = x'b ; e = y - xb
           ; alpha = (li - xb)/s  ; lambda = -N01(alpha)/(1-Phi(alpha))
           ; m1 = d*e^3 + d0*s^3*lambda*(2+alpha^2)
           ; m2 = (d*e^4 + d0*s^4*(3+lambda*(3*alpha+alpha^3))) - 3*s^4
           ; qx = (d*e/s + d0*lambda)/s
           ; qs = (d*((e/s)^2-1) + d0*lambda*alpha)/s $
NAMELIST   ; m = m1,m2  $
MATRIX     ; dd = Bhhh(x,one,qx,qs)
           ; mdb= m'[qx]x ; mds = m'qs ; md = [mdb, mds]
           ; v = m'm - md * <dd> * md'
           ; List ; cmtest = 1'm * <v> * m'1 $
CALC       ; List ; pvalue = 1 - Chi(cmtest,2) $
```

```
Matrix CMTEST   has  1 rows and  1 columns.
            1
       +--------------
      1|   30.16118
```

Applying the foregoing to our labor supply application produces a value of 30.16118. The critical chi squared value for two degrees of freedom is 5.99, so the hypothesis of normality is rejected based on this test.

Chesher and Irish's Generalized Residuals Test

The generalized residual based test devised by Chesher and Irish (1987) is based on a similar logic. The generalized residuals are computed as the derivatives of the log likelihood with respect to the constant term in the model. The Chesher and Irish test is based on the hypothesis that these will behave as if drawn from a normal distribution, the same as in the Pagan and Vella test. The computations are as follows, where d_{1i} denotes a nonlimit observation and $d_{0i} = 1 - d_{1i}$.

$$\varepsilon_I = y_i - \mathbf{x}_i'\boldsymbol{\beta}$$

$$a_i = [(y_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma]$$

$$\alpha_i = [(l_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma] \text{ where } l_i \text{ is the lower censoring limit, usually zero}$$

or

$$\alpha_i = [(\mathbf{x}_i'\boldsymbol{\beta} - u_i)/\sigma] \text{ where } u_i \text{ is the upper censoring limit, usually zero}$$

$$\lambda_i = \phi(\alpha_i)/\Phi(\alpha_i) \text{ where } \phi(.) = \text{normal PDF}, \Phi(.) = \text{normal CDF (lower)}$$

or

$$\lambda_i = -\phi(\alpha_i)/\Phi(\alpha_i) \text{ where } \phi(.) = \text{normal PDF}, \Phi(.) = \text{normal CDF (upper)}$$

$$e_{1i} = -d_{0i}\,\lambda_i + d_{1i}\,a_i$$

$$e_{2i} = -d_{0i}\,\alpha_i\lambda_i + d_{1i}\,(a_i^2 - 1)$$

$$e_{3i} = -d_{0i}\,(2+\alpha_i^2)\lambda_i + d_{1i}\,a_i^3$$

$$e_{4i} = -d_{0i}\,(3\,\alpha_i + \alpha_i^3)\lambda_i + d_{1i}\,(a_i^4 - 3)$$

$$\mathbf{c}_i = [\mathrm{e}_{1i}\mathbf{x}_i', \mathrm{e}_{2i}, \mathrm{e}_{3i}, \mathrm{e}_{4i}]'$$

Define the $n\times(K+3)$ matrix $\mathbf{C}$ so that its $\mathbf{i}$th row is $\mathbf{c}_i'$ and as before, let $\mathbf{i}$ be an $n\times1$ column of ones. Then, the test statistic is

$$\chi^2[2] = \mathbf{i}'\mathbf{C}\,(\mathbf{C}'\mathbf{C})^{-1}\mathbf{D}'\mathbf{i}$$

This would be straightforward to program in similar fashion to the Pagan and Vella test. It is reported automatically with the tobit model output, as shown below

```
-----------------------------------------------------------------------------
Limited Dependent Variable Model - CENSORED
Dependent variable                    Y
Estimation criterion         -3903.79391
Estimation based on N =    753, K =    7
Inf.Cr.AIC  =    7821.6 AIC/N =   10.387
Threshold values for the model:
Lower=     .0000     Upper=+infinity
LM test [df] for tobit=      32.508[  6]
Normality Test, LM     =     10.378[  2]
ANOVA  based fit measure =    .048112
DECOMP based fit measure =    .164940
--------+--------------------------------------------------------------------
```

E45.9.4 Generalized Residuals

The conditional moment test suggested by Pagan and Vella (1989) is one of a class of tests devised by Chesher and Irish (1987) based on what they label generalized residuals. Their specification tests are based on the standard approach to tests of specification in the regression model. Tests for omitted variables are based on covariances of residuals from the model with the omitted variables in question; tests of heteroscedasticity are based on covariances of squares of residuals with hypothesized exogenous variables; tests of normality are based on the means and variances of third and fourth moments of residuals, and so on. The problem with the extension of these methods to censored data models is that the residuals in the censored data are ill defined. Chesher and Irish defined the generalized residuals for these purposes. For censored data models based on an 'index function,' $\mathbf{x}_i'\boldsymbol{\beta}$ (which includes most of the cases we have examined) the generalized residuals for the ith observation are

$$e(1) = \frac{\partial \log f_i}{\partial \beta_1} \text{ and } e(2) = \frac{\partial \log f_i}{\partial \sigma}$$

where $\log f_i$ is the term for the ith observation in the log likelihood for the model and β_1 is the constant term in the regression. (Chesher and Irish do their analysis in terms of σ^2, but to maintain consistency with our earlier results, we will modify their formulations.) Their testing procedures extend to more general censored regression models, including the categorical data model we examined earlier, so we will consider the extension to that model as well. For an observation which is not censored,

$$e(1) = \frac{1}{\sigma}\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right) \text{ and } e(2) = \frac{1}{\sigma}\left[\left(\frac{y_i - \mathbf{x}_i'\boldsymbol{\beta}}{\sigma}\right)^2 - 1\right].$$

For an observation which falls in the open region $(Lower_i, Upper_i]$,

$$f_i = \Phi(\alpha_i^{Upper}) - \Phi(\alpha_i^{Lower}),$$

with $\alpha_i^{Lower} = (Lower_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma$ and $\alpha_i^{Upper} = (Upper_i - \mathbf{x}_i'\boldsymbol{\beta})/\sigma$,

so $$e(1) = -\frac{1}{\sigma}\left(\frac{\phi(\alpha_i^{Upper}) - \phi(\alpha_i^{Lower})}{\boldsymbol{\Phi}(\alpha_i^{Upper}) - \boldsymbol{\Phi}(\alpha_i^{Lower})}\right) = \frac{1}{\sigma}\lambda(\alpha_i^{Lower}, \alpha_i^{Upper}).$$

Notice we have extended the definition of the $\lambda(\bullet)$ function for this purpose. For our basic censored regression model, $U_i = \infty$, $\Phi(\alpha_i^U) = 1$, $\phi(\alpha_i^U) = 0$, and the results we used earlier emerge. This definition of a 'residual' makes sense. For the uncensored observation, $e(1) = (1/\sigma^2)\{E[y_i^*|y_i, \mathbf{x}_i] - \mathbf{x}_i'\boldsymbol{\beta}\}$, since when an observation is uncensored, $y_i = y_i^*$. For the censored regression with simple lower censoring at L_i, $Lower = -\infty$, $Upper = L_i$, – we'll maintain this for the moment, and extend it to the more general case presently – and

$$e(1) = -\frac{1}{\sigma}\left(\frac{\phi(\alpha_i^L) - 0}{\boldsymbol{\Phi}(\alpha_i^L) - 0}\right) = \frac{1}{\sigma}\lambda(\alpha_i^L).$$

As we noted earlier,

$$E[y_i^*|y_i, \mathbf{x}_i] = E[y_i^*|y_i^* \le L_i, \mathbf{x}_i] = \mathbf{x}_i'\boldsymbol{\beta} + \sigma\left(\frac{-\phi\left(\alpha_i^L\right)}{\Phi\left(\alpha_i^L\right)}\right),$$

so, once again, $e(1) = (1/\sigma^2)\{E[y_i^*|y_i, \mathbf{x}_i] - \mathbf{x}_i'\boldsymbol{\beta}\}$.

For uncensored observations, the other generalized residual is

$$\begin{aligned} e(2) &= \partial \log f_i/\partial\sigma = (1/\sigma^3)[(y_i^* - \mathbf{x}_i'\boldsymbol{\beta})^2 - \sigma^2] \\ &= (1/\sigma^3)\{[E[y_i^*|y_i, \mathbf{x}_i] - \mathbf{x}_i'\boldsymbol{\beta}]^2 - \sigma^2\}, \end{aligned}$$

since, once again, if the observation is uncensored, $y_i = y_i^*$. For a censored observation,

$$e(2) = \partial \log f_i/\partial\sigma = (1/\sigma)\alpha_i\lambda_i.$$

The previous expression produced the deviation of a square from its expectation, so the interpretation as a residual makes intuitive sense. In fact, this one does also. For the censored observation,

$$\begin{aligned} [E[y_i^*|y_i, \mathbf{x}_i] - \mathbf{x}_i'\boldsymbol{\beta}]^2 &= \mathrm{E}[\varepsilon_i^2|\varepsilon_i \le L_i - \mathbf{x}_i'\boldsymbol{\beta}] \\ &= \mathrm{Var}[\varepsilon_i|\varepsilon_i \le L_i - \mathbf{x}_i'\boldsymbol{\beta}] + \{\mathrm{E}[\varepsilon_i\,|\varepsilon_i \le L_i - \mathbf{x}_i'\boldsymbol{\beta}]\}^2 \\ &= \sigma^2[1 - \delta(\alpha_i)] + [\sigma\lambda(\alpha_i)]^2. \\ &= \sigma^2 + \sigma^2\alpha_i\lambda(\alpha_i). \end{aligned}$$

Therefore, $[E[y_i^*|y_i, \mathbf{x}_i] - \mathbf{x}_i'\boldsymbol{\beta}]^2 - \sigma^2 = \sigma^2\alpha_i\lambda(\alpha_i)$

which gives $e(2)$ the same interpretation for the censored observations.

Chesher and Irish provide the general expression for $e(2)$ in the categorical (grouped) data model.

$$e(2) = -\frac{1}{\sigma}\left(\frac{\alpha_i^{Upper}\phi\left(\alpha_i^{Upper}\right) - \alpha_i^{Lower}\phi\left(\alpha_i^{Lower}\right)}{\Phi\left(\alpha_i^{Upper}\right) - \Phi\left(\alpha_i^{Lower}\right)}\right)$$

as well as new expressions $e(3)$ and $e(4)$ which enter the computations of tests for normality. The latter two, with their testing procedure produce exactly the Pagan and Vella approach laid out earlier, so we'll not repeat them here. Chesher and Irish suggest several specification tests using their generalized residuals. The general approach, based on maximum likelihood estimates of the parameters and the BHHH estimator of the asymptotic covariance matrix for the estimators, uses the statistic

$$\chi^2[J] = \mathbf{i}'\mathbf{R}(\mathbf{R}'\mathbf{R})^{-1}\mathbf{R}'\mathbf{i}$$

where $\mathbf{R}$ is an $n\times(K+1+J)$ matrix of constructed observations. Each row of $\mathbf{R}$ consists of, first K+1 elements which are the derivatives of log f_i with respect to $\boldsymbol{\beta}$ and σ, followed by J elements which are the products of variables which are expected to be orthogonal to the generalized residuals. These first K+1 columns of $\mathbf{R}$ are the terms in the gradient of the log likelihood function, so for the first K+1 elements, at the maximum likelihood estimates, $\mathbf{i}'\mathbf{R} = \mathbf{0}$.

They suggest the following tests:

1. for J omitted variables, $z_1,..., J$ trailing elements in $\mathbf{R}_i$ are $e(1)_i\mathbf{z}_i'$,
2. for heteroscedasticity of a known functional form $\sigma_i^2 = \sigma^2 h(\mathbf{z}_i,\boldsymbol{\kappa})$ where $\boldsymbol{\kappa}$ is a $J\times1$ parameter vector such that $h(\mathbf{z}_i,\mathbf{0}) = 1$, J trailing elements are $e_i(2)\ \partial h(\mathbf{z}_i,\boldsymbol{\kappa})/\partial\boldsymbol{\kappa}|\boldsymbol{\kappa}=\mathbf{0}$,
3. for heteroscedasticity of unknown form, J trailing elements are the J unique terms in $e_i(2)$ $\mathbf{x}_i\otimes\mathbf{x}_i$, not including the constant term.

They also suggest a test for random parameter variation which is identical to test 3 save for the addition of $e(3)$ and $e(4)$ – see the earlier discussion of Pagan and Vella's test.

To operationalize this procedure, define as $\mathbf{g}_i'$ the first K+1 elements of the row in $\mathbf{R}$. As we observed, these are the elements of the derivatives of the log likelihood function. Denote the trailing J elements as $\mathbf{m}_i'$. If we arrange these in two sets of columns, then the matrix $\mathbf{R}$ becomes $[\mathbf{G},\mathbf{M}]$. With this in place, the test statistic becomes

$$\chi^2[J] \ = \ \begin{bmatrix}\mathbf{i'G} & \mathbf{i'M}\end{bmatrix}\begin{bmatrix}\mathbf{G'G} & \mathbf{G'M}\\ \mathbf{M'G} & \mathbf{M'M}\end{bmatrix}^{-1}\begin{bmatrix}\mathbf{G'i}\\ \mathbf{M'i}\end{bmatrix}.$$

Recall, $\mathbf{G'i}$ is the derivative vector (gradient) of the log likelihood function, which equals zero at the maximum likelihood estimates. Using the partitioned inverse formula, then, we reduce the statistic to

$$\chi^2[\text{J}] \ = \ \mathbf{i'M}[\mathbf{M'M} - \mathbf{M'G}(\mathbf{G'G})^{-1}\mathbf{G'M}]^{-1}\mathbf{M'i}$$

(which is identical to the Pagan and Vella statistic, as noted). Carrying out the test, therefore, requires computation of the moments in **M** and the derivatives in **G**, and a bit of matrix algebra. Chesher and Irish's results are quite convenient, and suggest a general strategy for a variety of other specification tests in the censored regression model.

Generalized residuals are computed automatically by the **TOBIT** (and **TRUNCATION** and **GROUPED**) estimators. After estimation, the variables *genres_1* and *genres_2* will contain the two generalized residuals noted above.

E45.9.5 Censoring with Unknown Censoring Limits

We have allowed for either lower or upper censoring based on known censoring points. It might be natural to ask if the censoring point could, itself, be unknown. One might know whether or not an observation had been censored, but the exact value of the censoring threshold might not be known. Can the censoring limit be treated as an unknown parameter, and estimated with the rest of the model? Unfortunately, no, as it is simple to show. Consider the log likelihood for the model with lower censoring that we examined earlier, and suppose that $\tilde{L}$ is an unknown parameter to be estimated. Then,

$$\partial\log L/\partial\tilde{L} \ = \ \phi/\Phi\times\theta \ > 0.$$

This expression is always positive. The only way to equate it to zero is to set θ to zero (infinite variance, σ^2, or to have $\phi(.)$ go to zero, which will happen if any coefficient in the model diverges. The upshot is that for identification in the censoring model, the censoring threshold must be known. It is not estimable.

E45.10 Powell's Symmetrically Censored LS Estimator

As noted earlier, a large body of research has focused on semiparametric alternatives to the normal based censored regression estimator. Powell's (1986) symmetrically censored least squares estimator is a simple one that can be implemented as a short procedure. The procedure and an application are as follows:

```
?==============================================================
? Powell's symmetrically censored least squares estimator
?==============================================================
? This is the only part of the estimator that is specific to the problem.
? Define the list of regressors and the dependent variable.
NAMELIST    ; x = one,wa,we,hhrs,ha,he,kl6,k618,ww,cit,ax $
CREATE      ; y = whrs $
? Use the tobit MLE as starting values for beta.
TOBIT       ; Quietly ; Lhs = y ; Rhs = x $
MATRIX      ; bj = b ; btobit = b ; vtobit = varb $
CALC        ; deltab = 1 $  Start delta large enough to begin.
PROCEDURE $   This procedure computes the scls estimator iteratively
CREATE      ; bx = x'bj ; bx2 = 2*bx ; ts = bx > 0 ; ys = Min(y,bx2) $
MATRIX      ; hj = <x'[ts]x> ; bj1 = hj  * x'[ts]ys ; db = bj1-bj $
? We check convergence using a scale free measure rather than db.
CALC        ; list(exec) ; deltab = Qfr(db,hj) $
MATRIX      ; bj = bj1 $
ENDPROC $
EXECUTE     ; While deltab > .00001 $
? Estimation is finished. Get covariance matrix and display results.
CREATE      ; vs = (y > 0)*(y < bx2) ; u2 = ts*(ys-bx)^2 $
MATRIX      ; c = x'[vs]x ; d = x'[u2]x  ; v = <c>*d*<c> $
DISPLAY     ; Labels = x ; Parameters = bj  ; Covariance = v
            ; Title = Symmetrically Censored Least Squares $
DISPLAY     ; Labels = x ; Parameters = btobit ; Covariance = vtobit
            ; Title = Maximum Likelihood Tobit Estimates $

E45.11 Double Hurdle Model for Censored Regression

The double hurdle model is a generalization of Cragg's specification in Section E45.9.2. The rather lengthy development in the literature is summarized in Yen and Jones (1997), which is used as the background for the implementation here. The model consists of a binary choice (probit) participation equation,

$$d^* = \boldsymbol{\alpha}'\mathbf{z} + v,\ v \sim \mathrm{N}[0,1],$$

$$d \;\; = 1(d^* > 0),$$

a latent intensity equation,

$$y^* \;=\; \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\ \varepsilon \sim \mathrm{N}[0,\sigma],$$

and an observation mechanism that extends the tobit model,

$$y \;=\; y^* \text{ if } d^* > 0 \text{ and } y^* > 0 \text{ and } y = 0 \text{ otherwise.}$$

(The tobit model implicitly assumes that $y^* > 0$ implies $d = 1$ by construction.) Yen and Jones motivate the specification based on separate purchase decision and frequency of purchase decisions. Our implementation builds on the basic model and adds three extensions (all of which were suggested by Yen and Jones). We note in Section E45.11.5 correction of a substantive error in the development in the Yen and Jones presentation.

The model is an extension of the tobit model. The basic command for estimation of the double hurdle model is

TOBIT ; Lhs = dependent variable
; Rhs = independent variables
; Hurdle $

Remaining options are the same as for the tobit model with the exception that censoring is always at zero from below. If your data are censored at some other point, C or C_i, then simply create the new variable y_i - C_i to conform to the assumption. If your data are censored from above, then create the new variable C_i - y_i, then reverse the signs of the estimates of $\boldsymbol{\beta}$ after estimation. The basic specification also assumes that the variables in the participation equation are the same as in the intensity equation. This assumption is relaxed immediately in the next section. Section E45.11.2 extends the model to allow correlation between the intensity and participation equations. Section E45.11.3 provides a transformation somewhat similar to the Box-Cox model that allows for different functional forms, e.g., linear vs. logarithmic and forms in between.

E45.11.1 Basic Model with Heteroscedasticity

The central specification of the double hurdle model provides for different variables in the two equations. The specification to accommodate the general model is

TOBIT ; Lhs = dependent variable
; Rhs = independent variables in intensity equation
; Hurdle = independent variables in participation equation $

If the variables in the two equations are the same, then use **; Hurdle** without a list in the command, as shown in the introduction to this section. A second extension is to allow heteroscedasticity in the variance in the tobit equation. The model is then

$$d^* = \boldsymbol{\alpha}'\mathbf{z} + v,\ v \sim N[0,1]$$

$$d = 1(d^* > 0)$$

$$y^* = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\ \varepsilon \sim N[0,\sigma_i],\ \sigma_i = \sigma \times \exp(\boldsymbol{\delta}'\mathbf{h}_i)$$

$$y = y^* \text{ if } d^* > 0 \text{ and } y^* > 0 \text{ and } y = 0 \text{ otherwise.}$$

The original double hurdle model returns if $\boldsymbol{\delta} = \mathbf{0}$. The extended model command is

TOBIT ; Lhs = dependent variable
; Rhs = independent variables in intensity equation
; Hurdle = independent variables in participation equation
; Hfn = variables in variance ; Heteroscedasticity $

Note that consistent with the model equation above, the Hfn list should not contain *one*. As always, **; Heteroscedasticity** may be abbreviated to **; Het**.

E45.11.2 Endogenous Participation

The participation becomes endogenous if v and ε are correlated. This produces a relatively large extension of the model – given the formulation, the extension is easily tested. The model specification becomes

$$d^* = \boldsymbol{\alpha}'\mathbf{z} + v,\ v \sim N[0,1]$$

$$d = 1(d^* > 0)$$

$$y^* = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\ \varepsilon \sim N[0,\sigma_i],\ \sigma_i = \sigma \times \exp(\boldsymbol{\delta}'\mathbf{h}_i)$$

$$y = y^* \text{ if } d^* > 0 \text{ and } y^* > 0 \text{ and } y = 0 \text{ otherwise,}$$

$$\begin{pmatrix} v \\ \varepsilon \end{pmatrix} \sim N\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & \rho\sigma_i \\ \rho\sigma_i & \sigma_i^2 \end{pmatrix}\right].$$

(Yen and Jones specified that the off diagonal element in the covariance matrix was constant. The (invalid) assumption is substantive, and would affect the estimation results.)

The endogeneity assumption is added with the command

```
TOBIT    ; Lhs = dependent variable
         ; Rhs = independent variables in intensity equation
         ; Hurdle = independent variables in participation equation
         ; Hfn = variables in variance ; Het
         ; Correlation $
```

Note that the list of variables in the hurdle equation and the heteroscedasticity specification are both optional. The simplest model with endogenous participation results with

```
TOBIT    ; Lhs = dependent variable
         ; Rhs = independent variables in intensity equation
         ; Hurdle
         ; Correlation $
```

Endogeneity and different participation and intensity equations or endogeneity and heteroscedasticity are specified with

```
TOBIT    ; Lhs = dependent variable
         ; Rhs = independent variables in intensity equation
         ; Hurdle = independent variables in participation equation
         ; Correlation $
```

and

```
TOBIT    ; Lhs = dependent variable
         ; Rhs = independent variables in intensity equation
         ; Hurdle
         ; Hfn = variables in variance ; Het
         ; Correlation $
```

E45.11.3 Inverse Hyperbolic Sine Transformation

The inverse hyperbolic sine transformation is suggested for this model as a device to extend the functional form beyond (or between) the usual levels or logarithms choices. The transformation is

$$T(y,\gamma) = \frac{\log\left[\gamma y + \left(1+\gamma^2 y^2\right)^{1/2}\right]}{\gamma}$$

where γ is the crucial new parameter that extends the model. The transformation approaches linearity ($T(y,\gamma) = y$) as γ approaches zero and approaches the log function as γ increases. The transformation is incorporated in the model with

$$d^* = \boldsymbol{\alpha}'\mathbf{z} + v,\ v \sim N[0,1]$$

$$d = 1(d^* > 0)$$

$$y^* = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\ \varepsilon \sim N[0,\sigma_i],\ \sigma_i = \sigma \times \exp(\boldsymbol{\delta}'\mathbf{h}_i)$$

$$T(y,\gamma) = y^* \text{ if } d^* > 0 \text{ and } y^* > 0 \text{ and } T(y,\gamma) = 0 \text{ otherwise,}$$

$$\begin{pmatrix} v \\ \varepsilon \end{pmatrix} \sim N\left[\begin{pmatrix} 0 \\ 0 \end{pmatrix}, \begin{pmatrix} 1 & \rho\sigma_i \\ \rho\sigma_i & \sigma_i^2 \end{pmatrix}\right].$$

To use the transformation, the command is modified to

```
TOBIT       ; Lhs = dependent variable
            ; Rhs = independent variables in intensity equation
            ; Hurdle = independent variables in participation equation
            ; Hfn = variables in variance ; Het
            ; Correlation
            ; Model = IHS $
```

All of the model permutations noted earlier may be used with this specification.

E45.11.4 Application

To illustrate the hurdle model, we have manipulated the income variable in the health care data set. The dependent variable is income = $\max\left(0, hhninc - \overline{hhninc}\right)$. The model is fit with the pooled data set – there is no panel data version of this specification.

```
SAMPLE      ; All $
CREATE      ; income = hhninc-xbr(hhninc) $
CREATE      ; income = max(0,income) $
NAMELIST    ; x = one,age,educ,hsat,married,hhkids $
NAMELIST    ; z = one,age,educ $
NAMELIST    ; h = female,married,age $
TOBIT       ; Lhs = income ; Rhs = x ; Hurdle = z ; Correlated ; Partial Effects
            ; Het ; Hfn = h ; Model = IHS ; Maxit = 15 $
```

Average partial effects are computed for three outcomes, Prob(y > 0), E[y] and E[y|y>0]. The partial effects are also computed for the three sets of variables in the model, **x** in the regression, **h** in the disturbance variance (heteroscedasticity) and **z** in the hurdle equation.

E45.11.5 Technical Details

The following technical details will, for convenience, replicate the results in Yen and Jones. As noted earlier, there is a point at which a substantive correction is needed in their results.

The relevant components of the log likelihood for the model are

$$\text{Prob}[T(y_i,\gamma) = 0] = \text{Prob}(y_i^* < 0 \text{ or } d_i^* < 0|\mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i)$$

$$= 1 - \text{Prob}(y_i^* > 0 \text{ and } d_i^* > 0|\, \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i)$$

$$(1) \qquad = 1 - \Phi_2\left[\boldsymbol{\alpha}'\mathbf{z}_i, \frac{\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}, \rho\right]$$

where $\Phi_2(\ldots)$ is a bivariate normal CDF. This term applies for censored, or 'limit' observations. (In Yen and Jones (1997, eqn (5)), the ρ in the preceding appears as σ_{12}/σ_i, which varies by observation. However, it must be the case in the joint distribution that the covariance equals the product of the correlation and the two standard deviations, so 'σ_{12}' must equal $\rho\times\sigma_i\times 1$. This produces the constant value ρ in the bivariate normal probability above. The necessity for this is clear; what must appear as the third argument in the probability is a correlation, but the erroneous term σ_{12}/σ_i which appears in its place in Yen and Jones's eqn (5) cannot be bounded in (-1,1).)

For nonlimit observations, the contribution to the likelihood function is the joint density of the observed y transformed by $T(y_i,\gamma)$ and the observation mechanism $d_i = 1$. This term is

$$f[y_i|T(y_i,\gamma),\ \{d_i=1|T(y_i,\gamma) > 0\}] = f[y_i|T(y_i,\gamma) \mid \{d_i=1|T(y_i,\gamma) > 0\}] \times \text{Prob}\{d_i = 1|T(y_i,\gamma) > 0\}.$$

The first term is the density for the observed nonzero y_i,

(2) $$[T(y_i,\gamma) \mid \{d_i = 1|\mathrm{T}(y_i,\gamma) > 0\}] = \left(1+\gamma^2 y_i^2\right)^{-1/2}\frac{1}{\sigma_i}\phi\left[\frac{T(y_i,\gamma)-\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}\right]$$

where the leading term is the Jacobian of the transformation from $T(y_i,\gamma)$ back to y_i. The second term is

(3) $$\text{Prob}\{d_i = 1|T(y_i,\gamma) > 0\} = \Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i+\rho[(T(y_i,\gamma)-\boldsymbol{\beta}'\mathbf{x}_i)/\sigma_i]}{\sqrt{1-\rho^2}}\right].$$

The log likelihood consists of logs of (1) for the limit observations and (2)×(3) for the nonlimit observations.

There are three expectations and three margins in this model. The probability of a nonlimit observation is

(4) $$P = \text{Prob}(y_i^* > 0 \text{ and } d_i^* > 0|\ \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i) = \text{Prob}(y_i > 0|\ \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i] = \Phi_2\left[\boldsymbol{\alpha}'\mathbf{z}_i,\frac{\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i},\rho\right].$$

The partial effects are fairly simple:

$$\frac{\partial\text{Prob}(y_i>0\,|\,\mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i)}{\partial\begin{pmatrix}\mathbf{x}_i\\ \mathbf{z}_i\\ \mathbf{h}_i\end{pmatrix}} = \frac{\partial\Phi_2\left[\boldsymbol{\alpha}'\mathbf{z}_i,\dfrac{\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i},\rho\right]}{\partial\begin{pmatrix}\mathbf{x}_i\\ \mathbf{z}_i\\ \mathbf{h}_i\end{pmatrix}} = \begin{pmatrix} g_{i2}\dfrac{\boldsymbol{\beta}}{\sigma_i}\\ g_{i1}\boldsymbol{\alpha}\\ -g_{i2}\left(\dfrac{\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}\right)\boldsymbol{\delta}\end{pmatrix} = \begin{pmatrix}P_{\mathbf{x}}\\ P_{\mathbf{z}}\\ P_{\mathbf{h}}\end{pmatrix}$$

where g_{i1} and g_{i2} are the partial derivatives of the bivariate normal CDF with respect to the first two arguments. For the bivariate normal PDF, $\Phi_2(\mathrm{w}_1,\mathrm{w}_2,\rho)$, these are obtained using

$$\frac{\partial\Phi_2(w_1,w_2,\rho)}{\partial w_1} = \phi(w_1)\Phi\left[\frac{w_2-\rho w_1}{\sqrt{1-\rho^2}}\right] \text{ and } \frac{\partial\Phi_2(w_1,w_2,\rho)}{\partial w_2} = \phi(w_2)\Phi\left[\frac{w_1-\rho w_2}{\sqrt{1-\rho^2}}\right].$$

(See Greene (2011, eqn (17-52).) Where parts have variables in common, the components are added. Note that for a variable that appears in all three vectors, the partial effect is the sum of the three terms.

The conditional expectation, $E[y_i|y_i > 0, \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i]$ is

$$E+ = E[y_i|y_i > 0, \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i] \; = \; \int_0^\infty y_i \frac{f(y_i \mid \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i)}{\text{Prob}(y_i > 0 \mid \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i)} dy_i .$$

The necessary components appear earlier;

$$E+ \; = \; \mathrm{E}[y_i|y_i > 0, \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i] \; =$$

$$\frac{1}{\Phi_2\left[\boldsymbol{\alpha}'\mathbf{z}_i, \dfrac{\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}, \rho\right]} \int_0^\infty y_i\left(1+\gamma^2 y_i^2\right)^{-1/2} \frac{1}{\sigma_i}\phi\left[\frac{T(y_i,\gamma)-\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}\right]\Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho[(T(y_i,\gamma)-\boldsymbol{\beta}'\mathbf{x}_i)/\sigma_i]}{\sqrt{1-\rho^2}}\right]dy_i .$$

The unconditional mean is $E = E[y_i|\, \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i] \; = P \times E+$. This is

$$E = \; E[y \mid \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i] = \int_0^\infty y_i\left(1+\gamma^2 y_i^2\right)^{-1/2} \frac{1}{\sigma_i}\phi\left[\frac{T(y_i,\gamma)-\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}\right]\Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho[(T(y_i,\gamma)-\boldsymbol{\beta}'\mathbf{x}_i)/\sigma_i]}{\sqrt{1-\rho^2}}\right]dy_i .$$

Computation of the expectations and the derivatives requires the integration shown above. The complexity of the computation is reduced somewhat by the following:

1. The limits of integration are not functions of any of the interesting variables.
2. Though the functions appear quite complex, they can be greatly simplified for present purposes.

Define quantities

$$J_i = \; y_i\left(1+\gamma^2 y_i^2\right)^{-1/2}$$

$$e_i \; = \; \frac{T(y_i,\gamma)-\boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i} .$$

We will also use

$$\partial e_i/\partial \mathbf{x}_i = -\boldsymbol{\beta}/\sigma_i,$$

$$\partial \sigma_i/\partial \mathbf{h}_i = \sigma_i\boldsymbol{\delta},$$

$$\partial e_i/\partial \sigma_i = -e_i/\sigma_i,$$

$$\partial e_i/\partial \mathbf{h}_i = \partial e_i/\partial \sigma_i \times \partial \sigma_i/\partial \mathbf{h}_i \; = \; (-e_i/\sigma_i)(\sigma_i\boldsymbol{\delta}) = -e_i\boldsymbol{\delta}.$$

Then, the unconditional mean can be written

$$\text{(5)} \qquad E \; = \; E[y \mid \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i] = \int_0^\infty J_i \frac{1}{\sigma_i}\phi\left[e_i\right]\Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right]d_{\;i} .$$

The relevant derivatives are now found as follows. We differentiate first with respect to e_i and σ_i. Thus,

$$
\begin{aligned}
\frac{\partial E[y \mid \mathbf{x}_i, \mathbf{z}_i, \mathbf{h}_i]}{\partial e_i} &= \int_0^\infty J_i \frac{1}{\sigma_i}\left(-e_i \phi[e_i]\right)\Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right] dy_i \\
&\quad + \frac{\rho}{\sqrt{1-\rho^2}}\int_0^\infty J_i \frac{1}{\sigma_i}\phi[e_i]\phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right] dy_i \\
&= E_1 + E_2 \times \frac{\rho}{\sqrt{1-\rho^2}} \\
&= E_e.
\end{aligned} \tag{6}
$$

$$
\begin{aligned}
\frac{\partial E[y \mid \mathbf{x}_i, \mathbf{z}_i, \mathbf{h}_i]}{\partial \sigma_i} &= \frac{-1}{\sigma_i}\int_0^\infty J_i \frac{1}{\sigma_i}\phi[e_i]\Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right] dy_i + \frac{\partial E[y \mid \mathbf{x}_i, \mathbf{z}_i, \mathbf{h}_i]}{\partial e_i}\frac{\partial e_i}{\sigma_i} \\
&= \frac{-1}{\sigma_i}E[y \mid \mathbf{x}_i, \mathbf{z}_i, \mathbf{h}_i] + E_e \frac{\partial e_i}{\sigma_i} \\
&= \frac{-1}{\sigma_i}E + \left(E_1 + E_2 \times \frac{\rho}{\sqrt{1-\rho^2}}\right)\left(\frac{-e_i}{\sigma_i}\right) \\
&= E_\sigma
\end{aligned} \tag{7}
$$

Collecting the parts, we obtain

$$
\begin{aligned}
\frac{\partial E[y \mid \mathbf{x}_i, \mathbf{z}_i, \mathbf{h}_i]}{\partial \mathbf{h}_i} &= E_\sigma \times (\sigma_i \boldsymbol{\delta}) = E_{\mathbf{h}} \\
\frac{\partial E[y \mid \mathbf{x}_i, \mathbf{z}_i, \mathbf{h}_i]}{\partial \mathbf{x}_i} &= E_e \frac{-1}{\sigma_i}\boldsymbol{\beta} = E_{\mathbf{x}} \\
\frac{\partial E[y \mid \mathbf{x}_i, \mathbf{z}_i, \mathbf{h}_i]}{\partial \mathbf{z}_i} &= \frac{\boldsymbol{\alpha}}{\sqrt{1-\rho^2}}\int_0^\infty J_i \frac{1}{\sigma_i}\phi[e_i]\phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right] dy_i = E_2 \times \frac{\boldsymbol{\alpha}}{\sqrt{1-\rho^2}} = E_{\mathbf{z}}
\end{aligned}
$$

Derivatives of $E[y_i|y_i > 0, \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i]$ are simple given the parts already computed. Since

$$E[y_i|y_i > 0, \mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i] = [1/\Phi_2(\ldots)]\times E[y_i|\mathbf{x}_i,\mathbf{z}_i,\mathbf{h}_i],$$

so the relevant derivatives are simply $E_{\mathbf{x}}^{+} = (1/P)\{E_{\mathbf{x}} - E \times P_{\mathbf{x}}\}$ and likewise for $\mathbf{z}$ and $\mathbf{h}$.

Computation all of these parts requires the three integrals,

$$E = \int_0^\infty J_i \frac{1}{\sigma_i}\phi\left[e_i\right]\Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right]dy_i,$$

$$E_1 = \int_0^\infty J_i \frac{1}{\sigma_i}\left(-e_i\phi\left[e_i\right]\right)\Phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right]dy_i,$$

$$E_2 = \int_0^\infty J_i \frac{1}{\sigma_i}\phi\left[e_i\right]\phi\left[\frac{\boldsymbol{\alpha}'\mathbf{z}_i + \rho e_i}{\sqrt{1-\rho^2}}\right]dy_i.$$

None of these are in forms amenable to Hermite or Gaussian quadrature. We use a 15 point Newton-Cotes trapezoid method. There is a final complication in that the method is used for proper integrals (with finite limits). As the upper limit here is infinite, a stopping rule is required – simple experimentation will take intolerably long. In the integrals, the main weighting function is $\phi(e_i)$. The Jacobian, J_i is essentially linear in y_i and the second function in the integrand, $\Phi[.]$ or $\phi[.]$ quickly asymptotes to 1 or 0 as e_i increases. The task then is to determine the practical limit for y_i which is then used to compute e_i. We solve for the y_i at which e_i reaches +8.0, where the standard normal PDF is essentially zero. This, in turn is solved using a first order approximation to $T(y_i,\gamma)$.

In order to use the delta method to compute standard errors, we require the Jacobians of the partial effects with respect to the full parameter vector. These, in turn, can all be computed from

$$J_E = \partial E/\partial\boldsymbol{\theta}' \text{ where } \boldsymbol{\theta}' = [\boldsymbol{\beta}',\sigma,\boldsymbol{\delta}',\alpha,\rho,\boldsymbol{\gamma}']$$

$$J_1 = \partial E_1/\partial\boldsymbol{\theta}'$$

$$J_2 = \partial E_2/\partial\boldsymbol{\theta}'$$

These must also be computed from the integrals. Numerical derivatives of the integrals are used for these three vectors.

E46: Panel Data Models for Censored Data and Truncated Distributions

E46.1 Introduction – Model Frameworks

This chapter will describe the extensions to panel data settings of the tobit model developed in Chapter E45. The estimators shown here are the same for the truncated regression (TRUNCATION) and grouped data model (GROUPED) that are discussed in Chapter E47. The full set of estimators developed for the binary choice models in Chapters E30 and E31 and for count data models in Chapter E44 are available here as well. The results are collected here for both the censoring and truncation models as the models are largely the same, with a slight variation in the assumption about the data observation process.

The three models described in this chapter are the tobit model of the previous chapter and two variations on it, the truncated regression and the grouped data, or interval censored regression: All three structures are based on the latent regression structure,

$$y_{it}^* = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it},\ \varepsilon_{it} \sim N[0,\sigma^2].$$

The three differ in the observation mechanism for the observed dependent variable. The tobit model is

$$\text{if } y_{it}^* \leq L_{it}, \text{ then } y_{it} = L_{it} \text{ (lower tail censoring)}$$

$$\text{if } y_{it}^* \geq U_{it}, \text{ then } y_{it} = U_{it} \text{ (upper tail censoring)}$$

$$\text{if } L_{it} < y_{it}^* < U_{it}, \text{ then } y_{it} = y_{it}^* = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it}.$$

A special case of the censored data regression model arises when the range of the dependent variable is completely censored. This is the case when data are reported only by interval category. For example, income data might be reported only by range. We assume that the finite (internal) terminal points are known variables or constants. The dependent variable is coded $y = 1, 2, ..., J$ (not 0,..., as in the case of the ordered probability models). For example, consider a survey of incomes, which reports ranges:

$$y = \begin{array}{lrcl} 1 \text{ if} & & y^* < & \$\,15{,}000, \\ 2 \text{ if} & \$\,15{,}000 \leq & y^* < & \$\,30{,}000, \\ 3 \text{ if} & \$\,30{,}000 \leq & y^* < & \$\,50{,}000, \\ 4 \text{ if} & \$\,50{,}000 \leq & y^* < & \$\,75{,}000, \\ 5 \text{ if} & & y^* \geq & \$\,75{,}000. \end{array}$$

The observation mechanism, once again based on the latent regression model, is

$$y_{it} = j \text{ if } A_{i,j-1} \leq y_{it}^* < A_{ij},\ j = 1,...,J,\ A_0 = -\infty,\ A_J = +\infty.$$

The truncated regression model applies to the nonlimit observations in the tobit formulation. The observation mechanism is simply

$$\text{if } L_{it} < y_{it}^* < U_{it}, \text{ then } y_{it} = y_{it}^* = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it},$$

y_{it} is unobserved otherwise.

E46.2 Panel Data Frameworks

Chapter E45 analyzed in detail several variants of a single equation, latent regression model of censoring in the linear (or nonlinear) regression context. The estimator is assumed to be based on a cross section. Since it is typically applied in micro-level data, the extension of the censored and truncated regression models to panel data is a natural direction. There are several formulations for extensions to panel data setting. These include, where *f*(.) denotes the density for the observed random variable (i.e., the model),

- **Fixed effects:** $f(y_{it}) = f(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i d_{it})$, $\text{Cov}(d_{it},\mathbf{x}_{it})$ not necessarily zero
- **Random effects:** $f(y_{it}) = f(\boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + u_i)$, $\text{Cov}(u_i,\mathbf{x}_{it}) = 0$
- **Random parameters:** $f(y_{it}) = f(\boldsymbol{\beta}_i'\mathbf{x}_{it})$

  $\boldsymbol{\beta}|i \sim h(\boldsymbol{\beta}|i)$ with mean vector $\boldsymbol{\beta}+\boldsymbol{\Delta}\mathbf{z}_i$ and covariance matrix $\boldsymbol{\Sigma}$
- **Latent class:** $f(y_{it}|\text{class } j) = f(\boldsymbol{\beta}_j'\mathbf{x}_{it})$, $\text{Prob}[\text{class} = j] = F_j(\boldsymbol{\theta})$

We will detail these for the tobit model. The commands and results are the same for the truncated and grouped data regressions, so they will be noted during the development.

To illustrate the various estimators, we will use an artificial data set containing 1,000 groups of 10 observations, or 10,000 observations in total. So that the applications can be replicated, we use the following data setup. We first set the seed for the random number generator so that data can be replicated and set the dimensions of the data set.

```
ROWS      ; 10000 $
CALC      ; Ran(12345) $
SAMPLE    ; 1-10000 $
```

If you are replicating these computations, note that the **ROWS** command may not be needed. When you start *LIMDEP*, the bar at the top of the project window will indicate the current setting of the number of rows in the data area. You will only need the **ROWS** command if the value shown is less than 10,000.

To begin, we create the group specific effects. (The values of **u** are used in generating the data at this point, while **v** is used later.)

```
MATRIX    ; u = Rndm(1000)
          ; v = Rndm(1000) $
```

The underlying data satisfy the assumptions of a fixed effects model. The group effect is correlated with one of the independent variables.

```
CREATE      ; i = Trn(10,0) $
CREATE      ; x1 = Rnn(0,1) ; x2 = Rnn(0,1)
            ; z1 = Rnn(0,1) ; z2 =  Rnd(2) - 1 $
MATRIX      ; x1b = Gxbr(x1,i) ; u = u + .5 * x1b $
CREATE      ; eit = Rnn(0,2) ; ui = u(i)  ; vi = .25 * v(i) $
CREATE      ; ys = x1 + x2 + eit + ui ; y = Max(0,ys) $
NAMELIST    ; x = x1,x2,z1,z2,one $
```

Note that the data are actually generated by a fixed effects model. We will also be including $z1$ and $z2$ in the equation, though the true coefficients on them are zero. The **MATRIX** command that creates $x1b$ also makes these group means part of the effects, thus inducing the correlation. The disturbance variance in the model is $\sigma_\varepsilon^2 = 2$.

This is the base case with no treatment for group effects. We compare the results for the tobit and truncated regressions. After this, we will focus on the tobit model.

```
TOBIT       ; Lhs = y ; Rhs = x ; Partial Effects $
TRUNCATE    ; Lhs = y ; Rhs = x ; Partial Effects $
```

The commands below estimate a fixed effects model, a random effects model and a random parameters model for the tobit framework. Results from these are shown below with development of the estimators. The truncation model is presented below as well. Note that the full set of results for the truncation model apply to the nonlimit data.

```
TOBIT       ; Lhs = y ; Rhs = x; Random Effects ; Pds = 10 ; Partial Effects $
TOBIT       ; Lhs = y ; Rhs = x
            ; RPM ; Fcn = one(n) ; Pds = 10 ; Pts = 20 ; Halton ; Partial Effects $
TOBIT       ; Lhs = y ; Rhs = x; FEM ; Pds = 10 ; Partial Effects $
```

The commands below simulates the conditions of a random parameters model – the coefficient on $x1$ has a normal distribution with mean 1 and standard deviation 0.25.

```
CREATE      ; y = (1+vi)*x1 + x2 + eit + ui
            ; y = (y > 0) * y $
TOBIT       ; Lhs = y ; Rhs = x
            ; RPM ; Fcn = one(n), x1(n) ; Correlated
            ; Pds = 10 ; Pts = 20 ; Halton $
```

This is the base case tobit model with no individual effects. Note that the three true values for the regression parameters are 0.0, 1.0, 1.0, 0.0, 0.0, respectively. The OLS starting values are not shown. The tobit and truncated regression MLEs are both consistent and are estimating the same parameters. The similarity in the two sets of results is to be expected. The tobit estimator is based on more information, so one would expect it to be more efficient (have smaller variances). This is, in fact, clearly evident in the results.

The base case results are followed by two estimators of the random effects model. The first one uses the Butler and Moffitt quadrature method. The second treats the random effects case as a random parameters model in which only the constant term is random. The model is estimated by maximum simulated likelihood. The results of the two methods are nearly identical. This is to be expected. It is striking, however, that the RP approach achieves the results with only 25 Halton draws, which is far less than what one would typically use in practice. The final set of results is the unconditional fixed effects estimator. The FEM includes estimates of the 1,000 dummy variable coefficients (not shown). In principle, the estimator is affected by the incidental parameters problem. However, with T = 10, this appears not to be the case here.

E46.3 Fixed Effects Models

The fixed effects model has the desirable characteristic that it is not necessary to assume that the individual component is orthogonal to the included variables. As such, it is a more robust specification than the random effects estimator. The complication is that in a data set with n groups or individuals, each observed T_i times, the fixed effects specification creates n new parameters to be estimated. In practical terms, n could be enormous (thousands), so approaches are devised to 'sweep' the coefficient of the fixed effects out of the estimating equations. Other issues concern the 'incidental parameters problem' and the attendant inconsistency of the estimator of the main parameters. *LIMDEP* contains a full, unrestricted fixed effects estimator. The issues of small T_i and the incidental parameters problem must be resolved outside the program. There is some evidence that even for fairly small T_i the issue of small sample bias of the fixed effects estimator is overstated. (See Heckman (1981). See also Greene (2004b) for evidence specifically about the tobit and truncated regression models. This study is discussed in Section E46.3.3.) The practical issue of potentially large numbers of parameters has been overcome – *LIMDEP* is able to fit up to 100,000 individual dummy variable parameters even in a model with no minimal sufficient statistics, such as the tobit or truncated regression models.

The command for estimation is

TOBIT ; Lhs = dependent variable
or TRUNCATE ; Rhs = independent variables
or GROUPED ; Pds = panel specification
; FEM (for fixed effects model) $

The default limit value is zero, with left censoring or truncation. The limit value and censoring in the lower tail may be changed with

; Limit = the nonzero value
and/or **; Upper censoring or ; Upper truncation**

This estimator only supports censoring in one tail. You may request residuals, fitted values, partial effects, and all other optional features with this model. Restrictions that you would impose with **; Rst,** however, must be built into the model at the outset. The algorithm does not accommodate restrictions.

NOTE: Your Rhs list should not include a constant term, as the fixed effects model fits a complete set of constants for the set of groups. If you do include *one* in your Rhs list, it is removed prior to beginning estimation.

The fixed effects models are estimated by maximum likelihood. The fixed effects model assumes a group specific effect:

$$f(y_{it}) = f(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i)$$

where α_i is the parameter to be estimated. You may also fit a two way fixed effects model

$$f(y_{it}) = f(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i + \gamma_t)$$

where γ_t is an additional, time (period) specific effect. The time specific effect is requested by adding

; Time

to the command if the panel is balanced, and

; Time = variable name

if the panel is unbalanced. For the unbalanced panel, we assume that overall, the sample observation period is

$$t = 1,2,..., T_{max}$$

and that the 'Time' variable gives for the specific group, the particular values of *t* that apply to the observations. Thus, suppose your overall sample is five periods. The first group is three observations, periods 1, 2, 4, while the second group is 4 observations, 2, 3, 4, 5. Then, your panel specification would be

; Pds = Ti, for example, where *Ti* = 3, 3, 3, 4, 4, 4, 4
and **; Time = Pd**, for example, where *Pd* = 1, 2, 4, 2, 3, 4, 5.

NOTE: See the discussion in Chapter R23 for technical details on how this model is estimated. It places an important restriction on the two way fixed effects model.

The only fitting algorithm available is Newton's method, and some of the options for control of the optimization routine are not available. Those that are available are shown in the list below. This estimator cannot accommodate restrictions, so

; Rst = list
and **; CML: specification**

are both ignored.

Starting values for the iterations are obtained by fitting the basic model without fixed effects by ordinary least squares. If you request the display of these results with **; OLS**, you will see a constant term in these results even though you have not included one in your commands. This is used to get the starting value for the fixed effects. Iterations begin with the restricted model that forces all the fixed effects to equal the constant term in the restricted model. You may provide your own starting values for the slope parameters with

; Start = ... the list of values for β,σ,α.

Do not include a set of constants in your starting values. The last value, if it is included (it is optional), provides a common starting constant.

Results that are kept for this model are

Matrices: *b* = estimate of β
varb = asymptotic covariance matrix for estimate of β
alphafe = estimated fixed effects

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variables*

Last Function: None

The upper limit on the number of groups is 100,000.

Standard Model Specifications for the Fixed Effects Tobit and Truncated Regression Models

This is the full list of general specifications available for this model estimator.

Controlling Output from Model Commands

; Par keeps ancillary parameter σ in main results vector *b*.
; Margin displays marginal effects.
; OLS displays least squares starting values when (and if) they are computed.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.

E46.3.1 Technical Notes

The fixed effects model is fit by 'brute force.' *LIMDEP* actually estimates the full K+N up to 100,150 coefficients by Newton's method. It is possible to fit the huge number of coefficients because we take advantage of the properties of the sparse second derivatives matrix. One of the implications, however, is that there is no covariance matrix computed for the fixed effects. It is possible to test for the fixed effects model with a likelihood ratio test (though the incidental parameters issue casts some doubt on the validity of this test), but since the covariance matrix is not computed, it is not possible to do any kind of inference for individual fixed effects. Marginal effects in the fixed effects model are computed at the means of the data and with the sample average of the fixed effects estimates as the constant term.

NOTE: The individual specific constant term cannot be computed for any group in which the dependent variable always takes the limit value (usually zero). The model results will show the count of such groups. For example, for the preceding data, the following output is produced:

```
-------------------------------------------------------------------------------
FIXED EFFECTS Tobit  Model
Maximum Likelihood Estimates
Dependent variable                    Y
Weighting variable                 None
Number of observations            10000
Iterations completed                  5
Log likelihood function       -12499.95
Sample is 10 pds and    1000 individuals.
Bypassed   12 groups with inestimable a(i).
TOBIT (censored) regression model
(Lower) truncation limit is     .00
-------------------------------------------------------------------------------
```

This shows that 12 of the 1,000 groups contained 10 observations in which *y* equals zero in all of them. The truncated regression estimator must also check for this condition in the data. In principle, your data will not contain limit observations for the truncation model. But, if in fact, it does, these observations are bypassed. If all of the observations in one or more groups are bypassed, then the same warning will appear for the truncation model.

The two way fixed effects estimator is computed by actually creating the time specific dummy variables and adding them to the model. This means that the 150 parameter limit on model size applies to the number of variables in the model plus the number of periods (minus one).

E46.3.2 Application

The following presents one and two way FEMs for the tobit model.

TOBIT ; Lhs = y ; Rhs = x ; FEM ; Pds = 10 ; Partial Effects $
TOBIT ; Lhs = y ; Rhs = x ; FEM ; Pds = 10 ; Time ; Partial Effects $

This is the truncated regression model estimated with the same data. Note that the sample is different for this model, because the estimator skips the limit observations. This eliminates the same 12 groups for which *y* is always zero, However, since the estimator is skipping all limit observations, the sample is in fact, greatly reduced. Indeed, the command set

```
CREATE      ; d = y > 0 $

The results are striking in another respect. Whereas the tobit estimator of the parameters seems to estimate them quite well, even with 10,000 observations, it appears that the tobit estimator has slightly underestimated σ^2. But, the truncated regression estimator, again, in spite of the large sample, has underestimated all of the parameters. These are precisely what would be predicted by the results on the incidental parameters problem in the next section.

E46.3.3 The Incidental Parameters Problem

Section R23.2.2 mentions the incidental parameters (IP) problem as a feature of the estimation of fixed effects models by maximum likelihood. As widely understood in econometrics, the IP problem is associated with a persistent upward bias in the parameter estimator in the FE model. Tables E46.1 and E46.2 below are extracted from the only received study of the IP problem in the tobit and truncated regression models, Greene (2004b). The remaining literature is focused on binary choice models. The tables describe a Monte Carlo study of censoring and truncation in the model

$$y_{it}^* = \alpha_i + \beta x_{it} + \delta_i d_{it} + \varepsilon_{it}$$

in which x_{it} is a continuous variable and d_{it} is a dummy variable. The underlying data are generated according to the fixed effects model – the effects are correlated with both x_{it} and d_{it}. The table entries show the estimates of the percentage biases of various estimators based on 1,000 replications of the model, with N also equal to 1,000. Surprisingly, the experiment suggests that the conventional wisdom is wrong for both the tobit and the truncated regression models. For the tobit case, the bias appears to manifest itself not in the estimator of β, but in the estimator of σ. The implications for the estimated marginal effects and for the estimated standard errors are shown in the lower rows of the table. Table E46.1 suggests that the truncated regression model works in the opposite direction – all model components appear to be biased downward. The overall conclusion here is also somewhat contradictory. Based on these results, one is tempted to conclude that once T reaches 5, the IP problem is relatively small for these particular models.

Table E46.2 Truncated Regression Model, Behavior of the MLE/FE, Percentage Bias

E46.4 Random Effects Models

The random effects model with censored data or truncation is based on the same latent regression used earlier, but with a different treatment of the common effect. Specifically,

$$y_{it}^* = \mathbf{x}_{it}'\boldsymbol{\beta} + \varepsilon_{it} + u_i.$$

$$\varepsilon_{it}, u_i \sim \text{ bivariate normal with means } (0,0), \text{ variances } (\sigma^2, \omega^2) \text{ and correlation } 0.$$

Data are observed by the mechanisms

$$y_{it} = \text{Max}(L_{it}, y_{it}^*) \text{ for the tobit model and}$$

$$y_{it} = y_{it}^* \text{ if } y_{it} \geq L_{it} \text{ and unobserved otherwise for the truncation model.}$$

The essential assumptions are that the random effect is the same in every period and the unique effect, ε_{it} is uncorrelated across periods. All effects are uncorrelated across individuals. Since the unique effects are independent across periods, all of our previous results apply to the conditional distribution of $y_{it}|u_i$.

As before, for the tobit model, let $d_{it} = 1$ if $y_{it} > L_{it}$ (uncensored) and 0 otherwise. Then, the density of the observed random variable, y_{it} is

$$f(y_{it}|u_i,d_{it} = 0) = \text{Prob}[y_{it}^* \leq L_{it} \mid u_i] = \Phi\left(\frac{L_{it} - \mathbf{x}_{it}'\boldsymbol{\beta} - u_i}{\sigma}\right) \text{ (censored)}$$

$$f(y_{it}|u_i,d_{it} = 1) = \frac{1}{\sigma}\phi\left(\frac{y_{it} - \mathbf{x}_{it}'\boldsymbol{\beta} - u_i}{\sigma}\right) \text{ (uncensored).}$$

(For convenience, we leave the dependence on $\mathbf{x}_{it}$ implicit.) For purposes of formulating the log likelihood, we will combine these by writing

$$f(y_{it}|u_i) = [f(y_{it}|u_i,d_{it} = 0)]^{1-d_{it}} \times [f(y_{it}|u_i,d_{it} = 1)]^{d_{it}}.$$

Since, conditioned on u_i, the observations are independent, the joint density of the T_i observations for group i is the product of the individual densities;

$$f(y_{i1},y_{i2},\ldots,y_{iTi}|u_i) = \prod_{t=1}^{T_i} f(y_{it}|u_i).$$

To form the log likelihood function, we need the unconditional distribution, the log of which then enters the function to be maximized. The unconditional density is obtained by integrating u_i out of the conditional density

$$f(y_{i1},y_{i2},\ldots,y_{iTi}|u_i) = \int_{-\infty}^{\infty} f(y_{i1}, y_{i2}, \ldots, y_{iT_i}|u_i)g(u_i)du_i$$

Recall $g(u) = (1/\omega)\phi(u_i/\omega)$. Combining all terms, then summing the logs to obtain the log likelihood function, we have log

$$\log L_{tobit} = \sum_{i=1}^{n} \log\left\{\int_{-\infty}^{\infty} \frac{1}{\omega\sqrt{2\pi}}\exp\left(-\frac{u_i^2}{2\omega^2}\right)\prod_{t=1}^{T_i}\left[\Phi\left(\frac{L_{it}-\mathbf{x}_{it}'\boldsymbol{\beta}-u_i}{\sigma}\right)\right]^{1-d_{it}}\left[\frac{1}{\sigma}\phi\left(\frac{y_{it}-\mathbf{x}_{it}'\boldsymbol{\beta}-u_i}{\sigma}\right)\right]^{d_{it}} du_i\right\}.$$

This function is to be maximized with respect to ($\boldsymbol{\beta}$,σ,ω). The same sequence of steps produces the counterpart for the truncated regression model,

$$\log L_{truncation} = \sum_{i=1}^{n} \log\left\{\int_{-\infty}^{\infty} \frac{1}{\omega\sqrt{2\pi}}\exp\left(-\frac{u_i^2}{2\omega^2}\right)\prod_{t=1}^{T_i}\left[\Phi\left(\frac{(\mathbf{x}_{it}'\boldsymbol{\beta}+u_i)-L_{it}}{\sigma}\right)\right]^{-1}\left[\frac{1}{\sigma}\phi\left(\frac{y_{it}-\mathbf{x}_{it}'\boldsymbol{\beta}-u_i}{\sigma}\right)\right] du_i\right\}.$$

There are two ways to maximize the log likelihoods, both of which will generally prove successful.

- The function and its derivatives can be evaluated by Hermite quadrature.

- Since the function and derivatives are equal to expectations, $E_u[h(...,u_i)]$, they can be approximated by simulation. At each point at which the function or derivative must be computed, the integral is replaced by the average of R function evaluations at random draws from the currently estimated distribution of u_i. The simulation method is considered in the next section.

  The quadrature based estimator can be requested with

```
TOBIT          ; Lhs  = dependent variable
or TRUNCATE    ; Rhs  = independent variables
               ; Pds  = panel specification of group sizes
               ; Random Effects $
```

(The quadrature based random effects estimator is not available for the GROUPED data model. The random parameters specification is provided for the **GROUPED** command, so a random effects model can be estimated by maximum simulated likelihood instead.)

The limit value and censoring in the lower tail may be changed with

```
               ; Limit = the nonzero value or variable name
and/or         ; Upper censoring
```

Censoring or truncation in both tails of the distribution are specified with

```
               ; Limits = lower specification, upper specification
```

where each specification may be a constant or the name of a variable. The other options, such as fitted values, marginal effects, and so on are the same as for the tobit model without the random effects treatment. Censoring may be in either or both tails and censoring limits may be constant or may vary by observation. As usual, zero, lower censoring is the default.

NOTE: There is no limit on the number of groups in this model. As always, the panel may be unbalanced. Also, in principle, there is no internal limit on the number of observations in a group. However, do note in this model, to compute the log likelihood, it is necessary actually to compute the joint probability for the T_i observations in a group. That is the product of probabilities, and, to the point, not the sum of the logs. Therefore, if your panel has a very large number of observations in a group – consider monthly observations on some variable, by firm, for a number of years – it will be necessary to compute the product of a large number of probabilities. It is possible that this value can become extremely small, and when so, accuracy is lost in the computations. On occasion, if the estimator claims it is unable to locate a maximum of the objective function, it is possible that this is the reason.

To illustrate the estimator, the following reports the random effects estimates of the model fit earlier.

TOBIT ; Lhs = y ; Rhs = x ; Random Effects ; Pds = 10 ; Partial Effects $
TOBIT ; Lhs = y ; Rhs = x
; RPM ; Fcn = one(n) ; Pds = 10 ; Pts = 20 ; Halton ; Partial Effects $

E46.5 Random Parameters Models

We have extended the random parameters model to the censored regression (tobit) and truncated regression models. (Full details on the random parameters model appear in Chapter R24.) The structure of the random parameters model is based on the conditional density

$$f(y_{it} \mid \mathbf{x}_{it}, \boldsymbol{\beta}_i) \;=\; f(\boldsymbol{\beta}_i'\mathbf{x}_{it}),\; i = 1,...,N,\; t = 1,...,T_i.$$

where $f(.)$ is the hybrid continuous/discrete density for the tobit model. The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals) mean

$$E[\boldsymbol{\beta}_i \mid \mathbf{z}_i] \;=\; \boldsymbol{\beta} \;+\; \boldsymbol{\Delta}\mathbf{z}_i,$$

(the second term is optional – the mean may be constant),

$$\text{Var}\,[\boldsymbol{\beta}_i \mid \mathbf{z}_i] \;=\; \boldsymbol{\Sigma}.$$

The model is operationalized by writing

$$\boldsymbol{\beta}_i \;=\; \boldsymbol{\beta} \;+\; \boldsymbol{\Delta}\mathbf{z}_i \;+\; \boldsymbol{\Gamma}\mathbf{v}_i.$$

As noted earlier, the heterogeneity term is optional. In addition, it may be assumed that some of the parameters are nonrandom. It is convenient to analyze the model in this fully general form here. One could easily accommodate nonrandom parameters just by placing rows of zeros in the appropriate places in $\boldsymbol{\Delta}$ and $\boldsymbol{\Gamma}$.

NOTE: If there is no heterogeneity in the mean, and only the constant term is considered random – the model may specify that some parameters are nonrandom – then this model is equivalent to the random effects model of the preceding section.

E46.5.1 Command for the Random Parameters Model

The basic model command for this form of the model is

```
      TOBIT          ; Lhs  = dependent variable
      or TRUNCATE    ; Rhs  = independent variables
      or GROUPED     ; Pds  = fixed periods or count variable
                     ; RPM
or                   ; RPM = list of variables in z
                     ; Fcn  = random parameters specification $
```

The limit value and censoring in the lower tail may be changed for the tobit and truncated regression models with

```
                     ; Limit = the nonzero value
and/or               ; Upper censoring
```

This estimator only supports censoring in one tail.

NOTE: For this model, your Rhs list should include a constant term.

NOTE: The **; Panel** specification is optional. You may fit these models with cross section data. There is nothing inherent in the model that limits it to a panel data application. However, identification can be a bit weak for cross section estimation, and it will often break down. Using this model in a cross section is likely to be successful only when the data and the model are strongly consistent with each other.

Standard Model Specifications for the Random Parameters Truncated Regression Model

This is the full list of general specifications applicable to this model estimator.

Controlling Output from Model Commands.

; Par keeps individual specific parameter estimates.
; Margin displays marginal effects. Marginal effects are computed by setting the heterogeneity terms to their expected values of zero.
; OLS displays least squares starting values when (and if) they are computed.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Robust sandwich estimator or robust VC for TSCS and some discrete choice.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name sets algorithm. The default (and best) algorithm for estimation is BFGS. But, all other algorithms are available.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E46.5.2 Specifying Random Parameters

The **; Fcn = specification** is used to define the random parameters. It is constructed from the list of Rhs names as follows: Suppose your model is specified by

; Rhs = one, x1, x2, x3, x4

This involves five coefficients. Any or all of them may be random; any not specified as random are assumed to be constant. For those that you wish to specify as random, use

; Fcn = variable name (distribution), variable name (distribution), ...

Numerous distributions may be specified. Three that are commonly used are

n = standard normal distribution, variance = 1,
t = triangular (tent shaped) distribution in [-1,+1], variance = 1/6,
u = standard uniform distribution [-1,1], variance = 1/3.

All random variables have mean zero. Note that each of these is scaled as it enters the distribution, so the variance is only that of the random draw before multiplication. The latter two distributions are provided as one may wish to reduce the amount of variation in the tails of the distribution of the parameters across individuals and to limit the range of variation. (See Train, 2010). Other options for the distributions of random parameters are described in Chapter R24. To specify that the constant term and the coefficient on *x*1 are normally distributed with fixed mean and variance, use

; Fcn = one(n), x1(n)

This specifies that the first and second coefficients are not random while the remainder are. The parameters estimated will be the mean and standard deviations of the distributions of these two parameters and the fixed values of the other three.

NOTE: The model with only a random constant term (**; Fcn = one(n)**) is precisely equivalent to the random effects model of the previous section.

E46.5.3 Application

The following example illustrates. Note that this simulates the assumptions of the model. The first instruction fits the RP model with only a random constant term, which is the random effects model. The second fits the model with both constant and one slope random.

```
SAMPLE    ; All $
CREATE    ; yrps = (1+vi)*x1 + x2 + eit + ui
          ; yrp = max(0,yrps) $
TOBIT     ; Lhs = yrp ; Rhs = x
          ; RPM ; Fcn = one(n), x1(n) ; Correlated
          ; Pds = 10 ; Pts = 20 ; Halton $
```

The results include estimates of the means and standard deviations of the distributions of the random parameters and the estimates of the nonrandom parameters. The log likelihood shown is conditioned on the random draws, so one might be cautious about using it to test hypotheses, for example, that the parameters are random at all by comparing it to the log likelihood from the basic model with all nonrandom coefficients. The random constant term model shown earlier is mathematically equivalent to the random effects model. The results for the quadrature based estimator are shown earlier with the simulation based estimates. They are strikingly close, in spite of the small number of draws used for the simulations. The marginal effects shown are for the simulation estimator. The results below are estimates of the model with two random parameters, the constant and the slope on $x1$. The true values of the two variance parameters for the random parameters are roughly 1.15 for the constant and .25 for the coefficient on $x1$. The true means are zero and one, while the true coefficient on $x2$ is also one.

Correlated Random Parameters

The default RP command defines an estimator for a model in which the covariance matrix of the random parameters is diagonal. To extend it to a model in which the parameters are freely correlated, add

; Correlation (or just ; Cor)

to the command. The example below estimates a random parameters model with correlated random constant term and random slope.

```

E46.5.4 Model Specifications

There are several additional model specifications and estimation controls that you can use with the random parameters model..

Heterogeneity in the Means

The preceding examples have specified that the mean of the random variable is fixed over individuals. If there is measured heterogeneity in the means, in the form of

$$E[\beta_{ki}] = \beta_k + \Sigma_m \delta_{km} z_{mi}$$

where z_m is a variable that is measured for each individual, then the command may be modified to

; RPM = list of variables in z

In the data set, these variables must be repeated for each observation in the group.

Controlling the Simulation

There are two parameters of the simulations that you can change. *R* is the number of points in the simulation. Authors differ in the appropriate value. Train (1999) recommends several hundred. Bhat suggests 1,000 is an appropriate value. The program default is 100. You can choose the value with

; Pts = number of draws, R

The value of 20 that we set in our experiments above was chosen purely to produce an example that you could replicate without spending an inordinate amount of waiting for the results.

The standard approach to simulation estimation is to use random draws from the specified distribution. As suggested immediately above, good performance in this connection requires very large numbers of draws. The drawback to this approach is that with large samples and large models, this entails a huge amount of computation and can be very time consuming. Some authors have documented dramatic speed gains with no degradation in simulation performance through the use of a small number of Halton draws instead of a large number of random draws. Authors (e.g., Bhat (1999)) have found that a Halton sequence of draws with only one tenth the number of draws as a random sequence is equally effective. To use this approach, add

; Halton

to your model command. The results below show the same model as estimated immediately above using five Halton draws instead of 20 simulated random draws. The estimates are essentially the same. The estimator based on the Halton sequences required roughly 20 seconds and 14 iterations to converge; the one based on the pseudorandom numbers required about 70 seconds and 15 iterations to reach the same estimates. (With ever faster computers, this consideration may ultimately be minor. However, we have of late heard from users who are employing data sets involving hundreds of thousands of observations. In a data set this large, use of the Halton sequences approach may produce a benefit worth pursuing.) Halton sequences are discussed in Section R24.7.

In order to replicate an estimation, you must use the same random draws. One implication of this is that if you give the identical model command twice in sequence, you will not get the identical set of results because the random draws in the sequences will be different. To obtain the same results, you must reset the seed of the random number generator with a command such as

CALC ; Ran(seed value) $

(Note that we have used **; Ran(12345)** before each of our examples above, precisely for this reason. The specific value you use for the seed is not of consequence; any odd number will do. You can also achieve replicability by using Halton sequences, which are not random, but are deterministic sequences.

E46.5.5 Model Estimates

Results saved by this estimator are:

Matrices:	*b*	=	estimate of θ
	varb	=	asymptotic covariance matrix for estimate of θ
	beta_i	=	individual specific parameters, if **; Par** is requested

Scalars:	*kreg*	= number of variables in Rhs
	nreg	= number of observations
	logl	= log likelihood function

Last Model: *b_variables*

Last Function: None

Section R24.5 describes a method of estimating the conditional mean of the distribution from which β_i is drawn When you include **; Parameters** in your command, the matrices of conditional means and conditional standard deviations are kept with the output of the model. The matrices below are generated by the model command in the previous section. These are in addition to *b* and *varb* shown below. The matrix *sdrpm* saves the implied estimates of the standard deviations of the random parameters. These are reported with the output as a matrix (column vector) of implied standard deviations. The matrix *gammarpm* is the lower triangular matrix assembled from the estimated parameter vector. In the vector of estimated parameters (see vector *b*), the diagonal elements of Γ appear first, followed by the below diagonal element(s). Finally, *beta_i* and *sdbeta_i* are computed with a row for each individual.

Figure E28.2 Matrix Results for RP Censored Regression

E46.6 Latent Class Models

The tobit, truncated and grouped data regression models for a panel of data, $i = 1,...,N$, $t = 1,...,T_i$ are denoted

$$f(y_{it} \mid \mathbf{x}_{it}) \;=\; f(y_{it},\boldsymbol{\beta}'\mathbf{x}_{it}) \;=\; f(i,t).$$

Henceforth, we will use the term 'group' to indicate the T_i observations on respondent i in periods $t = 1,...,T_i$. Unobserved heterogeneity in the distribution of y_{it} is assumed to impact the density in the form of a random effect. The continuous distribution of the heterogeneity is approximated by using a finite number of 'points of support.' The distribution is approximated by estimating the location of the support points and the mass (probability) in each interval. In implementation, it is convenient and useful to interpret this discrete approximation as producing a sorting of individuals (by heterogeneity) into J classes, $j = 1,...,J$. (Since this is an approximation, J is chosen by the analyst.)

Thus, we modify the model for a latent sorting of y_{it} into J 'classes' with a model which allows for heterogeneity as follows: The density of the observed y_{it} given that regime j applies is

$$f(i,t|j) \;=\; f(y_{it}|\, \mathbf{x}_{it}, j)$$

where the density is now specific to the group. The analyst does not observe directly which class, $j = 1,...,J$ generated observation $y_{it}|j$, and class membership must be estimated. Heckman and Singer (1984) suggest a simple form of the class variation in which only the constant term varies across the classes. This would produce the model

$$f(i,t|j) \;=\; f(y_{it},\, \boldsymbol{\beta}'\mathbf{x}_{it} \;+\; \delta_j),\ \text{Prob[class} = j] \;=\; F_{j.}$$

We formulate this approximation more generally as,

$$f(i,t|j) \;=\; f[y_{it} \mid \boldsymbol{\beta}'\mathbf{x}_{it} \;+\; \boldsymbol{\delta}_j'\mathbf{x}_{it},\, \sigma_j),$$

$$F_j \;=\; \exp(\theta_j) \,/\, \Sigma_j \exp(\theta_j),\ \text{with } \theta_J \;=0.$$

In this formulation, each group has its own parameter vector, $(\boldsymbol{\beta}_j',\sigma_j) = (\boldsymbol{\beta} + \boldsymbol{\delta}_j,\sigma_j)$ though the variables that enter the mean are assumed to be the same. (This can be changed by imposing restrictions on the full parameter vector, as described below.) This allows the Heckman and Singer formulation as a special case by imposing restrictions on the parameters. (A further generalization is discussed below.) The class probabilities can also be extended in the form of a multinomial logit model;

$$\theta_{ij} \;=\; \boldsymbol{\theta}_j'\mathbf{z}_i$$

by adding the variable names for these variables in the command as shown below.

E46.6.1 Commands for Latent Class Models

The estimation command for this model is

TOBIT ; Lhs = ...
or TRUNCATE ; Rhs = independent variables
or GROUPED ; LCM = list of variables in z if desired (= list is optional)
; Pds = panel data specification
; Pts = number of latent classes $

The default number of support points is five. You may set *J* to 2, 3, ..., 9 with

; Pts = the value you wish

The limit value and censoring in the lower tail may be changed with

; Limit = the nonzero value
and/or **; Upper censoring or truncation**

This estimator only supports censoring in one tail. Other options are the standard ones for the tobit and truncation models. Some particular values computed for the latent class model are

; Parameters to keep the individual specific parameter estimates.
; Group = name to retain the index of the most likely latent class
; Cprob = name to retain the estimated probability for the most likely latent class

You can obtain a listing of these two results by using

; List

Other model specifications appear in the list below.

This estimator does not support restrictions with **; CML** or **; Test:** However, you can use the **; Rst = list** option to constrain the model, for example to structure the latent class model so that different variables appear in different classes or that classes have common parameters as in the Heckman and Singer form of the model. To use these options, note, first, that the structure of the parameter vector is as follows:

$$\beta_1,\sigma_1,\ \beta_2,\sigma_2,\ ...,\ \beta_J,\sigma_J,\ \theta_1,\ \theta_2,...,\theta_J.$$

That is, the model parameters for the classes appear first, followed by the structural parameters for the class probabilities. Note that θ_J will be set equal to zero by the program, but if you use **; Rst**, you must treat θ_J as a free parameter. The example below demonstrates. In the following, we set up a three class model in which the two slope parameters and the disturbance variance parameters are forced to the same in all three classes, but the constants differ. This would correspond to Heckman and Singer's formulation of a random effects model.

The commands are as follows:

```
TOBIT   ; Lhs = y
        ; Rhs = one,x1,x2
        ; LCM
        ; Pts  = 3
        ; Pds = 10
        ; Rst = a1,b1,b2,sigmav, a2,b1,b2,sigmav, a3,b1,b2,sigmav,
                theta1,theta2,theta3 $
```

Standard Model Specifications for the Latent Class Truncated Regression Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par keeps individual specific parameter estimates.
; Margin displays marginal effects.
; OLS displays least squares starting values when (and if) they are computed.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Robust requests a sandwich estimator or robust VC for TSCS and some discrete choice models.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level ‘**n**’ is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E46.6.2 Model Estimates

Estimates retained by this model include

Matrices: *b* = full parameter vector, $[\boldsymbol{\beta}_1',\sigma_1, \boldsymbol{\beta}_2',\sigma_2, \ldots F_1,\ldots,F_J]$
varb = full covariance matrix
beta_i = individual specific parameters, if **; Par** is requested

Note that *b* and *varb* involve $J\times(K+2)$ estimates. Two additional matrices are created,

b_class = a $J\times K$ matrix with each row equal to the corresponding $\boldsymbol{\beta}_j$
class_pr = a $J\times 1$ vector containing the estimated class probabilities

Scalars: *kreg* = number of variables in Rhs list
nreg = total number of observations used for estimation
logl = maximized value of the log likelihood function
exitcode = exit status of the estimation procedure.

Last Function: None

E46.6.3 Applications

The first two sets of results fit three class latent class models to the simulated data used in the earlier examples. The third fits the Heckman and Singer random effects model noted earlier.

```
TOBIT      ; Lhs = y ; Rhs = one,x1,x2
           ; LCM
           ; Pts = 3
           ; Pds = 10 $
TRUNCATE   ; Lhs = y ; Rhs = one,x1,x2
           ; LCM
           ; Pts = 3
           ; Pds = 10 $
TOBIT      ; Lhs = y ; Rhs = x
           ; LCM
           ; Pts = 3
           ; Pds = 10
           ; Rst = b1,b2,b3,b4,a1,vv, b1,b2,b3,b4,a2,vv, b1,b2,b3,b4,a3,vv,
                   theta1,theta2,theta3 $
```

```

```

The following are the latent class estimates with variation only in the constant term. This model is comparable to the random effects model with continuous variation in the constant. The random effects model estimated earlier is shown below the latent class model. The estimates of the model parameters are strikingly similar. The similarity goes beyond that, however. After the results, we compute the standard deviation of the estimated random effects for the latent class model. Based on the three observations, the estimate is 0.9119797. The counterpart in the random effects model is 0.94842.

E47: Limited Dependent Variable Models

E47.1 Introduction

The models and estimators described in this chapter are (numerous) variations on the following general structure:

Latent Underlying Regression: $y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ \varepsilon_i \sim N[0,\sigma^2]$.

Observed Dependent Variable: if $y_i^* \leq L_i$, then $y_i = L_i$ (lower tail censoring)

if $y_i^* \geq U_i$, then $y_i = U_i$ (upper tail censoring)

if $L_i < y_i^* < U_i$, then $y_i = y_i^* = \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i$.

Truncation, in which only data in the third group are observed, is a related case which is discussed in Section E47.4. In practice, most of the received applications involve censoring, rather than truncation. The thresholds, L_i and U_i, may be constants or variables. We accommodate censoring in the upper or lower (or both) tails of the distribution. The most familiar case of this model in the literature is the 'tobit' model, in which $U_i = +\infty$ and $L_i = 0$, i.e., the case in which the observed data contain a cluster of zeros. In the standard 'censored regression,' or tobit model, the censored range of y_i^* is the half of the line below zero. (For convenience, we will drop the observation subscript at this point.) If y^* is not positive, a zero is observed for y, otherwise the observation is y^*. Models of expenditure are typical. We also allow censoring of the upper tail ('on the right'). A model of the demand for tickets to sporting events might be an application, since the actual demand is only observed if it is not more than the capacity of the facility (stadium, etc.). A somewhat more elaborate specification is obtained when the range of y^* is censored in both tails. This is the 'two limit probit' model. An application might be a model of weekly hours worked, in which less than half time is reported as 20 and more than 40 is reported as 'full time,' i.e., 40 or more.

The preceding gives the basic model. We also allow for several variations, including a model with heteroscedasticity and models for panel data.

E47.2 Tobit Model

The basic tobit model corresponds to the specification in the Introduction. This model is developed in Chapter E45. The sections to follow show some extensions of the tobit model, including heteroscedasticity and two bivariate models.

E47.2.1 Heteroscedastic Tobit Model

The disturbance in the tobit model may be heteroscedastic so that the variance term is

$$\sigma_i = \sigma e^{\boldsymbol{\gamma}'\mathbf{z}_i}.$$

This is the model of multiplicative heteroscedasticity used in several earlier models. This model is requested with

```
TOBIT        ; Lhs  = y ; Rhs = list for x
             ; Het ; Hfn = list for z $
```

Limit specifications are as usual, upper (**; Upper**) or lower (default) censoring, and the limit value may be supplied with **; Limit = value** and all other parts of the command and options are the same as for the basic model.

> **NOTE:** Do not include *one* in the Hfn list. Since σ is a free parameter, including *one* will put a redundant constant in the variance model. This will cause a singular covariance matrix. (Previous versions of *LIMDEP* used Rh2 instead of Hfn in this specification. You may continue to use that syntax.)

The full parameter vector is now [**β**,**γ**,σ]. Use this setup if you are providing starting values with **; Start = list** or imposing restrictions with **; Rst = list** or **; CML: restrictions**. The results saved are: log likelihood, identification of limit values, configuration of parameter vector, estimates of [**β**,**γ**,σ], etc. The matrices *b* and *varb* will include the estimates of **γ**. As before, σ is the ancillary parameter. The specification **; Par** adds σ to the retained parameter vector. Finally, the *Last Model* parameters are [*b_variables_in_x*, *c_variables_in_z*].

Testing for Heteroscedasticity

The three familiar testing procedures are available for testing for heteroscedasticity in the tobit model. The following template shows how to apply the three procedures: We first set up the variables that appear in the model

```
NAMELIST    ; x = the full Rhs for the mean in the model $
NAMELIST    ; z = the variables in the variance function, does not include one $
CREATE      ; y = the dependent variable $
```

The dimensions will be needed for degrees of freedom and matrix manipulations.

```
CALC        ; kx = Col(x) ; kz = Col(z) $
```

This is the restricted, homoscedastic model.

```
TOBIT       ; Lhs = y ; Rhs = x ; (if necessary, set up limits specification) $
CALC        ; Lr = logl ; vr = s $
```

This does the LM test. The command sends in restricted estimates and does no iterations.

```
TOBIT       ; Lhs = y ; Rhs = x ; Rh2 = z ; Het
            ; Start = b, kz_0, vr ; Maxit = 0 $
```

This does the likelihood ratio test.

```
TOBIT       ; Lhs = y ; Rhs = x ; Rh2 = z ; Het ; Par $
CALC        ; lu = logl ; List ; chisq = 2*(lu - lr) ; signif = 1 - Chi(chisq,kz) $
```

We now do the Wald test.

```
CALC        ; kx1 = kx+1 ; kxz = kx+kz $
MATRIX      ; ghet = b(kx1:kxz) ; vghet = Varb(kx1:kxz, kx1:kxz)
            ; List ; waldstat = ghet'<vghet>ghet $
CALC        ; List ; signif = 1 - Chi(waldstat,kz) $
```

Partial Effects

Let w_i be a variable which can appear in either $\mathbf{x}_i$ or $\mathbf{z}_i$ or both. The marginal effects for $\mathbf{x}_i$ were given earlier;

$$\frac{\partial E[y_i \mid \mathbf{x}_i, \mathbf{z}_i]}{\partial w_i} = [\Phi_{Ui} - \Phi_{Li}]\beta_{\mathrm{w}} = [\text{Prob(uncensored region)}] \times \text{coefficient},$$

where Φ_{ji} is the probability associated with the censored regions, lower or upper. (See the technical details below.) For the terms in the variance function, we have the result

$$\frac{\partial E[y_i \mid \mathbf{x}_i, \mathbf{z}_i]}{\partial w_i} = \sigma_i[\phi_{Li} - \phi_{Ui}]\,\gamma_{w\,=}\,\sigma_i\,[\text{difference in densities at censoring points}]\times\text{coefficient}.$$

Now, let w_i be a variable which is assumed to appear both in $\mathbf{x}_i$ and $\mathbf{z}_i$. Then,

$$\frac{\partial E[y_i \mid \mathbf{x}_i, \mathbf{z}_i]}{\partial w_i} = [\Phi_{Ui} - \Phi_{Li}]\beta_w + (\phi_{Li} - \phi_{Ui})\sigma_i\gamma_w.$$

This provides a decomposition of the marginal effect. The decomposition is reported in the table of marginal effects. (See the example below and the derivations in the technical details below.) As always, marginal effects are requested with

```
            ; Partial Effects
```

Partial Effect for a Dummy Variable

The partial effect for a binary variable will be more involved than that for a continuous variable. Define the following components, where C is the dummy variable

$$E[y^*|\mathbf{x},C{=}1] = \boldsymbol{\beta}'\mathbf{x} + \delta,\ \mathrm{Var}[\varepsilon|\mathbf{z},C{=}1] = \sigma\exp(\boldsymbol{\gamma}'\mathbf{z} + \lambda) = \sigma_1$$

$$E[y^*|\mathbf{x},C{=}0] = \boldsymbol{\beta}'\mathbf{x}\ ,\ \mathrm{Var}[\varepsilon|\mathbf{z},C{=}0] = \sigma\exp(\boldsymbol{\gamma}'\mathbf{z}) = \sigma_0$$

We assume that C can enter either the mean function, the standard deviation, or both. To accommodate all cases, either δ or λ may be zero, but neither need be.

Now, let the censoring limits be L and U,

$$\alpha_L^1 = (L - \boldsymbol{\beta}'\mathbf{x} - \delta)/\sigma_1,\ \alpha_L^0 = (L - \boldsymbol{\beta}'\mathbf{x})/\sigma_0$$

$$\alpha_U^1 = (U - \boldsymbol{\beta}'\mathbf{x} - \delta)/\sigma_1,\ \alpha_U^0 = (U - \boldsymbol{\beta}'\mathbf{x})/\sigma_0$$

$$\Phi_j^m = \Phi(\alpha_j^m),\ j = L,U,\ m = 0,1$$

$$\phi_j^m = \phi(\alpha_j^m),\ j = L,U,\ m = 0,1$$

The conditional mean functions for the two cases, $C = 1$ and $C = 0$, are

$$E[y|\mathbf{x},\mathbf{z},C] = \Phi_L^m L + (1 - \Phi_U^m)U + (\Phi_U^m - \Phi_L^m)(\boldsymbol{\beta}'\mathbf{x} + m) + \sigma_m(\phi_L^m - \phi_U^m),\ m = 0,1$$

This does not simplify in any convenient way. Taking the difference,

$$\begin{aligned}\text{E}[y|\mathbf{x},\mathbf{z},C{=}1] - \text{E}[y|\mathbf{x},\mathbf{z},C{=}0] = &\ (\Phi_L^1 - \Phi_L^0)L + (\Phi_U^0 - \Phi_U^1)U \\ &+ \beta'\text{x}\,(\Phi_U^1 - \Phi_L^1 - \Phi_U^0 + \Phi_L^0) + \delta(\Phi_U^1 - \Phi_L^1) \\ &+ \sigma_1(\phi_L^1 - \phi_U^1) - \sigma_0(\phi_L^0 - \phi_U^0)\end{aligned}$$

The internal program invoked with **; Partials** in the command computes effects for dummy variables using the scaled coefficients, as if the variable were continuous. To obtain partial effects (at the means, or averaged over the data), you should use the **PARTIALS** command instead. The example below illustrates.

The following illustrates the testing procedures and computation of partial effects for the heteroscedasticity model. It computes the LM, LR and Wald tests, respectively.

```
CREATE      ; kids = (kl6+k618)>0 ; y = whrs $
NAMELIST    ; x = one,kl6,k618,wa,we  ; z = wa,kids $
CALC        ; kx = Col(x) ; kz = Col(z) $
TOBIT       ; Lhs = y ; Rhs = x  $
CALC        ; lr = logl ; vr = s $
TOBIT       ; Lhs = y ; Rhs = x ; Hfn = z ; Het
            ; Start = b, kz_0, vr ; Maxit = 0 $

Technical Details for the Tobit Model with Heteroscedasticity

The parameters are not normalized by the Olsen transformation for this model. We let:

$$\varepsilon_i = y_i - \boldsymbol{\beta}'\mathbf{x}_i,$$

$$\theta_i = \sigma\varepsilon^{\boldsymbol{\gamma}'\mathbf{z}_i},$$

$$d_{0i} = 1 \text{ if } y_i < L \text{ or } y_i > U, 0 \text{ otherwise},$$

$$d_{1i} = 1 - \mathrm{d}_0,$$

$$r_i = 1 \text{ and } w_i = (\boldsymbol{\beta}'\mathbf{x}_i - L_i)/\theta_i \text{ if } y_i \le L_i,$$

$$r_i = -1 \text{ and } w_i = (U_i - \boldsymbol{\beta}'\mathbf{x}_i)/\theta_\mathrm{i} \text{ if } y_i \ge U_i,$$

$$P_i = \Phi(-w_i)$$

$$\phi_i = \phi(-w_i).$$

Then,

$$\log L_i = d_{0i}\log \mathrm{P}_i + d_{1i}(-\log\theta_i - (\varepsilon_i/\theta_i)^2/2 - \log(2\pi)/2),$$

$$\partial\log L_i/\partial\boldsymbol{\beta} = [(d_{1i}\varepsilon_i/\theta_i - d_{0i}\, r_i\phi_i/\Phi_i)/\theta_i]\mathbf{x}_i,$$

$$\partial\log L_i/\partial\boldsymbol{\gamma} = [\mathrm{d}_{1i}((\varepsilon_i/\theta_i)^2 - 1) + d_{0i}w_i\phi_i/\Phi_i]\mathbf{z}_\mathrm{i},$$

$$\partial\log L_i/\partial\sigma = [\mathrm{d}_{1i}((\varepsilon_i/\theta_i)^2 - 1) + d_{0i}w_i\phi_i/\Phi_i]/\sigma.$$

The BHHH estimator, using the outer product of the gradients, is used to estimate the asymptotic covariance matrix of the estimates.

The marginal effects in this model are complicated a bit by the fact that variables may appear in both the mean and the variance. The conditional mean function in the fully general model is

$$E[y_i|\mathbf{x}_i,\mathbf{z}_i] = \Phi_{Li}\times L_i + (1-\Phi_{Ui})Ui + (\Phi_{Ui} - \Phi_{Li})\left(\boldsymbol{\beta}'\mathbf{x}_i + \sigma_i\frac{\phi_{Li} - \phi_{Ui}}{\Phi_{Ui} - \Phi_{Li}}\right)$$

where

$$\Phi_{Li} = \Phi\left(\frac{L_i - \boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}\right) = \Phi(\alpha_{Li}), \text{ and let } a_{Li} = \partial\alpha_{Li}/\partial\sigma_i = -\alpha_{Li}/\sigma_i$$

$$\Phi_{Ui} = \Phi\left(\frac{U_i - \boldsymbol{\beta}'\mathbf{x}_i}{\sigma_i}\right) = \Phi(\alpha_{Ui}), \text{ and let } a_{Ui} = \partial\alpha_{Ui}/\partial\sigma_i = -\alpha_{Ui}/\sigma_i$$

$$\sigma_i = \sigma e^{\boldsymbol{\gamma}'\mathbf{z}_i}.$$

As derived in Greene (1999), marginal effects for the variables in the mean are simple;

$$\partial\mathrm{E}[y_i|\mathbf{x}_i,\mathbf{z}_i]/\partial\mathbf{x}_i = (\Phi_{Ui} - \Phi_{Li})\boldsymbol{\beta}$$

But, $\partial E[y_i|\mathbf{x}_i,\mathbf{z}_i]/\partial\sigma_i$ is considerably more involved (at least it appears so). The desired result is

$$\frac{\partial E[y_i \mid \mathbf{x}_i, \mathbf{z}_i]}{\partial\sigma_i} = \phi_{Li}L_i a_{Li} - \phi_{ui}U_i a_{Ui} + \boldsymbol{\beta}'\mathbf{x}_i\phi_{Ui}a_{Ui} - \boldsymbol{\beta}'\mathbf{x}_i\phi_{Li}a_{Li} + \phi_{Li} - \phi_{Ui}$$
$$- \sigma_i\alpha_{Li}\phi_{Li}\times(-\alpha_{Li})/\sigma_i + \sigma_i\alpha_{Ui}\phi_{Ui}\times(-\alpha_{Ui})/\sigma_i.$$

Collecting terms, and recalling the definitions of α_{Li} and α_{Ui} produces the striking result

$$\frac{\partial E[y_i \mid \mathbf{x}_i, \mathbf{z}_i]}{\partial \sigma_i} = \phi_{Li} - \phi_{Ui}$$

Now, let w_i be a variable which is assumed to appear both in $\mathbf{x}_i$ and $\mathbf{z}_i$. Then,

$$\frac{\partial E[y_i \mid \mathbf{x}_i, \mathbf{z}_i]}{\partial w_i} = [\Phi_{Ui} - \Phi_{Li}]\beta_w + (\phi_{Li} - \phi_{Ui})\sigma_i\gamma_w$$

Analytic results for the standard errors of the marginal effects are complicated considerably by the presence of the estimated ancillary parameter, σ. To simplify matters, let $\gamma_0 = \log\sigma$ and add a constant (one) to $\mathbf{z}_i$. Include this parameter in γ so that now, $\sigma_i = \exp(\boldsymbol{\gamma}'\mathbf{z}_i)$. The full parameter vector is now $\boldsymbol{\theta} = [\boldsymbol{\beta}', \boldsymbol{\gamma}']'$. In preparation for this, the entire last row of the $(K + L + 1)\times(K + L + 1)$ asymptotic covariance matrix for the directly estimated parameters, $\boldsymbol{\beta}$, $\boldsymbol{\gamma}$ (without γ_0), and σ, is multiplied by $1/\sigma$, then the last diagonal element is multiplied by $1/\sigma$ again. This gives us a parameter vector and asymptotic covariance matrix that are conveniently partitioned into two parts. With all this in place, we now obtain the estimates of the asymptotic standard errors for the marginal effects using the delta method. The marginal effects are

$$\boldsymbol{\delta}_{\mathbf{x}} = [\Phi_U - \Phi_L] \times \boldsymbol{\beta}$$

$$\boldsymbol{\delta}_{\mathbf{z}} = [\phi_L - \phi_U]\sigma \times \boldsymbol{\gamma}$$

(Observation subscripts are dropped for the moment. Recall, $\sigma = \exp(\boldsymbol{\gamma}'\mathbf{z})$. In order to use the delta method, we will require the following derivatives - the tedious algebra is omitted;

$$\frac{\partial \boldsymbol{\delta}_{\mathbf{x}}}{\partial \boldsymbol{\beta}'} = (\Phi_U - \Phi_L)\mathbf{I} - \frac{1}{\sigma}(\phi_U - \phi_L)\boldsymbol{\beta}\mathbf{x}'$$

$$\frac{\partial \boldsymbol{\delta}_{\mathbf{x}}}{\partial \boldsymbol{\gamma}'} = (\phi_L \alpha_L - \phi_U \alpha_U)\boldsymbol{\beta}\mathbf{z}'$$

$$\frac{\partial \boldsymbol{\delta}_{\mathbf{z}}}{\partial \boldsymbol{\beta}'} = (\phi_L \alpha_L - \phi_U \alpha_U)\boldsymbol{\gamma}\mathbf{x}'$$

$$\frac{\partial \boldsymbol{\delta}_{\mathbf{z}}}{\partial \boldsymbol{\gamma}'} = \sigma(\phi_L - \phi_U)(\mathbf{I} + \boldsymbol{\gamma}\mathbf{z}') + \sigma\left(\alpha_L^2\phi_L - \alpha_U^2\phi_U\right)\boldsymbol{\gamma}\mathbf{z}'$$

Collect these in the matrix $\mathbf{G}$ which is now partitioned conformably with the estimated asymptotic covariance matrix for the parameter estimates, $\mathbf{V}$. The estimated asymptotic covariance matrix for the marginal effects is then $\mathbf{GVG}'$. At completion, the last row and column, corresponding to the scale parameter, σ, are discarded. Finally, for variables which appear in both $\mathbf{x}$ and $\mathbf{z}$, the marginal effect is the sum. The estimated asymptotic variance for such a variable is simply the sum of the two estimated variances plus twice the estimated covariance.

E47.2.2 Bivariate and Nested Tobit Models

The equations of a bivariate tobit model would be

$$y_1^* = \boldsymbol{\beta}_1'\mathbf{x}_1 + \varepsilon_1$$

$$y_1 = \text{Maximum}(y_1^*, 0) \quad \text{(the usual tobit specification)}$$

$$y_2^* = \boldsymbol{\beta}_2'\mathbf{x}_2 + \varepsilon_2$$

$$y_2 = \text{Maximum}(y_2^*, 0) \quad \text{(the usual tobit specification)}$$

$$\varepsilon_1,\varepsilon_2 \sim N[0,0,\sigma_1^2,\sigma_2^2,\rho], \text{ covariance is } \sigma_{12} = \rho\sigma_1\sigma_2.$$

The parameters of the bivariate model may be estimated by full information maximum likelihood (FIML). The nested tobit variant of this model, as specified in Lee (1992) and Howe, et al. (1994) is another form of sample selection model: The model is defined by the additional specification

$$y_2,\mathbf{x}_2 \text{ observed only when } y_1 > 0.$$

The command for the bivariate tobit model is

BTOBIT ; Lhs = y1,y2 ; Rh1 = ... x1 ... ; Rh2 = ... x2 ... $

and for nested tobit model, it is

NTOBIT ; Lhs = y1,y2 ; Rh1 = ... x1 ... ; Rh2 = ... x2 ... $

The parameter vector for both models is $\boldsymbol{\theta} = [\boldsymbol{\beta}_1,\boldsymbol{\beta}_2,\sigma_1,\sigma_2,\rho]$. The default starting values for the iterations are OLS as usual for the tobit model, and zero for ρ. You may provide your own starting values with **; Start = list** and impose within equation restrictions on the parameters with **; Rst = list**. The limit points for both equations in this model must be zero. The **; Limits = ...** specification is not used, and is ignored if present.

The usual output and optimization options are available for this model, however, neither fitted values (**; Keep**, **; List**, **; Res**) nor marginal effects (**; Partial Effects**) are computed. The retrievable results are $b = (\boldsymbol{\beta}_1,\boldsymbol{\beta}_2)$ and *varb*. The specification **; Par** adds (σ_1,σ_2,ρ) to b and *varb*. The scalars are $kreg = k_1+k_2+3$, *nreg*, *logl*, *sigma*1, *sigma*2, *rho*, and *exitcode*. The *Last Model* labels for **WALD** are *b*1*_variables*, *b*2*_variables*, *sigma*1, *sigma*2, *r*12.

Technical Details

We use the Olsen normalization, $\boldsymbol{\gamma}_1 = \boldsymbol{\beta}_1/\sigma_1$, $\eta_1 = 1/\sigma_1$, $\boldsymbol{\gamma}_2 = \boldsymbol{\beta}_2/\sigma_2$, $\eta_2 = 1/\sigma_2$. The remaining parameter is $\rho = \text{Corr}[\eta_1\varepsilon_1,\eta_2\varepsilon_2]$. During estimation, we use the transformation of ρ, $\tau = \log((1+\rho)/(1-\rho))$. This transformed parameter ranges over the entire real line, so the parameter cannot go out of bounds during the iterations. Internally, ρ is obtained as $\rho = [\exp(\tau)-1]/][\exp(\tau)+1]$. Derivatives are modified accordingly. However, note that technical output shown during iterations will display τ, nor ρ.

Let

$$\delta = 1/(1 - \rho^2)^{1/2},$$

$$\varepsilon_1 = \eta_1 y_1 - \boldsymbol{\gamma}_1'\mathbf{x}_1,$$

$$\varepsilon_2 = \eta_2 y_2 - \boldsymbol{\gamma}_2'\mathbf{x}_2$$

Then, the log likelihood function for the nested tobit model is

$$\begin{aligned}\log L \quad = \quad & \Sigma_{y1=0}\log[1 - \Phi(\boldsymbol{\gamma}_1'\mathbf{x}_1)] \\ & + \Sigma_{y1=1,y2=0} \log\{\eta_1\phi(\eta_1 y_1 - \boldsymbol{\gamma}_1'\mathbf{x}_1)[1 - \Phi(\delta(\boldsymbol{\gamma}_2'\mathbf{x}_2 + \rho\varepsilon_1))]\} \\ & + \Sigma_{y1=1,y2=1} -\log 2\pi + \log(\eta_1\eta_2\delta - 2\delta^2(\varepsilon_1^2 + \varepsilon_2^2 - 2\rho\varepsilon_1\varepsilon_2).\end{aligned}$$

The third term is the log of the density of the bivariate normal distribution. Derivatives can be obtained from results above. The BHHH estimator is used for the asymptotic covariance matrix. For the bivariate tobit model, there are four cells. The second term above is accompanied by a counterpart which reverses the role of the two variables while the first is replaced with the joint probability of two limit observations. The result is

$$\begin{aligned}\log L \quad = \quad & \Sigma_{y1=0,y2=0}\log[\Phi_2(-\boldsymbol{\gamma}_1'\mathbf{x}_1, -\boldsymbol{\gamma}_2'\mathbf{x}_2, \rho)] \\ & + \Sigma_{y1>0,y2=0} \log\{\eta_1\phi(\eta_1 y_1 - \boldsymbol{\gamma}_1'\mathbf{x}_1)[1 - \Phi(\delta(\boldsymbol{\gamma}_2'\mathbf{x}_2 + \rho\varepsilon_1))]\} \\ & + \Sigma_{y1=0,y2>0} \log\{\eta_2\phi(\eta_2 y_2 - \boldsymbol{\gamma}_2'\mathbf{x}_2)[1 - \Phi(\delta(\boldsymbol{\gamma}_1'\mathbf{x}_1 + \rho\varepsilon_2))]\} \\ & + \Sigma_{y1=1,y2=1} -\log 2\pi + \log(\eta_1\eta_2\delta - 2\delta^2(\varepsilon_1^2 + \varepsilon_2^2 - 2\rho\varepsilon_1\varepsilon_2),\end{aligned}$$

where Φ_2 denotes the CDF for the bivariate standard normal distribution.

NOTE: Because of the use of the Olsen transformation, it is not possible to impose cross equation equality restrictions in this model. In principle they may be imposed, but equality of scaled (by σ_j) coefficients does not imply equality of the original coefficients.

Application

To illustrate this model, we have fit a bivariate tobit model for the wife's and husband's hours in the labor supply data. The command is

BTOBIT ; Lhs = whrs,hhrs ; Rh1 = one,kl6,k618
; Rh2 = one,ha,he,faminc,kids $

E47.3 Categorical (Grouped) Data

A special case of the censored data regression model arises when the range of the dependent variable is completely censored. This is the case when data are reported only by interval category. For example, income data might be reported only by range. We assume that the finite (internal) terminal points are known. The dependent variable is coded $y = 1, 2, ..., J$ (not 0,..., as in the case of the probability models). For example, consider a survey of incomes, which reports ranges:

$$y = \begin{cases} 1 \text{ if } & y^* < \$\,15{,}000, \\ 2 \text{ if } \$\,15{,}000 \le & y^* < \$\,30{,}000, \\ 3 \text{ if } \$\,30{,}000 \le & y^* < \$\,50{,}000, \\ 4 \text{ if } \$\,50{,}000 \le & y^* < \$\,75{,}000, \\ 5 \text{ if } & y^* \ge \$\,75{,}000. \end{cases}$$

Formally, the model is

$$\text{(unobserved)} \quad y^* = \boldsymbol{\beta}'\mathbf{x} + \varepsilon, \ \varepsilon \sim N[0,\sigma^2],$$

$$\text{(observed)} \quad y = j \ \text{if} \ A_{j-1} \le y^* < A_j, j = 1,...,J, A_0 = -\infty, A_J = +\infty.$$

The difference between this and the ordered probit model of Chapter E34 is that the threshold values are known here. Since that is true, there is information on the scale of y^* in the data. Hence an estimate of σ is produced. It is not necessary to normalize it to 1.0.

The command for the grouped data model is

```
GROUPED DATA        ; Lhs = dependent variable
(or just GROUPED)   ; Rhs = regressors
                    ; Limits = a1,a2,...,aJ-1 $
```

The limit points may be constants or variables. If your data are in J groups, there will always be exactly J-1 interior limit values, which must be given in increasing order. If the match is not found, the estimator aborts. The data will be inspected to determine the value of J. In addition, if there are any empty cells (i.e., intermediate values of y which are never observed), a diagnostic is given and the estimation is discontinued. The limits are also checked. If they are not in ascending order for every observation, it is necessary to stop the estimation. For the earlier example, the command would be

```
GROUPED DATA        ; Lhs = y
                    ; Rhs = ... regressors
                    ; Limits = 5000,7000,10000,15000 $
```

In this case, there are five values of the dependent variable, so four limit values are given.

The command is otherwise identical to the **TOBIT** command, and the other options (fitted values, restrictions, starting values, iteration controls, and so on) are the same. Output is likewise the same. Since the dependent variable is not observed, there is no obvious conditional mean function. As such, there are no marginal effects for this model. You can request a listing of predictions of a sort with **; List**. Let L_i and U_i denote the lower and upper limits of the range indicated by the observed y_i. Thus, if y_i equals one, L_i is -∞ and U_i is A_1, the first limit value given. The conditional mean function is then the expected value of y^* in this range, which is the same as that for the truncated regression model,

$$E[y^*|\mathbf{x}_i, L_i < y^* < U_i] = \boldsymbol{\beta}'\mathbf{x}_i + \sigma_i \frac{\phi_L - \phi_U}{\Phi_U - \Phi_L},$$

where

$$\alpha_j = (j - \boldsymbol{\beta}'\mathbf{x})/\sigma, j = L,U$$

$$\Phi_j = \Phi(\alpha_j)$$

$$\phi_j = \phi(\alpha_j).$$

The results displayed for this model are the same as for the tobit model including OLS results if you request them with **; OLS**, the iterations, then, the log likelihood, endpoints of all intervals, estimates of [$\boldsymbol{\beta}$,σ], and so on. The retrievable results (matrices *b* and *varb*, scalars, and *Last Model* labels) for this estimator are also the same as for the tobit model with the creation of an additional matrix,

limits = limit values, including large values for the outside limits ($-\infty$ and $+\infty$).

This matrix can be used in subsequent **GROUPED DATA** commands, for example, if you are using the same Lhs variable and just changing the specification on the right hand side.

NOTE: The OLS starting values are obtained by a crude transformation of the dependent variable. For $y = 1$, $y' = A_1$; if $y = J$, $y' = A_{J-1}$. For other values, y' is the average of the two bracketing limit values. Then, y' is regressed on the Rhs variables. This will produce a coefficient vector that has the same order of magnitude as the MLE.

E47.3.1 Grouped (Categorical) Panel Data

LIMDEP's full menu of panel data estimators is available for the categorical data regression model. (Full documentation on the modeling frameworks appears in Chapter R24 and below for the tobit model.) To estimate the model, you must provide the starting values, which you should do, in all cases, by first fitting the model with no individual effects. Thus, your command for this model will appear as

GROUPED ; Lhs = ... ; Rhs = ... ; Limits = the set of limits as described above $
GROUPED ; Lhs = ... ; Rhs = ... ; Limits = the set of limits as described above
; Pds = ... the specification of the panel structure

plus exactly one of

; FEM for the fixed effects model
or **; RPM ; Fcn = ... specification for the random parameters model**
or **; LCM ; Pts = J for the latent class model $**

Other parts of the specification for the categorical data model are the same as for other models of this type, e.g., tobit and truncation, that are documented elsewhere in this chapter.

E47.3.2 Heteroscedasticity

LIMDEP's generic formulation for heteroscedasticity,

$$\sigma_i = \sigma \times \exp(\boldsymbol{\delta}'\mathbf{z}_i)$$

is supported for the grouped data (interval censored) regression model. The option is requested with

; Het ; Hfn = list

Since the basic scale parameter σ is maintained, it plays the role of the constant term in the variance model, so your **; Hfn** list should not contain *one*.

E47.3.3 Grouped Data and Sample Selection

The grouped data model is also extended to the sample selection treatment. (This model is developed in Bhat (1994).) The model is as above with the added feature that data for the primary model are observed (or not) nonrandomly via a Heckman style selection equation. The model is as follows:

$$
\begin{aligned}
y^* &= \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\ \varepsilon \sim N[0,\sigma^2],\\
y &= j \text{ if } A_{j-1} \le y^* < A_j,\ j = 1,\ldots,J,\ A_0 = -\infty,\ A_J = +\infty,\\
d^* &= \boldsymbol{\alpha}'\mathbf{z} + u,\\
d &= 1 \text{ if } d^* > 0 \text{ and } 0 \text{ otherwise},\\
[\varepsilon,u] &\sim N_2[0,0,\sigma^2,1,\rho],\\
[y,\mathbf{x}] &\quad \text{are observed only when } d = 1.
\end{aligned}
$$

The correlation between ε and u is ρ. The selection aspect of the model arises when ρ is not equal to zero. Note that this extension is the same as its counterpart discussed below for the tobit model.

The command is

```
GROUPED     ; Lhs = y,d
            ; Rh1 = variables in x
            ; Rh2 = variables in z
            ; Limits = a1, a2,...,aJ-1 $
```

The **GROUPED DATA** command is exactly the same as in the nonselected case. As before, you give only the interior limit points. The difference is the specification of the probit equation by the second Lhs variable and the Rh2 list. (Since this model proceeds directly to the MLE, we do not begin with a separate **PROBIT** command, as we do with most other sample selection models.)

The usual options are available, including fitted values, residuals, optimization controls, etc., with two exceptions. First, the **; Partial Effects** option is not supported for this model. Second, the default algorithm is BFGS, and this cannot be changed. In addition, you may impose within equations restrictions with the **; Rst = list** option.

> **NOTE:** Cross equation restrictions in this model are problematic, because the model fits the transformed parameters, not the original ones. Unless you force the two standard deviations to be equal, it is not possible to force coefficients in the two equations to be equal.

The fitted values for this model are computed using Bhat's results: Let

$$\delta = 1/(1 - \rho^2)^{1/2},$$

$$\eta = 1/\sigma,$$

$$q = \boldsymbol{\alpha}'\mathbf{z}$$

$$W_m = \eta A_m - \boldsymbol{\gamma}'\mathbf{x},\ m = L,U \text{ (limits for the range in which } y \text{ falls)}$$

$$V_m = \delta(q + \rho W_m),\ m = L,U$$

$$T_m = \delta(W_m + \rho q),\ m = L,U.$$

Then

$$E[y^*|\mathbf{x},d=1] = \boldsymbol{\beta}'\mathbf{x} + \sigma \frac{\phi(W_L)\Phi(V_L) - \phi(WU)\Phi(V_U) + \rho\phi(q)[\Phi(T_U) - \Phi(T_L)]}{\Phi_2(W_U, q, -\rho) - \Phi_2(W_L, q, -\rho)}$$

The retrievable results from this model are

Matrices: *b*, *varb*; use **; Par** to add (σ,ρ) to the parameter vector

Scalars: *s*, *rho*, *logl*, *kreg*, *nreg*, *ybar*, *sy*, *exitcode*

Last Model: *b_variables* = elements of $\boldsymbol{\beta}$
a_variables = elements of $\boldsymbol{\alpha}$, *sigma*, *r*12

The grouped data model with sample selection is developed further in Section E47.3.3. The mathematical background and an application are presented there as well.

E47.3.4 Application

To illustrate the model, the dependent variable in the tobit hours equation was recoded as follows:

```
CREATE     ; whrss = whrs $
RECODE     ; whrss ; 0/600 = 1 ; 600.1/1000 = 2 ; 1000.1/1500 = 3
           ; 1500.1/2000 = 4 ; * = 5 $
NAMELIST   ; x = one,kl6,k618,wa,we $
```

Then,

```
GROUPED    ; Lhs = whrss
           ; Rhs = x
           ; List
           ; Limits = 600,1000,1500,2000 $
```

```

E47.3.5 Technical Details for the Grouped Data Regression Models

Optimization is the same as for **TOBIT**. All options, including **; Maxit**, **; Tlf**, **; Start**, **; Rst**, etc. operate the same. Olsen's transformation is used during the iterations. The log likelihood function for the grouped data model is

$$\log L \;=\; \Sigma_i\{\log[\Phi(\eta U - \boldsymbol{\gamma}'\mathbf{x}_i) - \Phi(\eta L - \boldsymbol{\gamma}'\mathbf{x}_i)]\}$$

where $\boldsymbol{\gamma} \;=\; \boldsymbol{\beta}/\sigma$ and $\eta \;=\; 1/\sigma$.

For this case, U is the upper limit of the range in which y_i falls, and L is the lower limit. Gradients and Hessians for these can be derived using the results shown earlier for the tobit model, as the terms are identical. The second derivatives are used in estimating the asymptotic covariance matrix for the estimates.

$$\partial \text{logL}/\partial(\boldsymbol{\gamma},\eta) \;=\; \sum_{i=1}^{n} \frac{1}{\Phi_U - \Phi_L}\left[\phi_U\begin{pmatrix}-\mathbf{x}_i\\ U\end{pmatrix} - \phi_L\begin{pmatrix}-\mathbf{x}_i\\ L\end{pmatrix}\right]$$

Let $\lambda_m \;=\; \phi_{\text{m}} \,/\, [\Phi_{\text{U}} - \Phi_{\text{L}}],\; m = L,U$

and $w_m \;=\; [-\mathbf{x},\, m]',\; m = L,U$

Then, $$\frac{\partial^2 \log L}{\partial(\boldsymbol{\gamma},\eta)\partial(\boldsymbol{\gamma},\eta)'} = \sum_{i=1}^{n} \{\lambda_U\mathbf{w}_U\,[(-\alpha_U - \lambda_U)\mathbf{w}_U' + \lambda_L\mathbf{w}_L']\} - \{\lambda_L\mathbf{w}_L\,[(-\alpha_L + \lambda_L)\mathbf{w}_L' - \lambda_U\mathbf{w}_U']\}.$$

E47.4 The Truncated Regression Model

The truncated regression model applies to the nonlimit observations in the tobit formulation. For the basic model with lower truncation at zero, the density is

$$f(y \mid \mathbf{x}) \quad = f(y^* \mid \mathbf{x}) \text{ if } y^* > 0.$$

But, $\quad \text{Prob}(y^* > 0 \mid \mathbf{x}) = \text{Prob}(\boldsymbol{\beta}'\mathbf{x} + \varepsilon > 0),\ \varepsilon \sim N[0,\sigma^2]$

$$= \text{Prob}(\varepsilon > -\boldsymbol{\beta}'\mathbf{x})$$

$$= \Phi[\boldsymbol{\beta}'\mathbf{x}/\sigma].$$

Therefore, $\quad f[y \mid \mathbf{x}] = (1/\sigma)\phi[(y - \boldsymbol{\beta}'\mathbf{x})/\sigma] \,/\, \Phi[\boldsymbol{\beta}'\mathbf{x}/\sigma].$

This is not a linear regression model. For a general specification in which the range of the variable is truncated in (possibly) both tails, the conditional mean function is

$$E[y_i|\mathbf{x}_i\,, L_i \le y_i \le U_i\,] = \boldsymbol{\beta}'\mathbf{x}_i + \sigma\frac{\phi_L - \phi_U}{\Phi_U - \Phi_L},$$

where the specification of the limits is the same as that for the tobit model and

$$\alpha_{limit} = (limit - \boldsymbol{\beta}'\mathbf{x})/\sigma,\ limit = U_i \text{ or } L_i$$

$$\Phi_{limit} = \Phi(\alpha_{limit})$$

$$\phi_{limit} = \phi(\alpha_{limit})$$

Least squares is inconsistent. The estimator used here is maximum likelihood. As with the tobit model, we allow truncation in either or both tails of the distribution, and the truncation points may be constants or variables. The specifications are identical to that for the tobit model described in Section E47.2 save for the command name:

```
TRUNCATION ; Lhs = y
           ; Rhs = covariates $
```

This specifies the default case of lower truncation at zero. Alternative specifications of the truncation limits use

; Limit = value or name for a different lower truncation limit
; Upper (only) for *upper* truncation at 0 (all observed *y*s will be negative)
; Limit = value ; Upper for a different, upper truncation limit
; Limits = lower, upper specification for truncation in both tails

E47.4.1 Truncated Regression for Panel Data

LIMDEP's full menu of panel data estimators is available for the categorical data regression model. (Full documentation on the modeling frameworks appears in Chapter E46 and below for the tobit model.) To estimate the model, you must provide the starting values, which you should do, in all cases, by first fitting the model with no individual effects. Thus, your command for this model will appear as

GROUPED ; Lhs = ... ; Rhs = ... ; Limits = the set of limits as described above $
GROUPED ; Lhs = ... ; Rhs = ... ; Limits = the set of limits as described above
; Pds = ... the specification of the panel structure

plus exactly one of

; FEM for the fixed effects model
or **; RPM ; Fcn = ... specification for the random parameters model**
or **; LCM ; Pts = J for the latent class model $**

Other parts of the specification for the categorical data model are the same as for other models of this type, e.g., tobit and truncation, that are documented elsewhere in this chapter.

Standard Model Specifications for the Truncated Regression Model

This is the full list of general specifications that are applicable to this model estimator

Controlling Output from Model Commands

; Par	keeps ancillary parameter σ with main parameter β vector in *b*.
; Margin	displays marginal effects.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix	displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Cluster = name	cluster form of corrected covariance estimator.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E47.4.2 Displayed and Retained Results

The display includes the log likelihood, the values or identity of the lower and upper bounds, and the estimates of [β,σ], once again, the same as the tobit model. For the truncated regression, the prediction displayed by **; List** and retained with **; Keep = name** is the conditional mean function listed above. We emphasize, the prediction is not $\beta'\mathbf{x}$. The residual that is kept with **; Res** is just the difference between actual and predicted values. Results saved by this estimator are:

Matrices: *b* and *varb* which contain the estimates for β. **; Par** adds σ to these.

Scalars:	*s*	=	σ
	ybar, *sy*		for the dependent variable
	kreg, and *nreg*		for the size of the estimation problem
	logl	=	log likelihood
	nonlimts	=	number of nonlimit observations for truncated regression.

Last Model: *b_variables, sigma*

Last Function: Conditional mean function

E47.4.3 Application

In the following results, a tobit model is reestimated as a truncated regression model. The results are based only on the nonlimit observations. A comparison of the coefficients and marginal effects to those of the tobit model is included in the results. Note that both the truncated regression and tobit models are estimating the same parameters, consistently, though results reveal substantial differences. The partial effects are quite different as well. These are finite sample effects.

```
NAMELIST    ; x = one,kl6,k618,wa,we $
TRUNCATION  ; Lhs = whrs ; Rhs = x ; Partial Effects $
TOBIT       ; Lhs = whrs ; Rhs = x ; Partial Effects $
```

E47.4.4 Technical Details

The log likelihood for the truncated regression model is maximized easily using Olsen's transformation of the parameters. After transformation, the log likelihood is

$$\Sigma_i \log L_i = \Sigma_i \log\theta - ½\log 2\pi - ½\, \varepsilon_i^2 - \log[\Phi(\theta U_i - \boldsymbol{\gamma}'\mathbf{x}_i) - \Phi(\theta L_i - \boldsymbol{\gamma}'\mathbf{x}_i)].$$

where $\theta = 1/\sigma$ and $\gamma = \beta/\sigma$. Derivatives are obtained from results given earlier for the tobit model;

$$\frac{\partial \log L_i}{\partial \begin{pmatrix}\boldsymbol{\gamma}\\ \theta\end{pmatrix}} = \varepsilon_i \begin{pmatrix}\mathbf{x}_i\\ -y_i\end{pmatrix} + \frac{1}{\Phi_U - \Phi_L}\left[\phi_U \begin{pmatrix}\mathbf{x}_i\\ -U_i\end{pmatrix} - \phi_L \begin{pmatrix}\mathbf{x}_i\\ -L_i\end{pmatrix}\right] + \begin{pmatrix}0\\ 1/\theta\end{pmatrix}$$

The Hessian is tedious, but obtained along similar lines. Newton's method is used for estimation, and the actual Hessian is used to estimate the asymptotic covariance matrix of the estimates.

HINT: The truncated regression model is sometimes less well behaved than the tobit model. If the data are clustered far from the assumed truncation point, the model will attempt to mimic ordinary least squares, but in so doing, the iterations can fail to converge. Thus, in an hours equation, if the range of yearly hours is 1,000 to 2,500, and you assume a truncation point of zero, in some data sets, the model (as specified) can be difficult or impossible to estimate.

HINT: Because the truncated regression is a bit volatile, Newton's method will occasionally break down. One of the symptoms is that the estimated variance goes out of range, and the function cannot be computed. If you are having trouble getting estimates, try the BFGS algorithm; add **; Alg = BFGS** to your command.

HINT: Discarding censored observations in the tobit setting does not legitimize OLS on the remaining observations. It produces the truncated regression model.

The conditional mean function in the truncated regression model is

$$E[y_i|\mathbf{x}_i, L_i \le y_i \le U_i] = \boldsymbol{\beta}'\mathbf{x}_i + \sigma\left(\frac{\phi_L - \phi_U}{\Phi_U - \Phi_L}\right),$$

As usual for nonlinear models, therefore, the coefficients are not the marginal effects. Differentiation of this function with respect to $\mathbf{x}_i$ produces the vector of slopes

$$\frac{\partial E[y_i \mid \mathbf{x}_i, L_i \le y_i \le U_i]}{\partial \mathbf{x}_i} = \beta\left[1 - \left(\frac{\alpha_L\phi_L - \alpha_U\phi_U}{\Phi_U - \Phi_L}\right) - \left(\frac{\phi_L - \phi_U}{\Phi_U - \Phi_L}\right)^2\right].$$

The term in brackets is the scale factor for the marginal effects shown in the examples above. Standard errors for the marginal effects are obtained by using the delta method. The effects are evaluated at the data means. The effects are written in terms of the parameters and the preceding scale factor as

$$\boldsymbol{\delta}(\boldsymbol{\beta},\sigma) \;=\; \boldsymbol{\beta} \times \mathrm{h}(\boldsymbol{\beta},\sigma)$$

Now, let $\boldsymbol{\Gamma} = \partial\boldsymbol{\delta}(\boldsymbol{\beta},\sigma)/\partial(\boldsymbol{\beta}',\sigma)$. The asymptotic covariance matrix is the sample estimate of

$$\mathbf{V} \;=\; \boldsymbol{\Gamma} \times \text{Asy.Var}\left[\hat{\boldsymbol{\beta}},\hat{\sigma}\right] \times \boldsymbol{\Gamma}'$$

The matrix $\boldsymbol{\Gamma}$ is extremely tedious. (For brevity, derivatives are omitted). The general form is

$$\partial\boldsymbol{\delta}(\boldsymbol{\beta},\sigma)/\partial(\boldsymbol{\beta}',\sigma) \;=\; [\mathbf{I} : \mathbf{0}] \;+\; [\partial \mathrm{h}/\partial(\boldsymbol{\beta}'\mathbf{x}) \times \boldsymbol{\beta}\mathbf{x}' \;:\; \boldsymbol{\beta}\partial \mathrm{h}/\partial\sigma]$$

Derivation makes repeated use of the rule

$$\partial[f(t)/F(t)]/\partial t \;=\; [1/F(t)]\partial f(t)/\partial t - [f(t)\,/\,F^2(t)]\,[\partial F(t)/\partial t]$$

and the template results for the standard normal distribution

$$\partial\Phi(t)/\partial \mathrm{t} \;=\; \phi(t),$$

$$\partial\phi(t)/\partial t \;=\; -t\phi(t),$$

$$\partial\alpha_{limit}/\partial\boldsymbol{\beta} \;=\; -\mathbf{x}/\sigma,$$

and

$$\partial\alpha_{limit}/\partial\sigma \;=\; -\alpha_{limit}/\sigma.$$

E48: Multiple Equation LDV Models

E48.1 Introduction

The models and estimators described in this chapter are variations on the following general simultaneous equations structure suggested in Maddala (1983) that encompasses most of the cases we wish to consider.

$$y_1^* = \gamma_1 y_2^* + \mathbf{x}_1'\boldsymbol{\beta}_1 + \varepsilon_1$$

$$y_2^* = \gamma_2 y_1^* + \mathbf{x}_2'\boldsymbol{\beta}_2 + \varepsilon_2$$

$$[\varepsilon_1,\varepsilon_2] \sim \text{BVN}\,[(0,0), (\sigma_{11},\sigma_{22}), \sigma_{12}], \text{ with correlation} = \rho.$$

The simultaneous equations model is stated in terms of the latent, continuous dependent variables, *before* censoring. The (assumed) existence of a reduced form ($\gamma_1\gamma_2 \neq 1$) is crucial. The literature is occasionally a bit ambiguous on this point. If, for example, it is assumed that the simultaneous equations model applies to observed variables, y_1 and y_2, while either or both are simple censored variables, for example, $y_{1i} = \text{Max}(L_i,y_{1i}^*)$, then restrictions are needed to insure that the model is even internally consistent, and, worse yet, for most formulations, that will not even be possible. (A large amount of useful discussion appears in Amemiya (1984) and Maddala (1983).) .

We consider two groups of models. The first is estimated by full information maximum likelihood. The estimators in the models in Sections E48.3 and E48.4 below use the two step maximum likelihood method. Details of this method for general applications are given in Section E48.6.

E48.2 Simultaneous Equations Model

The tobit model may be embedded in a recursive simultaneous equations model:

$$y_1 = \text{tobit as formulated above with } y_1^* = \boldsymbol{\beta}'\mathbf{x}_1 + \gamma y_2 + \varepsilon_1,$$

$$y_2 = \boldsymbol{\pi}_2'\mathbf{x}_2 + \varepsilon_2 \text{ in which Corr}[\varepsilon_1 ,\varepsilon_2] = \rho_{12}.$$

The estimator is full information maximum likelihood. (The second equation is a linear regression with observed dependent variable.) This model requires specification of a two equation model. As such, you must give both dependent variables and the Rhs for each equation. The command is

```
TOBIT    ; Lhs = y1,y2
         ; Rh1 = Rhs for tobit, including y2
         ; Rh2 = Rhs of regression model $
```

The primary object of estimation in this model is the tobit model. As such, the model output will show the regression results, but other statistics will be primarily related to the tobit equation, not the regression. Also, the retrievable results and fitted values will be for the tobit model only. An example appears below.

The results displayed include: log likelihood; identification of the model; description of the displayed parameter vector; separate estimates of σ_1^2, σ_2^2, ρ; then the parameter vector, $\boldsymbol{\beta}$ including γ the coefficient on y_2, $\boldsymbol{\pi}_2$, σ_{12}/σ_2^2, and $\sigma_{1.2} = [\sigma_1^2\,(1\text{-}\rho^2)]^{1/2}$.

The full set of model parameters is $[\boldsymbol{\beta},\boldsymbol{\pi}_2,\rho,\sigma_1^2,\sigma_2^2]$. But, for purposes of starting values and restrictions, base your specification of **; Start** and **; Rst** on the vector

$$\boldsymbol{\theta} = [\boldsymbol{\beta},\boldsymbol{\pi}_2,\rho,\sigma_{1.2}]$$

in which $\boldsymbol{\beta}$ includes the coefficient on y_2. (The variables need not be in such order that y_2 is the last variable in Rh1. Subscript '2' refers to the 2nd equation.); $\boldsymbol{\beta}$ in the first equation includes γ, the coefficient on y_2. The second disturbance variance, σ_2^2, is estimated separately as the mean squared residual. The estimated parameters are $\boldsymbol{\beta},\boldsymbol{\pi}_2$, $\psi = \sigma_{12}/\sigma_2^2$, and $\sigma_{11.2} = [\sigma_1^2(1 - \rho^2)]^{1/2}$.

Output is as usual for the tobit model. The initial OLS output will not include the second equation. These initial estimates will be inconsistent both because of the censoring and because of the endogeneity of y_2. OLS starting values are used for the second equation as well, but these are not displayed.

All other options for this model are the same as for the basic tobit model, including fitted values, iteration controls, marginal effects, and so on. The fitted values must be modified slightly for the simultaneous equations model. We condition on $\varepsilon_2 = (y_2 - \boldsymbol{\pi}_2'\mathbf{x}_2)$, so

$$E[y_i^* \,|\, y_2,\mathbf{x}_1, \varepsilon_2] = \boldsymbol{\beta}'\mathbf{x}_1 + \gamma y_2 + (\sigma_{12}/\sigma_2^2)\varepsilon_2.$$

Other computations are the same. Retrievable results, are also the same as for the tobit model of Section E45.2. For this model, the matrix *b* includes only the slopes in the tobit equation, including the coefficient on y_2. The specification **; Par** adds $\sigma_{1.2}$ to the parameter vector. Since σ_1 is saved in *s*, the estimate of ρ can be computed from these values. An additional matrix named *pi*2 is saved and contains the estimates of $\boldsymbol{\pi}_2$. The scalars and *Last Model* labels and coefficients saved are those of the tobit model.

E48.2.1 Application

To illustrate the model, we use the Mroz data and a contrived example in which

$$whrs = f_1(k618,wa,we,kl6)$$
and
$$kl6 = f_2(faminc,cit)$$

(that is, the number of small children is assumed to be endogenous). As might be expected, the data lend little support to the specification. (See the next subsection.)

```
TOBIT    ; Lhs = whrs,kl6
         ; Rh1 = one,k618,wa,we,kl6
         ; Rh2 = one,faminc,cit $
```

E48.2.2 Simultaneous Equations and Testing Exogeneity

In estimating the simultaneous equations model,

$$y_1^* \;=\; \boldsymbol{\beta}_1'\mathbf{x}_1 + \gamma y_2 \;+ \varepsilon_1 \;\; \text{(tobit)}$$

$$y_2 \;\;=\; \boldsymbol{\pi}_2'\mathbf{x}_2 \;+\; \varepsilon_2,$$

LIMDEP estimates $\boldsymbol{\beta}_1$, γ, $\boldsymbol{\pi}_2$, $\psi=\sigma_{12}/\sigma_2^2$, and $\sigma_{11.2} \;=\; [\sigma_1^2(1 - \rho^2)]^{1/2}$. Exogeneity of y_2 can be tested by a simple t test of the hypothesis that ψ equals zero. (I.e., that $\rho[\varepsilon_1, \varepsilon_2] = 0$.) This is just the second to last coefficient reported in the model output. Note in the application above that the t ratio is quite close to zero.

E48.2.3 Models with More than Two Equations

For models with more than one regression equation, a similar maximum likelihood procedure could be constructed (see Blundell and Smith (1986)). But, the authors show that there is a much simpler way to proceed. The model is:

$$y_1^* = \boldsymbol{\beta}_1'\mathbf{x}_1 + \gamma_2 y_2 + \gamma_3 y_3 + ... + \varepsilon_1 \text{ (tobit)},$$

$$y_2 = \boldsymbol{\pi}_2'\mathbf{x}_2 + \varepsilon_2,$$

$$y_3 = \boldsymbol{\pi}_3'\mathbf{x}_3 + \varepsilon_3,$$

and so on.

The authors show that under the null hypothesis of no simultaneity, the following procedure is asymptotically equivalent to a score, or Lagrange multiplier test of weak exogeneity, i.e., $\text{Cov}[\varepsilon_1, \varepsilon_j] = 0$, $j = 2,...$:

Step 1. Use OLS to regress y_j on $\mathbf{x}_j$ for $j = 2,...$ (the regression equations) and keep the residuals (as v_j, say).

Step 2. Estimate the tobit model as specified above by maximum likelihood, but include these residual vectors as additional Rhs variables.

Step 3. The hypothesis is tested by testing the joint hypotheses that the slopes on the residuals jointly equal zero.

E48.2.4 Technical Details

This model is examined in Blundell and Smith (1986). FIML is a straightforward method of estimation. The strategy is to factor the joint distribution of ε_{i1} and ε_{i2} as $f(\varepsilon_{i1},\varepsilon_{i2}) = f(\varepsilon_{i2})f(\varepsilon_{i1}|\varepsilon_{i2})$. The log likelihood function factors likewise. The second equation is a classical regression model, so the log likelihood function can be concentrated over σ_{22}. Regardless of how $\boldsymbol{\beta}_2$ is ultimately estimated, the estimator of σ_{22} will be

$$\hat{\sigma}_{22} = (1/n)\sum_{i=1}^{n}\left(y_{i2} - \mathbf{x}_{i2}'\hat{\boldsymbol{\beta}}_2\right)^2 .$$

To construct the remaining part of the log likelihood, define

$$v_{i2} = (y_{i2} - \mathbf{x}_{i2}'\boldsymbol{\beta}_2),$$

$$v_{i1} = (y_{i1} - \mathbf{x}_{i1}'\boldsymbol{\beta}_1 - \gamma_1 y_{i2} - \psi v_{i2})$$

$$\psi = \sigma_{12}/\sigma_{22}$$

$$\omega = [\sigma_{11}(1 - \rho^2)]^{1/2}$$

Then, the log likelihood consists of the sum of the concentrated log likelihood for the regression and the part for the censored regression based on conditional distribution:

$$\log L = \text{-}(n/2)\log(1/n)\sum_{i=1}^{n}\left(y_{i2} - \mathbf{x}_{i2}'\boldsymbol{\beta}_2\right)^2 + \sum_{d_{i1}=1}\log\left[\frac{1}{\psi}\phi\left(\frac{v_{i1}}{\psi}\right)\right]$$

$$+\sum_{d_{i1}=0}\log\Phi\left[\frac{L_{i1}\text{-}\,\mathbf{x}_{i1}'\boldsymbol{\beta}_1 - \gamma_1 y_{i2} - \psi v_{i2}}{\omega}\right]$$

The function is maximized over $\boldsymbol{\beta}_2$, $\boldsymbol{\beta}_1$, ψ, and ω. The second variance parameter is estimated residually, and then, σ_{12} and σ_{11} are recovered from the estimated parameters.

E48.3 Tobit Model with Sample Selection

The sample selection model detailed in Chapter E52 is extended to the tobit model. That is,

y = tobit as formulated earlier with $\mathbf{x}$ on the Rhs,

d = a probit model based on $z^* = \boldsymbol{\alpha}'\mathbf{z} + u$,

Corr[ε,u] = ρ,

[y ,$\mathbf{x}$] observed only when d = 1.

This model is a mixture of censoring and a type of truncation. The procedure for estimating this model follows the standard set of steps for selectivity models given in Section E52.2. Complete details are given there, so we will just sketch the procedure here. The procedure for estimating a sample selectivity model in *LIMDEP* is:

Step 1. Estimate the parameters of the probit model first and **; Hold** them aside for the next step in the procedure.

Step 2. Using the probit results from Step 1, fit the sample selection model.

The estimator to be described here is a full information maximum likelihood estimator. Nonetheless, at the beginning of Step 2, a second step least squares regression is computed in order to obtain the starting values for the MLE. These are corrected for selection, to a degree, *but they are still inconsistent*. The results given at this point are obtained by least squares, and, as such, are inconsistent in the same manner as the OLS coefficients are in the basic tobit model. As noted, these are just starting values for the iterations. The MLE is consistent and efficient.

The commands are:

PROBIT ; Lhs = d ; Rhs = list for z ; Hold $
SELECT ; Tobit ; MLE ; Lhs = ... ; Rhs = ... $

Note that the command for the tobit model in this case is **SELECT**, not **TOBIT**.

NOTE: As in the MLE for the selection model, there is no 'lambda' variable computed for this model. The estimator is not least squares. When a sample selection model is fit by maximum likelihood, there is no selection 'correction' variable added to the model.

The model parameters estimated by MLE are $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, σ, ρ. These are also the estimation parameters. The probit coefficients precede the regression parameters in the parameter vector. You may provide your own starting values for the iterations with

; Start = ... list

Fixed value and equality restrictions may be imposed with

; Rst = ... list

as well. Note that constraining σ and/or ρ will likely produce unsatisfactory results. In addition, cross equation restrictions that equate elements of $\boldsymbol{\alpha}$ to elements of $\boldsymbol{\beta}$ will be problematic because of the different scaling of the two dependent variables.

The first set of output from the **SELECT** command is the standard output from the two step least squares estimation of this model. The final output includes the log likelihood and an indication of the parts of the parameter vector. The parameter vector shown is $[\boldsymbol{\alpha},\boldsymbol{\beta},\sigma_1,\rho]$. Remaining output is the same as for the selection model. The retrievable results from this estimator are as follows:

Matrices: *b* and *varb* as usual. These contain $[\boldsymbol{\alpha},\boldsymbol{\beta},\sigma,\rho]$. Do not use **; Par**.
*bsr*1 = all of *b* except α.

Scalars: *logl, nreg, rho, varrho, s, ybar, sy, sigma*1,

Last Model: *a_variables*, *b_variables*, *r*12, *sigma*

Last Function: None

The tobit model with sample selection is developed further in Section E54.7, where derivation of the mathematical framework, an application, and further technical details are presented.

E48.4 Two Step Estimation of Censored Regression Models

The following will describe several multiple equations models. In principle, they can be generalized to an arbitrary numbers of equations. But, practical limitations, primarily the difficulty of computing multivariate normal integrals, have usually limited the applications to two equations. We will focus on this case. Some of the original sources noted suggest multivariate extensions.

E48.4.1 Recursive Simultaneous Equations Model

If $\gamma_2 = 0$, and only y_1 is censored, the resulting equation system is

$$y_{i1}^* = \gamma_1 y_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1},\; y_{i1} = \text{Max}(L_{i1}, y_{i1}^*)$$

$$y_{i2} = \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2}.$$

This estimator is programmed directly in *LIMDEP*, so FIML estimation is a preprogrammed procedure. (See Section E48.2.) But, this model is a candidate for the two step procedure, and offers a good illustration of the technique.

Since y_{i2} is directly observed without censoring, it can be inserted into the first equation, to obtain

$$y_{i1}^* = \gamma_1(\mathbf{x}_{i2}'\boldsymbol{\beta}_2) + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + (\varepsilon_{i1} + \gamma_1\varepsilon_{i2}),\; y_{i1} = \text{Max}(L_{i1}, y_{i1}^*)$$

$$y_{i2} = \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2}$$

Since the variance of ε_{i1} and the covariance of ε_{i1} and ε_{i2} are both free parameters, no generality is lost by writing the first equation as

$$y_{i1}^* = \gamma_1(\mathbf{x}_{i2}'\boldsymbol{\beta}_2) + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + u_i,\; y_{i1} = \text{Max}(L_{i1}, y_{i1}^*),\; \text{Var}[u_i] = \sigma_u^2.$$

So, in the two equation model, the second equation is a classical normal linear regression model and the first is a censored regression model with a nonlinear index function. We propose to fit this in two steps, then adjust the estimated asymptotic covariance matrix at the second step with the Murphy and Topel estimator. (Note, we will be reversing subscripts 1 and 2 in this presentation.)

Step 1. Step 1 is ordinary least squares, and $\hat{\boldsymbol{\beta}}_2$ is simply $\mathbf{b}_2 = (\mathbf{X}_2'\mathbf{X}_2)^{-1}\,\mathbf{X}_2'\mathbf{y}_2$. The estimated asymptotic covariance matrix would normally be $\mathbf{V}_2 = [\mathbf{e}_2'\mathbf{e}_2/(n - K_2)](\mathbf{X}_2'\mathbf{X}_2)^{-1}$. The rows of the matrix $\mathbf{D}$ are the derivatives of the log likelihood for the classical regression, which would be $\mathbf{d}_i = (1/s_2^2)e_{i2}\mathbf{x}_{i2}$.

Step 2. Step 2 is maximum likelihood estimation of the censored regression model, in which the index function is $\gamma_1 z_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1$ where $z_{i2} = \mathbf{x}_{i2}'\boldsymbol{\beta}_2$. The parameter vector $[\gamma_1, \boldsymbol{\beta}_1, \sigma_u]$ is estimated exactly as we estimated the censored regression earlier. The derivatives of the log likelihood will be

$$\mathbf{g}_i = \frac{1}{\sigma_u}\left[(1-d_{i1})\lambda_{i1}^0\begin{pmatrix} z_{i2} \\ x_{i1} \\ \alpha_{i1}\end{pmatrix} + d_{i1}\begin{pmatrix} z_{i2}e_{i1}/\sigma_u \\ x_{i1}e_{i1}/\sigma_u \\ (e_{i1}/\sigma_u)^2 - 1\end{pmatrix}\right].$$

Note there is an extra element for the new term γ_1,

$$e_{i1} = y_{i1} - \gamma_1 z_{i2} - \mathbf{x}_{i1}'\boldsymbol{\beta}_1,$$

$$\alpha_{i1} = (L_{i1} - \gamma_1 z_{i2} - \mathbf{x}_{i1}'\boldsymbol{\beta}_1)/\sigma_u,$$

and

$$\lambda_{i1}^0 = -\phi(\alpha_{i1})/\Phi(\alpha_{i1}).$$

These K_1+2 element vectors are stacked in the matrix **G**. Finally, we require the matrix **M** which is embodied in **G**. The rows of **M** would be

$$\mathbf{m}_i = \frac{1}{\sigma_u}\left[(1-d_{i1})\lambda_{i1}^0\gamma_1 + d_{i1}e_{i1}/\sigma_u\right]\mathbf{x}_{i2}.$$

The matrices **D**, **G**, and **M** are used to correct the asymptotic covariance matrix computed by the censored regression estimator. Note that the variance parameters estimated are σ_{22} by s_2^2 in the second equation, computed by OLS, and $\sigma_u^2 = \sigma_{11} + \gamma_1^2\sigma_{22} + 2\gamma_1\sigma_{12}$ by squaring the estimate of σ_u from the censored regression. The covariance, σ_{12} is not estimable by this method – we are using a limited information (LIML) estimator, not a FIML one. By construction, σ_{22} is unidentified as well. (In fact, it is possible to construct an estimator of the covariance parameter. We will return to this possibility in discussion of models of sample selection.)

This program computes Blundell and Smith's two step estimator of a two equation recursive simultaneous equations model with censoring in one equation. The structure is:

$$y_1^* = \gamma_1 y_2^* + \boldsymbol{\beta}_1'\mathbf{x}_1 + \varepsilon_1 \qquad y_1^* \text{ censored at lower limit } L_i$$
$$y_2^* = \boldsymbol{\beta}_2'\mathbf{x}_2 + \varepsilon_2, \qquad y_2^* \text{ observed directly}$$

Define the variable lists, $x1$ and $x2$, dependent variables, $y1$, $y2$, and censoring limit, *li*.

```
NAMELIST    ; x1 = ... ; x2 = ... $
CREATE      ; y1 = ... ; y2 = ... $
CREATE      ; li = ... $ (May be a variable or a constant. Use a variable for both.)
```

Estimate the second equation first by OLS, and retain fitted values, s-squared, and covariance matrix.

```
REGRESS     ; Quietly ; Lhs = y2 ; Rhs = x2 ; Keep = z2 ; Res = e2 $
CALC        ; s22 = ssqrd $
MATRIX      ; v2 = varb $
```

For the second step, use the censored regression for $y1$ with $z2$. Keep all parameters including σ.

```
TOBIT       ; Quietly ; Lhs = y1 ; Rhs = z2,x1 ; Limit = li ; par $
MATRIX      ; v1 = varb $
```

Now construct **G**, **M** and **D**. In the matrix products, **G**, **M** etc. are scalars times products of variables.

```
NAMELIST   ; z2x1= z2,x1 $                                 (all variables in censored regression)
CREATE     ; d1 = y1 > li $                                (censoring indicator)
CALC       ; k1 = Col(z2X1) $                              (number of slope parameters)
MATRIX     ; cb = b(1:k1) $                                (parameters without sigma)
CREATE     ; alpha = (li - z2x1'cb)/s
           ; lambdai0 = -N01(alpha)/Phi(alpha)
           ; e1 = (y1 - z2x1'cb)/s
           ; h1 = e1*e1 - 1
           ; gcb = ((1-d1)*lambdai0+d1*e1)/s               ? partial wrt slopes
           ; gs = ((1-d1)*lambdai0*alpha+d1*h1)/s          ? partial wrt s
           ; d2b = e2/s22                                  ? use for d2i
           ; mb = ((1-d1)*lambdai0+d1*e1)*b(1)/s
           ; gcbmb = gcb*mb
           ; gsmb = gs*mb
           ; gcbd = gcb*d2b
           ; gsd = gs*d2b  $
```

The matrix assembly is done here. **G**,**M** and **G**,**D** have two parts.

```
MATRIX     ; gmb = z2x1'[gcbmb]x2
           ; gms = gsmb'x2
           ; gm = [gmb/gms]
           ; gdb = z2x1'[gcbd]x2
           ; gds = gsd'x2
           ; gd = [gdb/gds] $
```

Now compute the revised covariance matrix and display the results.

```
MATRIX     ; q = gm * v2 * gm' - gd*v2*gm' - gm*v2*gd'
           ; v1star = v1 + v1*q*v1 $
CLIST      ; twostep = z2x1,sigma $
DISPLAY    ; Parameters = b ; Covariance = v1star ; Labels = twostep $
```

The results below illustrate with the following data setup using the Mroz labor supply data:

```
CREATE     ; numkids = kl6 + k618 $
NAMELIST   ; x1 = one,wa,we ; x2 = one,faminc $
CREATE     ; y1 = whrs ; y2 = numkids $
CREATE     ; li = 0 $
```

The intermediate results are suppressed. The final computations are shown below.

E48.4.2 Simultaneous Equations Model with Censoring

For this case, we retain the original structure,

$$y_{i1}^* = \gamma_1 y_{i2}^* + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_1$$

$$y_{i2}^* = \gamma_2 y_{i1}^* + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_2$$

$$[\varepsilon_1,\varepsilon_2] \sim BVN[(0,0),(\sigma_{11},\sigma_{22}),\rho\sigma_{11}\sigma_{22}]$$

and suppose that either or both variables are censored at lower limit L_i. For the first case, this is the model considered earlier without the restriction that γ_2 equals zero, while for the second, we assume that both variables are censored, so that least squares is inappropriate for both equations.

One Variable Censored

Once again, we depart from the reduced form of the equation system,

$$y_{i1}^* = \mathbf{x}_i'\boldsymbol{\pi}_1 + v_1$$

$$y_{i2}^* = \mathbf{x}_i'\boldsymbol{\pi}_2 + v_2$$

where $\mathbf{x}_i = \mathbf{x}_{i1} \cup \mathbf{x}_{i2}$ (all exogenous variables in the model). Suppose that variable y_{i1}^* is censored at L_i, but y_{i2}^* is observed without censoring. (This model is due to Nelson and Olsen (1978).) Insert the reduced form for y_{i2}^* into the structure for y_1^* to obtain the censored regression and linear regression model

$$y_{i1}^* = \gamma_1(\mathbf{x}_i'\boldsymbol{\pi}_2) + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + (\varepsilon_{i1} + \gamma_1 v_{i2}),\ y_{i1} = \text{Max}(L_{i1}, y_{i1}^*)$$

$$y_{i2} = \mathbf{x}_i'\boldsymbol{\pi}_2 + v_{i2}.$$

We propose the following two step estimation strategy for estimation of $(\gamma_1,\boldsymbol{\beta}_1)$:

Step 1. Estimate $\boldsymbol{\pi}_2$ by ordinary least squares regression of y_2 on all exogenous variables in the model.

Step 2. Estimate $\gamma_1,\boldsymbol{\beta}_1,\sigma_{11}$ by maximum likelihood in the censored regression model in the first equation. Then, use the Murphy and Topel correction for the asymptotic covariance matrix.

This procedure is exactly the one described in the previous section, as the partially reduced form shown above is precisely the recursive simultaneous equations model shown there. Thus, there is no need to develop the estimator in detail.

However, it remains to estimate $(\gamma_2,\boldsymbol{\beta}_2)$. We propose the following strategy: Insert the reduced form equation for y_{i1}* in the second equation to obtain the equation system

$$y_{i1}^* = \mathbf{x}_i'\boldsymbol{\pi}_1 + v_1, \; y_{i1} = \text{Max}(L_{i1}, y_{i1}^*)$$

$$y_{i2} = \gamma_2(\mathbf{x}_i'\boldsymbol{\pi}_1) + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + (\varepsilon_{i2} + \gamma_2 v_{i1}).$$

This is similar to the previous system, but is actually simpler. The two step estimation strategy is:

Step 1. Estimate $\boldsymbol{\pi}_1$ by maximum likelihood using the first equation, which is a censored regression model.

Step 2. Estimate $(\gamma_2,\boldsymbol{\beta}_2)$ in the second equation by ordinary least squares regression of y_{i2} on $z_{i1} = \mathbf{x}_i'\hat{\boldsymbol{\pi}}_1$ and $\mathbf{x}_{i2}$. Adjust the asymptotic covariance matrix at the second step using the Murphy and Topel results.

For this case, the various components of the estimator are as follows:

$$\mathbf{V}_2 = s_2^2[(\mathbf{z}_1,\mathbf{X}_2)'(\mathbf{z}_1,\mathbf{X}_2)]^{-1},$$

where s_2^2 is the usual residual variance estimator from this regression. From the Step 1 censored regression model, $\mathbf{V}_1$ is the $K\times K$ submatrix of the full estimated asymptotic covariance matrix, omitting the row and column that correspond to the MLE of σ_{v1}. The derivatives from this estimation are

$$\mathbf{d}_i = \frac{1}{\hat{\sigma}_{v1}}\left[(1-d_{i1})\lambda_{i1}^0 + d_{i1}\left(e_{i1}/\hat{\sigma}_{v1}\right)\right]\mathbf{x}_i$$

where $\quad \hat{\alpha}_{i1} = (L_{i1} - \mathbf{x}_i'\hat{\boldsymbol{\pi}}_1)/\hat{\sigma}_{v1}, \; e_{i1} = y_{i1} - \mathbf{x}_i'\hat{\boldsymbol{\pi}}_1,$

and $\quad \lambda_{i1}^0 = -\phi(\alpha_{i1})/\Phi(\alpha_{i1}).$

The remaining components are

$$\mathbf{g}_i = \frac{e_{i2}}{s_2^2}\begin{pmatrix} z_{i1} \\ \mathbf{x}_{i2} \end{pmatrix} \text{ and } \mathbf{m}_i = \frac{e_{i2}}{s_2^2}(\hat{\gamma}_2\mathbf{x}_{1i}).$$

The full set of variance parameters is not estimated by this procedure. Since we are using single equation ML techniques, the estimator uses no information about σ_{12} and, therefore, only σ_{22} is estimable. The first equation produces only an estimate of $\sigma_{v1} = (\sigma_{11}+\gamma_1^2\sigma_{22}+2\gamma_1\sigma_{12})^{1/2}$. Maddala (1983) proposes an alternative estimation technique for this model which appears to require an estimate of σ_{12}, but does not provide the necessary expression for obtaining one. Greene (1997, p. 735) observes this omission, and suggests an approach based on a two step estimator of Heckman's (1979). Greene's result, albeit correct, is unnecessary. As noted above, the simple functions of sample moments provides all the information needed to compute the asymptotic covariance matrix.

The program below completes the Blundell and Smith's two step estimator of a two equation recursive simultaneous equations model with censoring in one equation:

$$y_1^* = \boldsymbol{\pi}_1'\mathbf{x}_1 + \varepsilon_1 \qquad y_1^* \text{ censored at lower limit } L_i$$

$$y_2^* = \gamma_2(\boldsymbol{\pi}_1'\mathbf{x}_1) + \boldsymbol{\beta}_2'\mathbf{x}_2 + \varepsilon_2, \qquad y_2^* \text{ observed directly}$$

We begin with the usual data setup for the specific application.

```
NAMELIST   ; x1 = ... ; x2 = ...
           ; x = OR (x1,x2) $
CREATE     ; y1 = ... ; y2 = ... $
CREATE     ; li = ... (May be a variable or a constant. Use for both) $
```

The initial tobit estimator fits the reduced form for the first equation. The variance estimator picks up only the part for $\boldsymbol{\pi}_1$.

```
TOBIT      ; Quietly ; Lhs = y1 ; Rhs = x ; Limit = li $
MATRIX     ; pi1 = b ; v1 = varb $
```

This obtains the scale factor for the slope derivatives from the tobit equation.

```
CREATE     ; zi1 = pi1'x
           ; alphai1 = (li - zi1)/s
           ; ei = y1 - zi1
           ; lambdai0 = -N01(alphai1)/Phi(alphai1)
           ; di = (y1 <= li)*lambdai0/s + (y1 > li)*ei/s^2 $
```

This is the second step linear regression. Variable *gi* is the slope derivatives.

```
NAMELIST   ; z1x2 = zi1,x2 $
REGRESS    ; Lhs = y2 ; Rhs = z1x2 ; Res = ei2 $
CREATE     ; gi = ei2/s^2 ; mi = gi*b(1) $
```

Compute the corrected covariance matrix, then report results.

```
CREATE     ; gimi =  gi*mi
           ; gidi  =  gi*di $
MATRIX     ; a =  z1x2'[gimi] x * v1 * x'[gimi]z1x2
                - z1x2'[gidi ] x * v1 * x'[gimi]z1x2
                - z1x2'[gimi] x * v1 * x'[gidi]z1x2
           ; v2star = varb + varb * a * varb $
DISPLAY    ; Parameters = b ; Covariance = v2star ; Labels = z1x2 $
```

The results below continue the analysis of the model above with the following data setup using the Mroz labor supply data. This estimates the second equation in the system and corrects the asymptotic covariance matrix.

```
CREATE      ; numkids = kl6 + k618 $
NAMELIST    ; x1 = one,wa,we
            ; x2 = one,faminc  $
NAMELIST    ; x = OR (x1,x2) $
CREATE      ; y1 = whrs
            ; y2 = numkids  $
CREATE      ; li = 0 $
```

```

```

Both Variables Censored

Finally, suppose both variables are censored. The structural equation system is

$$y_{i1}^* = \gamma_1 y_{i2}^* + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1}$$

$$y_{i2}^* = \gamma_2 y_{i1}^* + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2}$$

$$[\varepsilon_{i1},\varepsilon_{i2}] \sim \text{BVN}[(0,0),(\sigma_{11},\sigma_{22}),\rho\sigma_{11}\sigma_{22}].$$

The reduced form is, as before,

$$y_{i1}^* = \mathbf{x}_i'\boldsymbol{\pi}_1 + v_{i1},\ y_{i1} = \text{Max}(L_{i1},y_{i1}^*)$$

$$y_{i2}^* = \mathbf{x}_i'\boldsymbol{\pi}_2 + v_{i2},\ y_{i2} = \text{Max}(L_{i2},y_{i2}^*).$$

For the first equation, the partially reduced form is

$$y_{i1}^* = \gamma_1(\mathbf{x}_i'\boldsymbol{\pi}_2) + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1} + \gamma_1\varepsilon_{i2}$$

and likewise for the second.

A two step estimator can be obtained by combining the elements of the previous procedures:

Step 1. Estimate ($\boldsymbol{\pi}_1$, $\boldsymbol{\pi}_2$) separately by maximum likelihood estimation of the two reduced form censored regression models. Retain for each estimation, the part of the asymptotic covariance matrix corresponding to the slope parameters and the variables needed to compute the derivatives.

Step 2. Estimate $\gamma_1,\boldsymbol{\beta}_1,\sigma_{11}$ by maximum likelihood in the first equation, with variables $z_{i2} = \mathbf{x}_i'\boldsymbol{\pi}_2$ and $\mathbf{x}_{i2}$ on the right hand side. Correct the asymptotic covariance matrix.

The estimator is symmetric for estimation of $\gamma_2,\boldsymbol{\beta}_2,\sigma_{22}$

The program below shows the full set of computations for estimation of the parameters of the first equation. The procedure is symmetric in the two variables, so the counterpart for the second equation would be obtained by repeating the computations with subscripts reversed. The structure for the program is

$$y_1^* = \gamma_1(\boldsymbol{\pi}_2'\mathbf{x}) + \boldsymbol{\beta}_1'\mathbf{x}_1 + \varepsilon_1 \quad y_1^* \text{ censored at lower limit } L_{i1}$$

$$y_2^* = \gamma_2(\boldsymbol{\pi}_1'\mathbf{x}) + \boldsymbol{\beta}_2'\mathbf{x}_2 + \varepsilon_2 \quad y_2^* \text{ censored at lower limit } L_{i2}$$

As usual, we begin by setting up the specific application.

```
NAMELIST    ; x1 = ... ; x2 = ...
            ; x = OR (x1,x2) $
CREATE      ; y1 = ... ; y2 = ... $
CREATE      ; l1 = ... limits for first equation
            ; l2 = ... limits for second equation $
```

This initial reduced form tobit will estimate π_2. Pick up variance estimator from tobit model. This picks up only the π_2 part; the σ_{22} part is not needed. The derivatives from the tobit estimation are also picked up here.

```
TOBIT       ; Quietly ; Lhs = y2 ; Rhs = x ; Limit = l2 $
MATRIX      ; v1 = varb $
CREATE      ; q1 = y1 > l1  ;  q2 = y2 > l2 $
CREATE      ; z2 = b'x
            ; alpha2 = (l2 - z2)/s
            ; e2 = y2 - z2
            ; lamda2 = -N01(alpha2)/Phi(alpha2)
            ; d2i = (1-q2) * lamda2/s + q2*e2/s^2 $
```

This is the second step tobit with corrected asymptotic covariance matrix for the first equation. The correction must pick up the estimated sigma now, as in tobit, Cov(**b**,*s*) is not zero.

```
NAMELIST    ; z2x1= z2 , x1 $
TOBIT       ; Lhs = y1 ; Rhs = z2x1  ; Limit = l1 ; Par $
CALC        ; k21 = Col(z2x1) $
MATRIX      ; bz = b(1:k21) $
CREATE      ; v = bz'z2x1 ; alpha = (l1 - v)/s
            ; e = y1 - v ; lambda = -N01(alpha)/Phi(alpha)
            ; gbi = (1-q1)* lambda/s + q1*e/s^2
            ; gsi = (1-q1)* lambda*alpha/s +  q1*(1/s)*(((e/s)^2 - 1)/s - 1)
            ; mi = gbi*b(1) $
CREATE      ; gmi = gbi * mi   $
MATRIX      ; gbm= z2x1'[gmi]x
            ; gsm = gsi'[mi]x
            ; gm = [gbm / gsm]  $
CREATE      ; gdi = gbi * d2i $
MATRIX      ; gbd = z2x1'[gdi] x
            ; gsd = gsi   '[d2i] x
            ; gd = [gbd /gsd ]  $
MATRIX      ; a = gm*v1*gm' - gd*v1*gm' - gm*v1*gd' $
MATRIX      ; v1star = varb + varb * a * varb  $
CLIST       ; twostep = z2x1,sigma $
DISPLAY     ; Parameters = b ; Covariance = v1star ; Labels = twostep $
```

To illustrate use of the program, we have fit hours equations for husband and wife using the labor supply data. The data setup is

```
NAMELIST    ; x1 = one,kl6,k618,wa,we
            ; x2 = one,ha,he,faminc,cit
            ; x = OR (x1,x2) $
CREATE      ; y1 = whrs ; y2 = hhrs $
CREATE      ; l1 = 0 ?...  limits for first equation
            ; l2 = 0 $     limits for second equation
```

We have omitted the intermediate results. The output below shows the original tobit estimates for the wife's hours followed by the estimates with the corrected covariance matrix. The counterpart for the second equation would be obtained from the proceeding by reversing the subscripts in the commands or, perhaps more simply, by reversing the definitions of $y1$,$x1$ and $y2$,$x2$ in the data setup.

```

E48.5 Models with Binary Variables

The two step methods used for censored variables in the previous section can also be used when the endogenous variables are binary. We examine two models.

E48.5.1 Simultaneous Equations Model with Binary Variables

In principle, this is a fairly straightforward extension of the earlier results that combines a censored regression with the probit model discussed in Chapter E27. Suppose the model is formulated as

$$y_{i1}^* = \gamma_1 y_{i2}^* + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1},\ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$

$$y_{i2}^* = \gamma_2 y_{i1}^* + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2},\ y_{i2} = \text{Max}(L_{i2}, y_{i2}^*).$$

Thus, the first equation is a probit model and the second is a censored regression. As before, we can manipulate the reduced form to obtain the needed two step estimator. We should note before proceeding, that the sample data provide no information about the scale of y_{i1}^*, so there is no point to carrying the parameter σ_{11} through the analysis – nothing is lost by assuming $\sigma_{11} = 1$ at the outset. The reduced form of the equation system in the latent variables is, as before,

$$y_{i1}^* = \mathbf{x}_i'\boldsymbol{\pi}_1 + v_{i1},\ \ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$

$$y_{i2}^* = \mathbf{x}_i'\boldsymbol{\pi}_2 + v_{i2},\ \ y_{i2} = \text{Max}(L_{i2}, y_{i2}^*).$$

The reduced form parameters can be estimated by applying maximum likelihood to the probit model in the first equation and the censored regression in the second. We may now insert the estimated equations in the partial reduced forms

$$y_{i1}^* = \gamma_1(\mathbf{x}_i'\boldsymbol{\pi}_2) + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1} + \gamma_1 v_{i2},\ \ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$

$$y_{i2}^* = \gamma_2(\mathbf{x}_i'\boldsymbol{\pi}_1) + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2} + \gamma_2 v_{i1},\ \ y_{i2} = \text{Max}(L_i, y_{i2}^*).$$

The first equation can now be estimated as a probit model and the second as a censored regression. As a consequence of the loss of scale information, the probit estimator in the first equation estimates γ_1 and $\boldsymbol{\beta}_1$ scaled down by $\text{Var}[\varepsilon_{i1} + \gamma_1 v_{i2}]$. This is the fundamental indeterminacy in the model. The second equation can be estimated as a censored regression model. In both cases, we then adjust the estimated asymptotic covariance matrix. Both of these can be programmed using the results already given in the previous sections.

E48.5.2 Two Binary Variables

Finally, suppose both observed variables are binary. The resulting model is

$$y_{i1}^* = \gamma_1 y_{i2}^* + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1},\ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$
$$y_{i2}^* = \gamma_2 y_{i1}^* + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2},\ y_{i2} = \mathbf{1}(y_{i2}^* > 0).$$

Estimation can be done using the strategy suggested earlier. Once again, the observed data contain no information on scaling of the latent variables, so we assume $\sigma_1 = \sigma_2 = 1$ at the outset, with no loss of generality. Thus, $\text{Cov}[\varepsilon_1,\varepsilon_2] = \text{Corr}[\varepsilon_1,\varepsilon_2] = \rho$. This would be a conventional simultaneous equations model but for the censoring. The reduced form system is

$$y_{i1}^* = \mathbf{x}_i'\boldsymbol{\pi}_1 + v_{i1},\ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$
$$y_{i2}^* = \mathbf{x}_i'\boldsymbol{\pi}_2 + v_{i2},\ y_{i2} = \mathbf{1}(y_{i2}^* > 0)$$

where $\mathbf{x}_i = \mathbf{x}_{i1} \cup \mathbf{x}_{i2}$. The partial reduced form system is

$$y_{i1}^* = \gamma_1(\mathbf{x}_i'\boldsymbol{\pi}_2) + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1} + \gamma_1 v_{i2},\ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$
$$y_{i2}^* = \gamma_2(\mathbf{x}_i'\boldsymbol{\pi}_1) + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2} + \gamma_2 v_{i1},\ y_{i2} = \mathbf{1}(y_{i2}^* > 0).$$

The model can be estimated using the two step method described earlier. Note what can be estimated by this method, and what cannot. Since we have normalized σ_1 and σ_2 to one in the original structure, in the reduced form, the two variances are (after skipping a bit of algebra) $\text{Var}[v_{i1}] = \theta_1^2 = (1 + \gamma_1^2 + 2\rho\gamma_2)/(1-\gamma_1\gamma_2)^2$ and $\text{Var}[v_{i2}] = \theta_2^2 = (1 + \gamma_2^2 + 2\rho\gamma_2)/(1-\gamma_1\gamma_2)^2$. The full reduced form equations can both be estimated as probit models using maximum likelihood, but as always, the coefficients are implicitly scaled. Thus, probit estimation of the reduced form produces estimates of $(1/\theta_1)\boldsymbol{\pi}_1$ and $(1/\theta_2)\boldsymbol{\pi}_2$. The partial reduced form for y_1^* is, therefore,

$$\begin{aligned} y_{i1}^* &= \theta_2\gamma_1(\mathbf{x}_i'\boldsymbol{\pi}_2/\theta_2) + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1} + \gamma_1 v_{i2} \\ &= \theta_2\gamma_1 z_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1} + \gamma_1 v_{i2} \end{aligned}$$

Taking z_{i2} as known, we could now fit this as a probit model. Once again, however, there will be a scaling because of the lack of information about the scale of the latent variable. The algebra is a bit tedious, but it follows from the fact that the partial reduced form is the true reduced form that has $\varepsilon_{i1} + \gamma_1 v_{i2}, = v_{i1}$. Therefore, probit estimation of the parameters of the first partial reduced form equation by maximum likelihood produces estimates of $(\theta_2/\theta_1)\gamma_1$ and $(1/\theta_1)\boldsymbol{\beta}_1$. Likewise, the MLEs in the second equation are of $(\theta_1/\theta_2)\gamma_2$ and $(1/\theta_2)\boldsymbol{\beta}_2$. Therefore, this two step estimator produces estimates not of the original parameters, but of these scaled versions of them. Can the original parameters be recovered? No, because this method produces no estimate of the correlation coefficient between ε_{i1} and ε_{i2} or v_{i1} and v_{i2}. The product of γ_1 and γ_2 can be recovered, in an obvious way, but that is as far as one can go.

In fact, there is a way to estimate all of the parameters of the model. We return to the original structural equations. The reduced form for the system can be written

$$\begin{aligned}
y_{i1}^* &= \gamma_1\gamma_2 y_{i1}^* + \gamma_1\mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1} + \gamma_1\varepsilon_{i2} \\
&= [1/(1-\gamma_1\gamma_2)]\mathbf{x}_{i1}'\boldsymbol{\beta}_1 + [\gamma_1/(1-\gamma_1\gamma_2)]\mathbf{x}_{i2}'\boldsymbol{\beta}_2 + [1/(1-\gamma_1\gamma_2)](\varepsilon_{i1} + \gamma_1\varepsilon_{i2}) \\
&= \mathbf{x}_{i1}'\boldsymbol{\delta}_1 + \gamma_1(\mathbf{x}_{i2}'\boldsymbol{\delta}_2) + v_{i1} \\
y_{i2}^* &= \gamma_2(\mathbf{x}_{i1}'\boldsymbol{\delta}_1) + \mathbf{x}_{i2}'\boldsymbol{\delta}_2 + v_{i2}.
\end{aligned}$$

This is a bivariate probit model, which can be fit by maximum likelihood. The estimation is fairly complicated, because all of the cross equation restrictions must be imposed, and the index parts of the equations are nonlinear. But, it is a conventional programming problem. The variances of v_{i1} and v_{i2} were given earlier. The maximum likelihood procedure will produce estimates of γ_1/θ_1, γ_2/θ_2, and Corr(v_{i1},v_{i2}), which are extremely complicated, but invertible functions of γ_1, γ_2, and ρ. Finally, with these in hand, $\boldsymbol{\delta}_1$ and $\boldsymbol{\delta}_2$ could be unscaled to recover $\boldsymbol{\beta}_1$ and $\boldsymbol{\beta}_2$. Obviously, this is far more complicated than the two step approach. It does demonstrate the different quantities estimated by the two approaches. Finally, we note, that the primary difference between the FIML approach and the two step (LIML) approach is that the former estimates ρ while the latter does not.

The two step estimator is by far the simpler of the two procedures. For estimation of the first equation,

Step 1. Fit the reduced form for the second equation and compute $z_{i2} = \mathbf{x}_i'\boldsymbol{\pi}_2$ using the MLE. Let $\mathbf{V}_1$ denote the asymptotic covariance matrix computed at this step. At this step, also compute

$$\mathbf{d}_{i2} = (2y_{i2}-1)\phi(\mathbf{x}_i'\boldsymbol{\pi}_2)/\Phi[(2y_{i2}-1)(\mathbf{x}_i'\boldsymbol{\pi}_2)] \times \mathbf{x}_i = \lambda_{i1}\mathbf{x}_i$$

Step 2. Fit the structural probit equation on z_{i2} and $\mathbf{x}_{i1}$. Denote the asymptotic covariance matrix computed at this step as $\mathbf{V}_2$. The vectors needed at this step for the corrected asymptotic covariance matrix are

$$\mathbf{g}_{i1} = \{(2y_{i1}-1)\phi(\gamma_1 z_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1)/\Phi[(2y_{i1}-1)(\gamma_1 z_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1)]\}\begin{bmatrix} z_{i2} \\ \mathbf{x}_{i1}\end{bmatrix} = \lambda_{i2}\mathbf{x}_{i1}^*$$

$$\mathbf{m}_{i1} = \{(2y_{i1}-1)\phi(\gamma_1 z_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1)/\Phi[(2y_{i1}-1)(\gamma_1 z_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1)]\}\gamma_1\,\mathbf{x}_i = \lambda_{i2}\mathbf{x}_i.$$

(Note, $\mathbf{x}_{i1}^* = (z_{i2},\mathbf{x}_{i1}')'$) With these in hand, the corrected asymptotic covariance matrix can be computed as usual. In this case, the estimator has a particularly simple form. Let $\boldsymbol{\Lambda}_1 = \text{diag}(\lambda_{i1})$ and $\boldsymbol{\Lambda}_2 = \text{diag}(\lambda_{i2})$, and suppose we use the BHHH estimator for the asymptotic covariance matrix for both probit estimators. Then, $\mathbf{V}_1 = [\mathbf{X}'\boldsymbol{\Lambda}_1^2\mathbf{X}]^{-1}$, $\mathbf{V}_2 = [\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2^2\mathbf{X}_2^*]^{-1}$, $\mathbf{G}'\mathbf{M} = \gamma_1[\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2^2\mathbf{X}]$, and $\mathbf{G}'\mathbf{D} = [\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2\boldsymbol{\Lambda}_1\mathbf{X}]$. Multiplying out the parts produces

$$\begin{aligned}
\mathbf{V}_2^* = [\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2^2\mathbf{X}_2^*]^{-1} + \gamma_1[\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2^2\mathbf{X}_2^*]^{-1}\{&\gamma_1 [\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2^2\mathbf{X}][\mathbf{X}'\boldsymbol{\Lambda}_1^2\mathbf{X}]^{-1}[\mathbf{X}'\boldsymbol{\Lambda}_2^2\mathbf{X}_2^*] \\
&- [\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2\boldsymbol{\Lambda}_1\mathbf{X}] [\mathbf{X}'\boldsymbol{\Lambda}_1^2\mathbf{X}]^{-1}[\mathbf{X}'\boldsymbol{\Lambda}_2^2\mathbf{X}_2^*] \\
&- [\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2^2\mathbf{X}][\mathbf{X}'\boldsymbol{\Lambda}_1^2\mathbf{X}]^{-1}[\mathbf{X}'\boldsymbol{\Lambda}_2\boldsymbol{\Lambda}_1\mathbf{X}_2^*]\}[\mathbf{X}_2^{*\prime}\boldsymbol{\Lambda}_2^2\mathbf{X}_2^*]^{-1}
\end{aligned}$$

The roles of equations 1 and 2 are reversed to obtain the counterparts for the second equation.

The following program can be used for estimation of an equation system with two binary variables as the observed data. Data setup is the usual. Note in this application, *y*1 and *y*2 are binary, and there is no need to define the censoring limits. The right hand sides of the two equations and the union are defined first.

```
NAMELIST    ; x1 = ... ; x2 = ... $
CREATE      ; y1 = ... ; y2 = ... $
NAMELIST    ; x = OR (x1,x2) $
```

We now do the estimation for the first equation. To repeat for the second equation, it is simplest just to reverse the subscripts in the data setup above. Fit the reduced form for the second equation first.

```
PROBIT      ; Lhs = y2 ; Rhs = x ; Hold(IMR = di) $
CREATE      ; z2 = b'x $
MATRIX      ; v1 = varb $
```

Estimate the structure for the first equation, for *y*1.

```
NAMELIST    ; z2x1= z2,x1 $
PROBIT      ; Lhs = y1 ; Rhs = z2x1 ; Hold(IMR = gi) $
```

This is all that is needed to compute the corrected covariance matrix.

```
CREATE      ; migi = gi*gi*b(1) ; digi = di*gi $
MATRIX      ; a = z2x1'[migi]x * v1 * x'[migi]z2x1
                - z2x1'[digi] x * v1 * x'[migi]z2x1
                - z2x1'[migi]x * v1 * x'[digi]z2x1
            ; v2star = varb + varb * a * varb $
DISPLAY     ; Parameters = b ; Covariance = v2star ; Labels = z2x1 $
```

Second equation. Same procedure.

```
PROBIT      ; Lhs = y1 ; Rhs = x ; Hold(IMR = di) $
CREATE      ; z1 = b'x$
MATRIX      ; v1 = varb $
NAMELIST    ; z1x2 = z1,x2 $
PROBIT      ; Lhs = y2 ; Rhs = z1x2 ; Hold(IMR = gi) $
CREATE      ; migi = gi*gi*b(1) ; digi = di*gi $
MATRIX      ; a = z1x2'[migi]x * v1 * x'[migi]z1x2
                - z1x2'[digi] x * v1 * x'[migi]z1x2
                - z1x2'[migi]x * v1 * x'[digi]z1x2
            ; v2star = varb + varb * a * varb $
DISPLAY     ; Parameters = b ; Covariance = v2star ; Labels = z1x2 $
```

To illustrate the procedure, we have fit a model for the wife's labor force participation, and for the husband, whether they are working 'full time,' that is, at least 2,000 hours for the year.

```
NAMELIST    ; x1 = one,kl6,k618,wa,we
            ; x2 = one,ha,he,faminc,cit
            ; x = OR(x1,x2) $
CREATE      ; y1 = whrs > 0
            ; y2 = hhrs >= 2000  $
```

These are the two step structural estimates for the wife's labor force participation.

```

E48.5.3 Endogenous Binary Variables

A problem with the approach of the previous section is that unlike censored regressions, in which arguably the latent regressands, y_j^*, might be of interest, researchers would not ordinarily analyze a model involving a binary variable in terms of the latent regression. The dummy variable is generally viewed as a shift parameter in the equation, and, as such, y_{i1}, not y_{i1}^*, is what would typically appear in the second equation. The reduced form analysis we have done above greatly simplifies the derivations, but they may substitute a simpler estimation process for the one really of interest.

Results have been obtained for cases of 'endogenous' dummy variables – the extensive literature of Maddala (1983), Heckman (1979), Terza (1998), and others will apply. Many of these results are based on placing endogenous binary variables in linear regression models – that is, models without censoring. In this case, the conditional mean function, rather than the likelihood function turns out to be the platform on which consistent estimation can be performed. Consider, first, a regression model with a binary variable, but no censoring:

$$y_{i1}^* = \gamma_1 y_{i2} + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1},\; y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$
$$y_{i2} = \gamma_2 y_{i1} + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2},$$

This model cannot be internally consistent unless γ_1 equals zero. (A sketch of a proof appears in Maddala (1983).) With $\gamma_1 = 0$, a fairly common specification emerges – this is often employed as a 'treatment effects' model. In this formulation, the binary variable y_{i1} indicates presence or absence of some treatment (such as participation in a program or experiment), and y_{i2} measures the outcome variable of interest, such as income, grade improvement, health improvement, and so on. There are at least three approaches to estimation, FIML, instrumental variables, and the two step estimator pioneered by Heckman (1979). We will analyze this model in some detail in the chapter on the sample selection model, so we consider it only briefly here.

An important part of the development will be that y_{i2} is fully observed. One approach to estimation can be based on constructing the conditional mean functions. From the first equation, $E[y_{i1}|\mathbf{x}_{i1}] = \Phi(\mathbf{x}_{i1}'\boldsymbol{\beta}_1)$ – recall, $\gamma_1 = 0$ - so $y_{i1} = \Phi(\mathbf{x}_{i1}'\boldsymbol{\beta}_1) + u_{i1}$ where $E[u_{i1}|\mathbf{x}_{i1}] = 0$ and, as usual for conditional mean functions, $\text{Cov}[u_{i1},\Phi(\mathbf{x}_{i1}'\boldsymbol{\beta}_1)] = 0$. Inserting these into the second equation, we obtain

$$\begin{aligned} y_{i2} &= \gamma_2\Phi(\mathbf{x}_{i1}'\boldsymbol{\beta}_1) + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + (\varepsilon_{i2} + \gamma_2 u_{i1}) \\ &= \gamma_2 z_{i1} + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + v_{i2}. \end{aligned}$$

At least in terms of the population values, this is a classical regression model. It is interesting to note that the conventional rules for identification in simultaneous equations models do not apply here. Even though this is a recursive model, consistent estimation will not require that ε_1 and ε_2 be uncorrelated. Moreover, because of the nonlinearity of the conditional mean function, it is not necessary for there to be variables excluded from either equation – the standard rank and order conditions do not apply to nonlinear systems.

This is a natural candidate for the two step estimator. The first step would be consistent estimation of $\boldsymbol{\beta}_1$ by treating the first equation as a probit model. Estimates of the variable z_{i1} are computed using this maximum likelihood estimator of $\boldsymbol{\beta}_1$. At the second step, γ_2 and $\boldsymbol{\beta}_2$ are consistently estimated by least squares regression of y_{i2} on $[z_{i1},\mathbf{x}_{i2}]$. The asymptotic covariance matrix at the second step is adjusted by the Murphy and Topel estimator. Let $\mathbf{V}_1$ denote the asymptotic covariance matrix computed for the probit estimator at the first step, and let $\mathbf{V}_2$ denote the estimated asymptotic covariance matrix computed at step 2. Then, as in the other cases,

$$\mathbf{V}_2^* = \mathbf{V}_2 + \mathbf{V}_2[\mathbf{G}'\mathbf{M}\,\mathbf{V}_1\mathbf{M}'\mathbf{G} - \mathbf{G}'\mathbf{D}\mathbf{V}_1\mathbf{M}'\mathbf{G} - \mathbf{G}'\mathbf{M}\,\mathbf{V}_1\,\mathbf{D}'\mathbf{G}]\mathbf{V}_2$$

where

$$\mathbf{g}_i = e_i[z_{i1,}\mathbf{x}_{i2}]/\sigma^2,$$

$$\mathbf{m}_i = e_i\{\gamma_2\phi(\mathbf{x}_{i1}'\boldsymbol{\beta}_1)]\mathbf{x}_{i2}\}/\sigma^2, \text{ and}$$

$$\mathbf{d}_i = (2y_{i1}\text{-}1)\phi(\mathbf{x}_{i1}'\boldsymbol{\beta}_1)/\Phi[(2y_{i1}\text{-}1)(\mathbf{x}_{i1}'\boldsymbol{\beta}_1)]\mathbf{x}_{i1}.$$

Our interest at this juncture is in a model which includes censoring of the dependent variable in the second equation, so we consider that case now. A fully operational estimator for the simultaneous equations model

$$y_{i1}^* = \gamma_1 y_{i2}^* + \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1},\ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$
$$y_{i2}^* = \gamma_2 y_{i1} + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2},\ y_{i2} = \text{Max}(L_i, y_{i2}^*) \text{ (note, } y_{i1}, \text{ not } y_{i1}^*)$$

remains to be derived. Estimation is not the only difficulty. It is unclear whether the model is even internally consistent. (Maddala shows that the model cannot be internally consistent if γ_1 is nonzero.) This restricts us to recursive models. Consider, then, the model with $\gamma_1 = 0$

$$y_{i1}^* = \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1},\ y_{i1} = \mathbf{1}(y_{i1}^* > 0)$$
$$y_{i2}^* = \gamma_2 y_{i1} + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2},\ y_{i2} = \text{Max}(L_i, y_{i2}^*).$$

The two step estimator is problematic in this case. The partial reduced form for y_{i2}^* is not available – the precise prediction that should be inserted for y_{i1} is unclear. But, a full information maximum likelihood estimator is quite feasible, so we will develop that.

We continue to assume that ε_1 and ε_2 are bivariate normally distributed with zero means, variances one and σ_1^2, and correlation ρ. Consider, first, the cases in which y_{i2}^* is censored. The probabilities associated with these outcomes are the probabilities of the joint events,

$$\text{Prob}[y_{i2} = L_{i2}\,,\, y_{i1} = 0] \text{ and } \text{Prob}[y_{i2} = L_{i2}\,,\, y_{i1} = 1].$$

These are simply the bivariate standard normal integrals,

$$\text{Prob}[y_{i2} = L_{i2}, y_{i1} = 0] = \text{Prob}[\varepsilon_{i1} \le \text{-}\mathbf{x}_{i1}'\boldsymbol{\beta}_1, (\varepsilon_{i2}/\sigma_2) \le (L_{i2} - \mathbf{x}_{i2}'\boldsymbol{\beta}_2)/\sigma_2 \mid \rho]$$

and

$$\text{Prob}[y_{i2} = L_{i2}, y_{i1} = 1] = \text{Prob}[\varepsilon_{i1} > \text{-}\gamma - \mathbf{x}_{i1}'\boldsymbol{\beta}_1, (\varepsilon_{i2}/\sigma_2) \le (L_{i2} - \mathbf{x}_{i2}'\boldsymbol{\beta}_2)/\sigma_2 \mid \rho]$$
$$= \text{Prob}[\varepsilon_{i1} \le \gamma + \mathbf{x}_{i1}'\boldsymbol{\beta}_1, (\varepsilon_{i2}/\sigma_2) \le (L_{i2} - \mathbf{x}_{i2}'\boldsymbol{\beta}_2)/\sigma_2 \mid \text{-}\rho],$$

so these are the terms in the likelihood function for the fully censored data. It might seem odd that this has ignored the simultaneity. However, the result can be obtained trivially by writing Prob[$y_{i2} = L_{i2}$, $y_{i1} = 1$] = Prob[$y_{i2} = L_{i2}| \, y_{i1} = 1$]Prob[$y_{i1} = 1$]. The former probability is just the joint probability divided by the marginal, which then cancels out of the product, and, of course, conditioned on y_{i1}, we are free to treat y_{i1} as a constant. The 'simultaneity' only becomes an issue in regression because of the use of covariances and moments. In this instance, we are using the probabilities directly.

For the uncensored observations, we require the mixed distributions, $f(y_{i1}=0,y_{i2})$ and $f(y_{i1}=1,y_{i2})$. The first of these, $f(y_{i1}=0,y_{i2})$, is derived from

$$
\begin{aligned}
f(\varepsilon_{i1} \le -\mathbf{x}_{i1}'\boldsymbol{\beta}_1, \varepsilon_{i2}) &= \int_{-\infty}^{-\mathbf{x}_{i1}'\boldsymbol{\beta}_1} f(\varepsilon_{i1},\varepsilon_{i2})d\varepsilon_{i1} \\
&= \int_{-\infty}^{-\mathbf{x}_{i1}'\boldsymbol{\beta}_1} f(\varepsilon_{i2})f(\varepsilon_{i1}\,|\,\varepsilon_{i2})d\varepsilon_{i1} \\
&= f(\varepsilon_{i2})\int_{-\infty}^{-\mathbf{x}_{i1}'\boldsymbol{\beta}_1} f(\varepsilon_{i1}\,|\,\varepsilon_{i2})d\varepsilon_{i1} \\
&= \frac{1}{\sigma_2}\phi\left(\frac{y_{i2}-\mathbf{x}_{i2}'\boldsymbol{\beta}_2}{\sigma_2}\right)\int_{-\infty}^{-\mathbf{x}_{i1}'\boldsymbol{\beta}_1}\frac{1}{\sqrt{1-\rho^2}}\phi\left(\frac{\varepsilon_{i1}-(\rho/\sigma_2)\varepsilon_{i2}}{\sqrt{1-\rho^2}}\right)d\varepsilon_{i1} \\
&= \frac{1}{\sigma_2}\phi\left(\frac{y_{i2}-\mathbf{x}_{i2}'\boldsymbol{\beta}_2}{\sigma_2}\right)\int_{-\infty}^{-\mathbf{x}_{i1}'\boldsymbol{\beta}_1}\frac{1}{\sqrt{1-\rho^2}}\phi\left(\frac{\varepsilon_{i1}-(\rho/\sigma_2)\left(y_{i2}-\mathbf{x}_{i2}'\boldsymbol{\beta}_2\right)}{\sqrt{1-\rho^2}}\right)d\varepsilon_{i1} \\
&= \frac{1}{\sigma_2}\phi\left(\frac{y_{i2}-\mathbf{x}_{i2}'\boldsymbol{\beta}_2}{\sigma_2}\right)\Phi\left(\frac{-\mathbf{x}_{i1}'\boldsymbol{\beta}_1+(\rho/\sigma_2)(y_{i2}-\mathbf{x}_{i2}'\boldsymbol{\beta}_2)}{\sqrt{1-\rho^2}}\right).
\end{aligned}
$$

For $f(y_{i1}=1,y_{i2})$, the numerator inside the CDF is changed to $\mathbf{x}_{i1}'\boldsymbol{\beta}_1+(\rho/\sigma_2)(y_{i2} - \gamma - \mathbf{x}_{i2}'\boldsymbol{\beta}_2)$, and other parts remain the same. These four results, then, give the parts of the likelihood function, which can then be maximized to estimate the parameters.

The following estimation program is for a censored regression with an endogenous binary variable. The equation system is

$$
\begin{aligned}
y_{i1}^* &= \mathbf{x}_{i1}'\boldsymbol{\beta}_1 + \varepsilon_{i1},\ y_{i1} = \mathbf{1}(y_{i1}^* > 0) \\
y_{i2}^* &= \gamma_2 y_{i1} + \mathbf{x}_{i2}'\boldsymbol{\beta}_2 + \varepsilon_{i2},\ y_{i2} = \text{Max}(L_i, y_{i2}^*).
\end{aligned}
$$

The left and right hand sides of the two equations are defined for the specific problem. The censoring limit for the second equation will typically be zero, but can be nonzero. That is defined here as well. The rest of the command set is generic, and can be used without modification.

```
NAMELIST   ; x1  = the Rhs of the probit model $
NAMELIST   ; x2  = exogenous variables in the censored regression $
CREATE     ; y1  = binary dependent variable $
CREATE     ; y2  = censored dependent variable $
CREATE     ; li  = censoring limit $
```

Obtain the dimensions of the problem, and pointers to partition the parameter vector.

```
CALC        ; k2 = Col(x2) ; k21=k2+1 ; k1=Col(x1) $
```

Get the starting values for the probit model. These are consistent, but LIML, so they are inefficient.

```
PROBIT      ; Lhs = y1 ; Rhs = x1 $
MATRIX      ; beta10 = b $
```

Obtain the starting values for censored regression. These are inconsistent, but better than zero.

```
TOBIT       ; Lhs = y2 ; Rhs = y1,x2 $
CALC        ; gamma0 = b(1) $
MATRIX      ; beta20 = b(2:k21) $
```

Compute a starting value for σ in the tobit equation, then use the Olsen transformation.

```
CALC        ; s20 = s ; h20 = 1/s $
CREATE      ; d = y2 > li ; q1 = 2*y1 - 1 $
```

Finally, compute the FIML estimator of all model parameters using maximum likelihood.

```
MAXIMIZE    ; Quietly ; Labels = k1_b1,c,k2_b2,h2,r

E48.6 Murphy and Topel's Two Step Estimator

We consider limited information maximum likelihood (LIML) estimation of a model which can be formulated in terms of two marginal distributions, $f_1(y_1|\mathbf{x}_1,\boldsymbol{\theta}_1)$ and $f_2(y_2|\mathbf{x}_1,\mathbf{x}_2,\boldsymbol{\theta}_1,\boldsymbol{\theta}_2)$. We propose to estimate this model in two steps: First, estimate $\boldsymbol{\theta}_1$ by maximum likelihood estimation based on $f_1(y_1|\mathbf{x}_1,\boldsymbol{\theta}_1)$. Second, estimate $\boldsymbol{\theta}_2$ by maximum likelihood based on $f_2(y_2|\mathbf{x}_1,\mathbf{x}_2,\boldsymbol{\theta}_1,\boldsymbol{\theta}_2)$, after inserting the estimate of $\boldsymbol{\theta}_1$ obtained at Step 1, and treating it as known. The consistency of the MLE of $\boldsymbol{\theta}_1$ implies that this strategy will produce a consistent estimator at the second step. However, the conventional asymptotic covariance matrix computed at Step 2 will be inappropriate because of the variation introduced by the estimated value of $\boldsymbol{\theta}_1$. The Murphy and Topel (2002) result provides a strategy for computing an appropriate covariance matrix at the second step. Let

$$\log L_1 \;=\; \sum\nolimits_{i=1}^{n} \log f_1(y_{i1}\,|\,x_{i1},\boldsymbol{\theta}_1)$$

The first step MLE of $\boldsymbol{\theta}_1$ is obtained by maximizing log L_1. Let $\mathbf{V}_1$ denote an appropriate estimator of the asymptotic covariance matrix of $\hat{\boldsymbol{\theta}}_1$, however computed – this might be based on the actual Hessian (Newton's method), the expected Hessian (scoring), or the BHHH estimator. Let

$$\log L_2^c \;=\; \sum\nolimits_{i=1}^{n} \log f_2\left[\, y_{i2}|\mathbf{x}_{i2},\boldsymbol{\theta}_2,\left(\mathbf{x}_{i1},\hat{\boldsymbol{\theta}}_1\right)\right]$$

denote the conditional log likelihood for y_2 with the first step MLE of $\boldsymbol{\theta}_1$ inserted as if it were the known $\boldsymbol{\theta}_1$. We obtain the two step MLE of $\boldsymbol{\theta}_2$ by maximizing log L_2^c with respect to $\boldsymbol{\theta}_2$. Let $\mathbf{V}_2$ denote the estimated asymptotic covariance matrix for this estimator, however computed,

assuming(incorrectly) that $\hat{\boldsymbol{\theta}}_1$ is the true value of $\boldsymbol{\theta}_1$. The matrix $\mathbf{V}_2$ underestimates the asymptotic covariance matrix for $\hat{\boldsymbol{\theta}}_2$. Murphy and Topel show that an appropriate estimator is found as follows:
Let $\mathbf{g}_i$ be the vector of partial derivatives of the ith term in log L_2^c

$$\mathbf{g}_i = \partial \log f_2(\mathrm{y}_2|\mathbf{x}_1,\mathbf{x}_2, \hat{\boldsymbol{\theta}}_1, \boldsymbol{\theta}_2)/\partial\boldsymbol{\theta}_2$$

The matrix $\mathbf{G}$ constructed by stacking the rows $\mathbf{g}_i$ contains the derivatives of the log likelihood for $\boldsymbol{\theta}_2$, so $\partial \log L_2/\partial\boldsymbol{\theta}_2 = \mathbf{G}'\mathbf{i}$, which is $\mathbf{0}$ at the MLE. The BHHH estimator would be $[\mathbf{G}'\mathbf{G}]^{-1}$ when $\mathbf{G}$ is computed using $\hat{\boldsymbol{\theta}}_2$. Let

$$\mathbf{m}_i = \partial \log f_2(y_2|\mathbf{x}_1,\mathbf{x}_2, \hat{\boldsymbol{\theta}}_1, \boldsymbol{\theta}_2)/\partial\boldsymbol{\theta}_1.$$

The matrix $\mathbf{M}$ contains the derivatives of log L_2^c with respect to $\boldsymbol{\theta}_1$ (the first step parameter vector), so $\partial \log L_2^c/\partial\theta_1 = \mathbf{M}'\mathbf{i}$ – this is not necessarily $\mathbf{0}$. Finally, return to the first step maximum likelihood estimation procedure, and define

$$\mathbf{d}_i = \partial \log f_1(y_1|\mathbf{x}_1,\boldsymbol{\theta}_1)/\partial\boldsymbol{\theta}_1.$$

The matrix $\mathbf{D}$ contains the derivatives of log L_1 with respect to $\boldsymbol{\theta}_1$, so $\partial \log L_1/\partial\boldsymbol{\theta}_1 = \mathbf{D}'\mathbf{i}$. This vector does equal $\mathbf{0}$ when evaluated at $\hat{\boldsymbol{\theta}}_1$. With these in place, the Murphy and Topel estimator of the appropriate estimator for the two step maximum likelihood estimator, $\hat{\boldsymbol{\theta}}_2 \,|\, \hat{\boldsymbol{\theta}}_1$ is

$$\mathbf{V}_2^* = \mathbf{V}_2 + \mathbf{V}_2[(\mathbf{G}'\mathbf{M})\mathbf{V}_1(\mathbf{M}'\mathbf{G}) - (\mathbf{G}'\mathbf{D})\mathbf{V}_1(\mathbf{M}'\mathbf{G}) - (\mathbf{G}'\mathbf{M})\mathbf{V}_1(\mathbf{D}'\mathbf{G})]\mathbf{V}_2$$

where $\mathbf{G}$, $\mathbf{M}$, and $\mathbf{D}$ are computed using the two sets of maximum likelihood estimates.

For most of the familiar econometric models, including the ones we will consider here, the variables, $\mathbf{x}_1$ and $\mathbf{x}_2$ enter the log likelihoods through linear index functions, $\mathbf{x}_1'\boldsymbol{\theta}_1$ and $\mathbf{x}_2'\boldsymbol{\theta}_2$. This means that frequently, we will find $\mathbf{g}_i = w_{i22}(\mathbf{x}_{i1}, \mathbf{x}_{i2}, \hat{\boldsymbol{\theta}}_1, \hat{\boldsymbol{\theta}}_2) \times \mathbf{x}_2$ for some scalar function $w_i(.)$, and likewise for a w_{i21} for $\mathbf{m}_i$ and w_{i11} for $\mathbf{d}_i$. This would make, for example,

$$\mathbf{G}'\mathbf{M} = \sum_{i=1}^{n} w_{i22}(\mathbf{x}_{i1}, \mathbf{x}_{i2}, \hat{\boldsymbol{\theta}}_1, \hat{\boldsymbol{\theta}}_2) \times w_{i12}(\mathbf{x}_{i1}, \mathbf{x}_{i2}, \hat{\boldsymbol{\theta}}_1, \hat{\boldsymbol{\theta}}_2) \times \mathbf{x}_2 \times \mathbf{x}_1'.$$

If we denote the product of scalars as simply w_i, arrange these scalars in an $n\times n$ diagonal matrix, $\mathbf{W}$, and define data matrices $\mathbf{X}_1$ and $\mathbf{X}_2$ in the obvious way, then this computation will simplify to

$$\mathbf{G}'\mathbf{M} = \sum_{i=1}^{n} w_i(\mathbf{x}_{i1}, \mathbf{x}_{i2}, \hat{\boldsymbol{\theta}}_1, \hat{\boldsymbol{\theta}}_2) \times \mathbf{x}_2 \times \mathbf{x}_1' = \mathbf{X}_2'\mathbf{W}\mathbf{X}_1.$$

This is a pattern that occurs often enough that the Murphy and Topel results are usually far simpler than first appearances would suggest. We made use of it in several of the applications described earlier.

E49: Generalized Linear Models – 1: Discrete

E49.1 Introduction

This chapter and Chapters E50 and E51 present a group of 'generalized linear models' (GLMs) that can be used for dependent variables whose range is generally restricted, either because they are discrete (such as a binary variable) or because they naturally vary over only a restricted range (such as variables that are only nonnegative). The class of generalized linear models was defined in the pioneering works of Nelder and Wedderburn (1972) and McCullagh and Nelder (1983). As shown below, many of these are models that *LIMDEP* fits under a different heading, but it is convenient to group them here. Formally, the class of models is a group in which the conditional mean function is of the form $E[y|\mathbf{x}] = h(\boldsymbol{\beta}'\mathbf{x})$ for some continuous function $h(.)$. (McCullagh and Nelder and others since have focused on 'exponential families,' but we take some license here, and broaden their class.) This class includes most of the single index function models already considered, such as the binary choice models, censored regression, truncated regression, and all of the count models considered in Chapters E41-E44. These chapters will present a group of models not already considered and also organize several from earlier chapters for the convenience of the user interested in this class of models.

The basic command for estimation of the models described in this chapter is

```
GLIM          ; Lhs = dependent variable
              ; Rhs = independent variables
              ; Model = type of model $
```

where '**type of model**' is one of the 25 generalized linear models presented here.

The most convenient way to organize these models is by type of dependent variable. This chapter will describe several models for discrete dependent variables, such as the probit and logit model. Chapter E50 will describe models for continuous variables, such as some for variables constrained to lie in the interval (0,1). Chapter E51 will extend both types of models to several panel data settings.

In each framework, the estimation procedure is maximum likelihood, based on the formal specification of the distribution of the observed random variable. We begin the development with some methodological points about GLIM models.

E49.2 Estimating Generalized Linear Models

The following are the central features of Nelder and Wedderburn's (1972) and McCullagh and Nelder's (1983) GLM approach to specification. (We present this as an application to panel data to simplify the presentation in Chapter E51.) The generalized linear model is specified by a 'link' to the conditional mean function,

$$f(E[y_{it} \mid \mathbf{x}_{it}]) = \boldsymbol{\beta}'\mathbf{x}_{it},$$

and a 'family' of distributions,

$$y_{it} \mid \mathbf{x}_{it} \sim g(y_{it}, \boldsymbol{\beta}'\mathbf{x}_{it}, \boldsymbol{\theta})$$

where $\boldsymbol{\beta}$ and $\mathbf{x}_{it}$ are as already defined and $\boldsymbol{\theta}$ is zero or more ancillary parameters, such as the dispersion parameter in the negative binomial model (which is a GLM). Many of the models already discussed fit into this framework, such as the standard probit model which has link function $f(.) = \Phi^{-1}(P)$ and Bernoulli distribution family and the classical normal linear regression which has link function equal to the identity function and normal distribution family. More generally, for the single index binary choice models estimated by *LIMDEP*, if $\text{Prob}(y_{it} = 1) = F(\boldsymbol{\beta}'\mathbf{x}_{it})$, then this is the conditional mean function, and the link function is simply (by definition)

$$f(E[y_{it} \mid \mathbf{x}_{it}]) = F^{-1}[F(\boldsymbol{\beta}'\mathbf{x}_{it})] = \boldsymbol{\beta}'\mathbf{x}_{it}.$$

This includes the probit, logit, Gompertz, complementary log log, arctangent and Burr (scobit) models described in Chapter E27. A like result holds for the count models, Poisson, negative binomial, etc. presented in Chapter E41 (and the extensions in Chapters E42-E44) for which the link is simply the log function.

E49.2.1 Internally Consistent Generalized Linear Models

One can create a vast array of models by crossing a menu of link functions with a second menu of distributional families. (As shown below, *LIMDEP* offers at least 25 different distributional families.) Consider, for example, the following matrix of a few possibilities.

		Link Functions				
Kind of r.v.	**Family**	Identity	Logit	Probit	Log	Reciprocal
Binary	Bernoulli	X	•	•	X	X
Continuous	normal	•	•	•	•	•
Count	Poisson	X	X	X	•	X
Nonnegative	gamma	X	X	X	•	X

Table E49.1 Families and Link Functions for Generalized Linear Models

We choose four distributional families to provide models for the indicated kinds of random variables and five link functions. There is no theoretical restriction on the mesh between links and families. But, in fact, most of the combinations are internally inconsistent. For example, for the binary dependent variable, only the probit and logit links make sense; the others imply a conditional mean that is not bounded by zero and one. For the continuous random variable, any link could be chosen; this just defines a linear or nonlinear regression model. For the count variable, only the log transformation insures an appropriate nonnegative mean. The logit and probit transformations also imply a positive mean, but one would not want to formulate a model for counts that forces the conditional mean function to be a probability between zero and one, so these make no sense either. The exact same considerations rule out all but the log transformation for the gamma family. The preceding lists most of the commonly used link functions. More than half of our table is null. Of the nine combinations that are internally consistent, five are just nonlinear regressions. But, the nonlinear regression model is a much broader class than this, and one would unduly restrict the model if they limited it to the GLIM framework for nonlinear regression analysis. The end result of this development is that typically, only one link function is appropriate for most of the distributional families. (Similar analyses appear in other popular programs such as *SAS* and *Stata*. In general, the matrix of model combinations is usually about one third full, with most cells containing unusable or inconsistent combinations such as the ones noted above.)

The upshot of all this is that you can fit nearly all of the internally consistent 'generalized linear models in common use' – partly because in the end, the set of them is surprisingly small. The width of the class is deceptive because of this consideration of consistency of the model and the specification of the conditional mean function.

E49.2.2 The Similarity of Different Link Functions

The generic form of the GLIM implies that

$$E[y \mid \mathbf{x}] = h(\boldsymbol{\beta}'\mathbf{x}).$$

As noted in many previous applications, the implication of this is that while coefficients in different forms of the models for a given dependent variable may differ substantially, the differences often disappear (or nearly so), when one computes the partial effects. Generally, for index function models, the partial effects are scaled versions of the structural coefficient vector;

$$\boldsymbol{\delta} = \frac{\partial E[y \mid \mathbf{x}]}{\partial \mathbf{x}} = h'(\boldsymbol{\beta}'\mathbf{x})\boldsymbol{\beta}\ .$$

The different scale factors tend to eliminate the differences in the associated parameter vectors. The effect is strikingly persistent in binary choice modeling, but it is likewise prevalent more generally in the analysis of generalized linear models. Consider an example, based on the German health care data analyzed earlier and again in the sections to follow. Suppose y is income, which we model with an exponential regression model,

$$p(y_{it} \mid \mathbf{x}_{\mathrm{it}}) = \lambda_{it} \exp(-y_{it}\, \lambda_{it}).$$

Then, this constitutes the 'family' of distributions. For this model, $E[y_{it}|\mathbf{x}_{it}] = 1/\lambda_{it}$. We consider two possible 'link' functions, the log function, for which $\lambda_{it} = \exp(\boldsymbol{\beta}'\mathbf{x}_{it})$ and the identity function, $\lambda_{it} = \boldsymbol{\beta}'\mathbf{x}_{it}$. For the first of these, $\boldsymbol{\delta}_{it} = (-1/\lambda_{it})\boldsymbol{\beta}$, while for the second, $\boldsymbol{\delta}_{it} = (-1/\lambda_{it}^2)\boldsymbol{\beta}$. The following program does these computations for a model of incomes and displays the coefficients and the marginal effects.

```
SAMPLE      ; All $
REJECT      ; _groupti <  7 $
NAMELIST    ; x = one,age,educ,hhkids,female,married $
CALC        ; k = Col(x) $
MAXIMIZE    ; Labels = k_blog ; Start = k_0
            ; Fcn = bx = blog1'x | ti = Exp(bx) | Log(ti) - hhninc*ti  $
MATRIX      ; xb = Mean(x) $
CALC        ; eb = -Exp(-b'xb) $
MATRIX      ; deltae = eb*b $
CALC        ; k1 = k-1 ; yb1 = 1/Xbr(hhninc) $
MAXIMIZE    ; Labels = k_biden ; Start = yb1,k1_0
            ; Fcn = bx = b1'x | ti = bx | Log(ti) - hhninc*ti $
CALC        ; eb = -1/(b'xb)^2 $
MATRIX      ; deltal = eb*b ; List ; deltas = [deltae,deltal] $
```

Though the coefficient vectors appear to be quite different, the marginal effects are, in fact, close to the same. Moreover, the pattern of significance in the coefficients is the same as well. The upshot, as illustrated in this example, is that there is generally little impact of the choice of the link function on quantities usually of interest in the model. However, there is a cost to imposing the restriction of an internally inconsistent conditional mean on a model, for example, in forcing the mean of a Poisson variable to be a probability.

The similarity of these effects seems to be little noted in the literature and on websites that discuss the generalized linear models. For example, displays such as that in Figure E49.1 are meant to suggest the difference between the identity link E[y|**x**] = $\boldsymbol{\beta}'\mathbf{x}$ and log link E[y|**x**] = exp($\boldsymbol{\beta}'\mathbf{x}$).

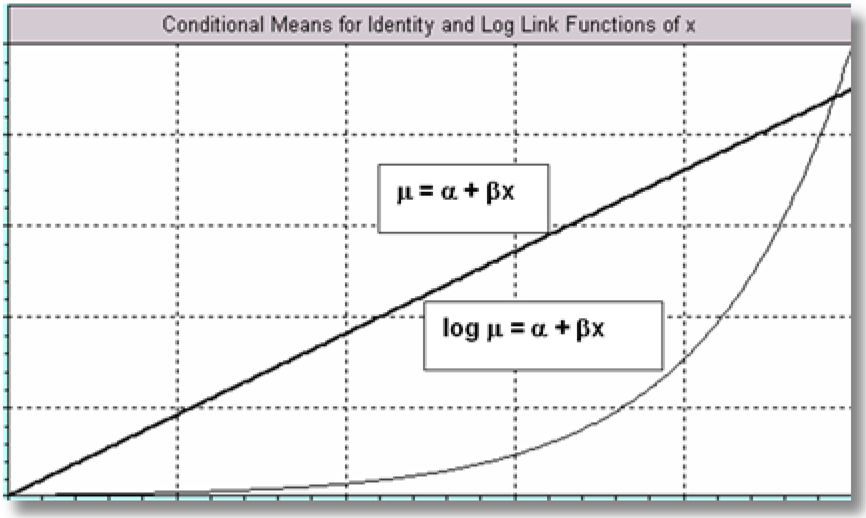

Figure E49.1 Link Functions for GLMs

But, these figures vastly exaggerate what will occur when the methods are applied to a model and a data set. The scaling by the coefficients, and the inherent relationships among the variables will obscure the differences in functional form. Consider the earlier example. We now refit this model as a normal family regression model with identity and log link functions, and the same regressors. We then hold the other variables constant at their means, and plot the conditional mean functions as a function of *age*. The figure shows that the impact of the choice of link function is minor.

The commands are:

```
NAMELIST   ; x0 = one,educ,hhkids,female,married $
REGRESS    ; Quietly ; Lhs = hhninc ; Rhs = x0,age $

           ; Grid ; Yaxis = E[y|x] $
```

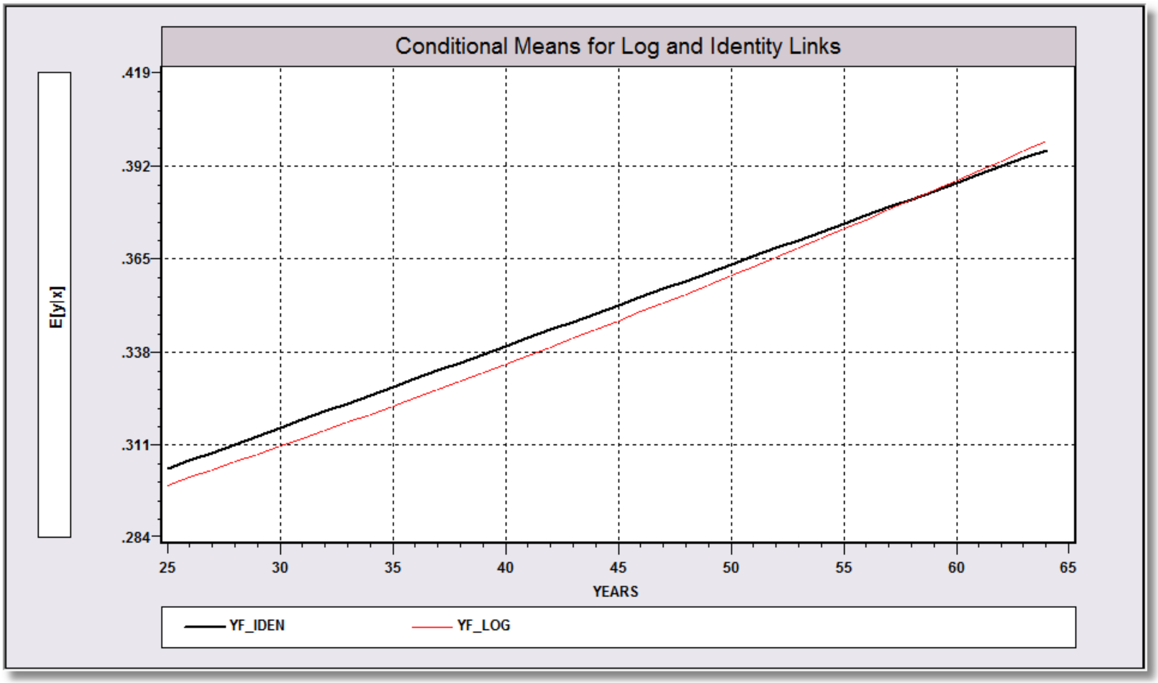

Figure E49.2 Estimated Conditional Means for Two Link Functions

E49.2.3 Estimation Methods

One of the useful byproducts of the early development of the generalized linear models methodology was an implied estimation technique, which has been labeled 'iteratively reweighted least squares,' or IRWLS. Since the conditional mean function is identified, it implies a kind of nonlinear weighted least squares estimator. Among the virtues of the GLM specifications is that this weighted least squares procedure is quite simple to compute – at least simple in that it should be easy to program. In most cases, at convergence, IRWLS will produce the maximum likelihood estimator. Since the GLIM estimator is based on a fully specified parametric model of the density for the observed random variable, the maximum likelihood estimator is fully efficient, and, where it differs from the MLE, the IRWLS estimator is not. (This will be the case in models that contain ancillary parameters, such as the overdispersion parameter in the negative binomial model.) All of *LIMDEP*'s estimators for these models are MLEs not weighted least squares estimators. (You may, as in other models, provide any observation specific weights you wish, but these are applied to terms in the log likelihood, not in any form of least squares.)

E49.2.4 Generalized Linear Models

As noted earlier, many of the single index function models described in the preceding chapters fall under the definition of GLMs in that the conditional mean function is a function of the linear index. However, in some of these cases, such as the censored regression, the inverse transformation to the index will be difficult or impossible to obtain. Table E49.2 lists most of *LIMDEP*'s GLMs – some not listed here are documented elsewhere in the manual, though perhaps not specifically identified as GLMs. The table also indicates the subset of the indicated families that are typically analyzed in the formal literature on GLMs. As can be seen, we have extended the class a bit. The third column defines the one 'link function' used in each of these cases. As discussed earlier, typical tabulations in the literature provide a menu of link functions. However, in most cases, only a single link function makes sense in any particular context. Moreover, in actual practical terms, except where they impose a strong inappropriate restrictions on the model – such as using a probability as the conditional mean in a count or regression model – different link functions will produce similar empirical results.

As shown in the top half of Table E49.2, many of the models have already been documented in earlier chapters. All of the models above may be requested with the command

GLIM ; Lhs = ... ; Rhs = ... ; Model = the model name given above $

For those models with command names given in the top half of the table, the command will be the same as if you had used the earlier command. That is, for example, the following two commands are identical:

GLIM ; Lhs = y ; Rhs = x ; Model = Logit $
LOGIT ; Lhs = y ; Rhs = x $

The remaining models may all be invoked with the **GLIM** command. For these ten models (only), the command **GLIM** is also synonymous with **LOGLINEAR**. So, for example, the following two commands are identical:

GLIM ; Lhs = y ; Rhs = x ; Model = Beta $
LOGLINEAR ; Lhs = y ; Rhs = x ; Model = Beta $

In the developments below, the results for the first group of models will only be sketched. The reader is directed to the full, earlier chapters on the subjects. Most of this chapter will relate to the additional models detailed in the lower half of the table – the 'loglinear' models.

Model	**Dependent Variable**	**Conditional Mean**	**Command**
Models developed in preceding chapters			
Probit[b]	Binary	$\Phi(t)$	**PROBIT**
Logit[b]	Binary	$\Lambda(t)$	**LOGIT**
Gompertz[b]	Binary	$\exp(-\exp(-t)$	**GOMPERTZ**
Comp. log log[b]	Binary	$1 - \exp(- \exp(t))$	**LOG**
Arctangent	Binary	$2/\pi$ Arctan(exp(t))	**ARCTANGENT**
Burr	Binary	$\Lambda(t)^{\gamma}$	**BURR**
Poisson[b]	Count	$\exp(t)$	**POISSON**
NB1 Neg. Bin.	Count	$\exp(t)$	**NEGBIN**
NB2 Neg. Bin[b].	Count	$\exp(t)$	**NEGBIN**
NBP Neg. Bin.	Count	$\exp(t)$	**NEGBIN**
Polya-Aeppli	Count	$\exp(t)/(1-\theta)$	**POISSON**
GP, Generalized Poisson	Count	$\exp(t)$	**POISSON**
PGamma, Poisson/Gamma	Count	$\exp(t)/\alpha$ (approx.)	**POISSON**
Linear[b]	Continuous	t	**REGRESS**
Loglinear models developed in this chapter			
Lognormal	Nonnegative	t	**LOGNORMAL**
Binomial[b]	Count of successes	$K\Lambda(t)$	
Geometric[b]	Count until success	$\exp(t)$	
Beta	Bounded in (0,1)	$\exp(t_a)/[\exp(t_a)+\exp(t_b)]$	
Power	Bounded in (0,1)	$[\exp(t)+1]/[\exp(t)+2]$	
Normal (Loglinear)	Continuous	$\exp(t)$	
Gamma	Nonnegative	$P\exp(-t)$	
Weibull	Nonnegative	$[\exp(-t)]^{1/P}\Gamma[(P+1)/P]$	
Exponential[b]	Nonnegative	$\exp(-t)$	
Rayleigh	Nonnegative	$[\pi\exp(-t)/2)]^{1/2}$	
Inverse Gaussian[b]	Nonnegative	$P\exp(-t)$	

[a] In all models, $t = \boldsymbol{\beta}'\mathbf{x}$.
[b] Exponential families typically included in analysis of 'Generalized Linear Models'

Table E49.2 Generalized Linear Models[a]

E49.2.5 Residual Analysis

Many types of 'residuals' are suggested for model assessment of GLMs. Three that have some useful characteristics are the 'Pearson residual,' the 'deviance residual' and Chesher and Irish's generalized residuals. Unfortunately, none of the three are useful for all of the models considered here, though they do come close. The deviance residuals are based on models for which the log likelihood can be written in terms of the conditional mean function. For this computation, the estimated model is compared to one in which y_i is predicted perfectly at every observation. Thus, in computing the log likelihood for the 'saturated' model, we replace the estimator of the conditional mean with the actual value of y_i. Thus, the deviance measures the extent to which the model fails to predict perfectly. The 'deviance residual' is

$$e_{D,i} = \log L_i(y_i) \ - \ \log L_i(\hat{y}_i)$$

where $\hat{y}_i$ is the model prediction of y_i using the estimated parameters to compute the conditional mean function. The 'deviance' for the model is

$$D \ = 2\ \Sigma_i\ d_i \ = \ -2\times [\Sigma_i \log L_i(\hat{y}_i) - \Sigma_i \log L_i(y_i)].$$

Consider two examples. For a binary choice model, the conditional mean is $\hat{P}_i$ based on whatever model is used to estimate the probability model. The model that produces a perfect fit would have $\hat{P}_i = y_i$. Therefore, the deviance residual would be

$$e_{D,i} \ = \ [(1-y_i)\log(1-y_i) + y_i\log y_i] - [(1-y_i)\log(1-\hat{P}_i) + y_i\log\hat{P}_i]$$

(where 0log0 = 0). The first term in square brackets is zero. The model deviance would be

$$D \ = \ -2\ \Sigma_i\ [(1-y_i)\log(1-\hat{P}_i) + y_i\log\hat{P}_i]$$

which is just -2 times the log likelihood for the model. Second, consider a Poisson model, in which $\hat{y}_i = \hat{\lambda}_i$. The deviance residual would be

$$\begin{aligned} e_{D,i} \ &= \ [-y_i + y_i\log y_i - \log\Gamma(y_i+1)] - [-\hat{\lambda}_i + y_i\log\hat{\lambda}_i - \log\Gamma(y_i+1)] \\ &= \ -(y_i - \hat{\lambda}_i) + y_i\log(y_i/\hat{\lambda}_i) \end{aligned}$$

(where as before 0log0 = 0). The deviance for the model is

$$D \ = \ -2\Sigma_i\ [(y_i - \hat{\lambda}_i) - y_i\log(y_i/\hat{\lambda}_i)].$$

These measures are not computed internally for the models. However, they are easily computed using the predictions from the models. Catalogs of formulas for many generalized linear models can be found in the vast literature on GLMs.

Deviance measures of 'fit' compute in the opposite direction from familiar measures of fit. For example, in linear models, the R^2 compares the estimated model to a model that provides no fit. Likewise, the so called 'pseudo R^2' for maximum likelihood estimation, 1 - log$L$/logL_0 compares the estimated model to one which has no coefficients other than a constant term. Again, the intent is to compare the estimated model to one which provides no fit. The deviance measure, in contrast, compares an estimated model to one which predicts the dependent variable perfectly. The scale of the measure is unclear. For example, for a binary choice model, the deviance is simply -2 times the log likelihood. For the Poisson (and other) models, the measure is not a simple function of the log likelihood. Moreover, it should be noted that the model itself, is not estimated in order to predict the dependent variable well with the estimated conditional mean function. For example, for a binary choice model, the maximum score estimator will outperform any MLE. Thus, it remains ambiguous what is being computed by the deviance measures.

The second residual of interest is the 'Pearson residual,'

$$e_{P,i} = \frac{y_i - \hat{y}_i}{\sqrt{V\hat{a}r(y_i)}}$$

In many treatments, the denominator is assumed to be a function of $\hat{y}_i$. We leave it in the more general form to accommodate those cases in which the conditional variance is not a simple function of the conditional mean. These can also be computed easily with the model results. The predictions are all available after estimation with **; Keep = variable name**. To complete the computation, the conditional variances are required. These are given in Table E49.3. These are saved for the models listed in the table when the commands for these models (only) contain

; Pres = variable name

Note that *LIMDEP* supports many variants of these models for which these residuals are not computed (and sometimes not computable). For example, by the various constructions in this chapter, the censored, truncated, zero inflated and hurdle versions of the Poisson and negative binomial models are all GLMs, however, they are not included in the set of models analyzed here.

A third useful quantity in some analyses is Chesher and Irish's (1987) 'generalized residual,' which for the models in which they are useful, can be computed as the derivative of the log likelihood with respect to the constant term. (For the normal linear regression model, it coincides with the Pearson residual above.) The quantity is useful for specification testing in latent regression models based on the normal distribution. Applications appear in Chapter E29 for the probit model and Chapter E47 with the development of the tobit model.

Finally, there are an array of variations on the Pearson and deviance residuals for the GLMs, such as the Anscombe residuals and variations thereon.

Model	Conditional Mean	Conditional Variance
Probit	$\Phi(t) = F$	$F(1 - F)$
Logit	$\Lambda(t) = \lambda/(1+\lambda) = F$	$F(1 - F)$
Gompertz	$\exp(-1/\lambda) = F$	$F(1 - F)$
Comp. log log	$1 - \exp(-\lambda) = F$	$F(1 - F)$
Arctangent	$1/\pi \text{ Arctan}(\lambda)$	$F(1 - F)$
Burr	$\Lambda(t)^{\gamma} = F$	$F(1 - F)$
Poisson	λ	λ
NB1 Neg. Bin.	λ	$\lambda(1 + \lambda)$
NB2 Neg. Bin.	λ	$\lambda(1 + \theta\lambda)$
NBP Neg. Bin.	λ	$\lambda(1 + \theta^{P-1}\lambda)$
Polya-Aeppli	$\lambda/(1-\theta)$	$\lambda(1 + \theta)/(1 - \theta)^2$
GP, Generalized Poisson	λ	$\lambda(1 + \theta\lambda)^2$
PGamma, Poisson/Gamma[b]	λ/α	λ/α^2
Linear	t	σ^2
Lognormal	t	$\sigma^2[t]^2$
Binomial	$K\Lambda(t) = K F$	$K F (1 - F)$
Geometric	λ	$\lambda(1 + \lambda)$
Beta	$\lambda_a/(\lambda_a + \lambda_b)$	$\lambda_a\lambda_b/[(\lambda_a+\lambda_b+1)(\lambda_a+\lambda_b)^2]$
Power	$(\lambda+1)/(\lambda+2)$	$(\lambda+1)/(\lambda+3) - [(\lambda+1)/(\lambda+2)]^2$
Normal (Loglinear)	λ	σ^2
Gamma	P/λ	P/λ^2
Weibull	$(1/\lambda)^{1/P}\Gamma[(P+1)/P)]$	$(1/\lambda)^{2/P}\{\Gamma[(P+2)/P)] - \Gamma^2[(P+1)/P]\}$
Exponential	$1/\lambda$	$1/\lambda^2$
Rayleigh	$[\pi/(2\lambda)]^{1/2}$	$(4 - \pi)/(2\lambda)$
Inverse Gaussian	P/λ	P/λ^3

[a] In all results given, $t = \boldsymbol{\beta}'\mathbf{x}$ and $\lambda = \exp(t) = \exp(\boldsymbol{\beta}'\mathbf{x})$.
[b] Mean and variance for the gamma count model are approximate based on increasing event window. See Winkelmann (2003, p. 55).

Table E49.3 Means and Variances of Variables in Generalized Linear Models[a]

E49.2.6 Standard Model Specifications for the Loglinear Regression Models

This is the full list of general specifications that are applicable to this group of model estimators.

Controlling Output from Model Commands

; Par	keeps ancillary parameter p in main results vector b.
; Margin	displays marginal effects.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Cluster = spec requests computation of the cluster form of corrected covariance estimator. (**; Stratum = specification** for stratified clustered data).
; Robust requests a 'sandwich' estimator or robust covariance matrix for TSCS and several discrete choice models.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E49.2.7 Estimated Results for Loglinear Models

As noted earlier, the models in the top half of Table E49.2 are documented extensively in earlier chapters. For those in the bottom half, which are the main subject of this chapter, the following are the estimated results:

Matrices: *b* = estimates of β, or
b = estimates of α followed by β for the beta model
varb = estimated asymptotic covariance matrix for MLE of *b*

Scalars: *logl* = log likelihood
kreg = number of variables in Rhs
nreg = number of observations
pgamma = P for the gamma model
pweibull = P for the Weibull model
pinverse = P for the inverse Gaussian model
s = σ for the normal (exponential regression) model, or
s = σ for the lognormal regression model
exitcode

Last Model: for the **WALD** command using *b_name* for the parts of *b*

Last Function: conditional mean function

E49.3 Discrete Dependent Variable Models

Four types of discrete dependent variables are supported in the GLM group, binary, count, count of successes (binomial) and number of trials until first success (geometric). The fourth of these does not naturally describe a count outcome, but as shown in the application below, purely from the standpoint of a functional form, it might be preferable to the Poisson model.

E49.3.1 Binary Dependent Variables

Six parametric model formulations are provided as internal procedures in *LIMDEP* for binary choice models. The probability models and loglinear forms are shown in Table E49.4.

Model	Probability for $Y = 1$	Loglinear Form*
Probit	$F = \int_{-\infty}^{\boldsymbol{\beta}'\mathbf{x}_i} \frac{\exp(-t^2/2)}{\sqrt{2\pi}}dt = \Phi(\boldsymbol{\beta}'\mathbf{x}_i)$	$F = \Phi(\log\lambda_i)$
Logit	$F = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)} = \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)$	$F = \lambda_i / (1 + \lambda_i)$
Comp. log log	$F = 1 - \exp(-\exp(\boldsymbol{\beta}'\mathbf{x}_i)) = C(\boldsymbol{\beta}'\mathbf{x}_i)$	$F = 1 - \exp(-\lambda_i)$
Gompertz	$F = \exp(-\exp(-\boldsymbol{\beta}'\mathbf{x}_i)) = G(\boldsymbol{\beta}'\mathbf{x}_i)$	$F = \exp(-1/\lambda_i)$
Arctangent	$F = 2/\pi \text{ Arctan}(\exp((\boldsymbol{\beta}'\mathbf{x}_i))$	$F = 2/\pi \tan^{-1}(\lambda)$
Burr	$F = \left[\frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)}\right]^\gamma = [\Lambda(\boldsymbol{\beta}'\mathbf{x}_i)]^\gamma, \gamma > 0$	$F = [\lambda_i / (1 + \lambda_i)]^\gamma$.

* $\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$

Table E49.4 Binary Choice Models

These may be invoked with the command

GLIM ; Lhs = dependent variable
; Rhs = independent variables
; Model = Probit, Logit, Comploglog, Gompertz, Arctangent or Burr $

The **GLIM** command is a synonym for the respective commands for each of these, **PROBIT**, **LOGIT**, **COMPLOGLOG**, **GOMPERTZ, ARCTANGENT** and **BURR**. The **GLIM** command does not change the model request; it is merely an equivalent form. The binary choice models are documented in Chapter E27 for cross section and pooled data, and in Chapters E30 and E31 for the various panel data estimators.

E49.3.2 Count Variables

Chapters E41-E44 document a wide variety of models for counts. The basic platform is the Poisson model,

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\exp(-\lambda_i)\lambda_i^{y_i}}{y_i!},\ y_i = 0,1,...;\ \lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i).$$

The crucial feature of the Poisson model is its equidispersion property,

$$\text{Var}[y_i|\lambda_i] = E[y_i|\lambda_i] = \lambda_i.$$

Many variations have been developed to relax the equidispersion assumption. The most popular is the negative binomial model (NB2), which has density

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta + y_i)}{\Gamma(\theta)\Gamma(y_i+1)} u_i^{\theta}(1-u_i)^{y_i}$$

where $\theta = 1/\alpha$

and $u_i = \theta / (\theta + \lambda_i)$.

In the negative binomial (NB2) model,

$$\text{Var}[y_i|\lambda_i] = E[y_i|\lambda_i]\{1 + \alpha\, E[y_i|\lambda_i]\}.$$

There are a variety of other forms for the negative binomial model, based on the relationship

$$\text{Var}[y_i|\lambda_i] = E[y_i|\lambda_i]\{1+ \alpha^{P\text{-}1} E[y_i|\lambda_i]\}.$$

The NB2 model above has $P = 2$. The NB1 model, with $P = 1$, has density

$$\text{Prob}(Y = y_i|\mathbf{x}_i) = \frac{\Gamma(\theta\lambda_i + y_i)}{\Gamma(\theta\lambda_i)\Gamma(y_i+1)} w^{\theta\lambda_i}(1-w\ )^{y_i}$$

where $w = \theta / (\theta + 1)$.

The general form of the model is the NBP form, which has density

$$\text{Prob}(Y = y_i|\mathbf{x}_i) \quad = \quad \frac{\Gamma(\theta\lambda_i^Q + y_i)}{\Gamma(\theta\lambda_i^Q)\Gamma(y_i+1)}\left(\frac{\theta\lambda_i^Q}{\theta\lambda_i^Q+\lambda_i}\right)^{\theta\lambda_i^Q}\left(\frac{\lambda}{\theta\lambda_i^Q+\lambda_i}\right)^{y_i}$$

where $Q = P - 2$.

Several other model forms for counts are supported. The gamma (based) probability model is

$$\text{Prob}[y_i = j] \quad = \quad G(\alpha j, \lambda_i) - G(\alpha j + \alpha, \lambda_i)$$

where $\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$ (as usual)

and $G(\alpha j, \lambda_i) = 1$ if $j = 0$, or $\dfrac{1}{\Gamma(\alpha j)}\int_0^{\lambda_i} u^{\alpha j-1}e^{-u}du$ if $j > 0, j = 1,...$

The dispersion parameter is α; there is underdispersion if $\alpha > 1$, overdispersion if $\alpha < 1$, and equidispersion if $\alpha = 1$, which reduces the gamma probability to the Poisson model. The gamma distributed count variable may be underdispersed or overdispersed. Underdispersion is usually of lesser interest.

The generalized Poisson model is another that has overdispersion. The density for the generalized Poisson model is

$$\text{Prob}[Y = y_i \mid \mathbf{x}_i] = \left(\frac{\lambda_i}{1+\theta\lambda_i}\right)^{y_i}\frac{(1+\theta y_i)}{y_i!}\exp\left(-\frac{\lambda_i(1+\theta y_i)}{1+\theta\lambda_i}\right), y_i = 0,1,2,...;\ \lambda_i = e^{\boldsymbol{\beta}'\mathbf{x}_i}.$$

The mean and variance of this random variable are

$$E[y_i \mid \mathbf{x}_i] = \lambda_i,\ \text{Var}[y_i \mid \mathbf{x}_i] = \lambda_i(1+\theta\lambda_i)^2.$$

Finally, the density for the Polya-Aeppli form of the Poisson model is

$$\text{Prob}[Y = 0 \mid \mathbf{x}_i] = \exp(-\lambda_i),$$

$$\text{Prob}[Y = y_i \mid \mathbf{x}_i] = \exp(-\lambda_i)(1-\theta)^{y_i}\sum_{j=1}^{y_i}\binom{y_i-1}{j-1}\frac{[\lambda_i(1-\theta)/\theta]^j}{j!}, y_i = 1,2,...$$

$$\lambda_i = e^{\boldsymbol{\beta}'\mathbf{x}_i}$$

$$0 < \theta < 1.$$

The mean and variance of this random variable are

$$E[y_i \mid \mathbf{x}_i] = \frac{\lambda_i}{(1-\theta)} \text{ and } \text{Var}[y_i \mid \mathbf{x}_i] = \frac{\lambda_i(1+\theta)}{(1-\theta)^2} = E[y_i \mid \mathbf{x}_i]\frac{(1+\theta)}{(1-\theta)}.$$

All of these models are requested with the command

POISSON ; Lhs = … ; Rhs = … ; Model = NegBin, NB1, NB2, Polya, etc. $

E49.3.3 Number of Successes in *K* Trials – The Binomial Regression Model

The binomial regression model describes the number of success in *K* trials. The model is supported for both cross section and panel data applications. The discrete probability model is

$$\text{Prob}(Y = y_i \mid K_i, \mathbf{x}_i) = \binom{K_i}{y_i} \theta_i^{y_i} (1-\theta_i)^{K_i - y_i},\ y_i = 0,1,\ldots,K_i$$

$$\theta_i = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)} = \frac{\lambda_i}{1+\lambda_i}, 0 < \theta_i < 1.$$

The success probability on any single trial is θ_i. The number of trials may differ at every observation, or may be constant. The conditional mean function is

$$E[y_i|K_i,\mathbf{x}_i] = K_i\theta_i,$$

so the vector of marginal effects is

$$\boldsymbol{\delta}_i = \partial E[y_i|K_i,\mathbf{x}_i]/\partial \mathbf{x}_i = K_i\theta_i (1-\theta_i)\boldsymbol{\beta}.$$

These can be averaged over observations or computed at the sample means, as usual. The command for this model is

```
LOGLINEAR ; Lhs = y ; Rhs = …
          ; Model = Binomial
          ; Trials = specification
          ; ... other options $
```

The **; Trials** definition is the same as a panel data declaration. If the number is constant, then that number is given. If the number is variable, then the name of the variable is provided instead.

A Zero Inflated Binomial Model

An extension to the binomial regression model that allows the zero probability to be inflated would be

$$\text{Prob}(Y = 0 \mid K_i, \mathbf{x}_i) = (1-\Lambda_i) + \Lambda_i \binom{K_i}{0} \theta_i^{0} (1-\theta_i)^{K_i - 0}$$

$$= (1-\Lambda_i) + \Lambda_i (1-\theta_i)^{K_i}$$

$$\text{Prob}(Y = y_i \mid K_i, \mathbf{x}_i) = \Lambda_i \binom{K_i}{y_i} \theta_i^{y_i} (1-\theta_i)^{K_i - y_i},\ y_i = 1,\ldots,K_i$$

$$\theta_i = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)} = \frac{\lambda_i}{1+\lambda_i}, 0 < \theta_i < 1$$

$$\Lambda_i = \frac{\exp(\boldsymbol{\gamma}'\mathbf{z}_i)}{1+\exp(\boldsymbol{\gamma}'\mathbf{z}_i)} = \frac{\phi_i}{1+\phi_i}, 0 < \Lambda_i < 1$$

This formulation shifts some of the mass to the zero outcome. This is a counterpart to the 'zero inflated Poisson model' presented in Chapter E43. The 'regime' probability, Λ_i, is taken to be a logit model. It may involve covariates $\mathbf{z}_i$ or it may be a constant. This model is requested with

LOGLINEAR ; Lhs = y
; Rhs = …
; Model = Binomial
; Trials = specification
; ZIB = list of variables in z
; ... other options $

If the zero inflation probability is to be a constant, then use **; ZIB = one**.

Marginal effects in this model are exerted by the variables in both parts of the probability. The conditional mean is

$$E[y_i|K_i,\mathbf{x}_i] = \Lambda_i K_i \theta_i,$$

so the marginal effects, assuming that variables in $\mathbf{x}_i$ might also appear in $\mathbf{z}_i$, are

$$\boldsymbol{\delta}_i = \partial E[y_i|K_i,\mathbf{x}_i]/\partial \mathbf{x}_i = \Lambda_i K_i \theta_i (1-\theta_i)\boldsymbol{\beta} + \Lambda_i(1-\Lambda_i)K_i\theta_i\boldsymbol{\gamma}.$$

Variables which appear in both $\mathbf{x}_i$ and $\mathbf{z}_i$ exert both terms; those only in $\mathbf{x}_i$, the first, and those only in $\mathbf{z}_i$, only the second.

Technical Details

The log likelihood for the binomial regression model is

$$\log L = \sum_{i=1}^{N} \log \frac{\Gamma(K_i+1)}{\Gamma(y_i+1)\Gamma(K_i-y_i+1)} + y_i \log\theta_i + (K_i - y_i)\log(1-\theta_i)$$

The derivatives of the log likelihood are

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{N} \left(\frac{y_i}{\theta_i} - \frac{K_i - y_i}{1-\theta_i}\right)\frac{\partial\theta_i}{\partial\boldsymbol{\beta}}$$

The necessary derivative is $\partial\theta_i/\partial\boldsymbol{\beta} = \theta_i(1-\theta_i)\mathbf{x}_i$. Collecting terms, then

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{N} \left(\frac{y_i}{\theta_i} - \frac{K_i - y_i}{1-\theta_i}\right)\theta_i(1-\theta_i)\mathbf{x}_i$$
$$= \sum_{i=1}^{N} \left(y_i(1-\theta_i) - (K_i - y_i)\theta_i\right)\mathbf{x}_i$$

The second derivatives are obtained by using the earlier result and collecting terms;

$$\frac{\partial^2 \log L}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'} = \sum_{i=1}^{N} \; -K_i \theta_i (1-\theta_i) \mathbf{x}_i \mathbf{x}_i'$$

The same result can be used to obtain the derivatives for the computation of the covariance matrix of the marginal effects. The necessary term is

$$\mathbf{G}_i = \partial \boldsymbol{\delta}_i / \partial \boldsymbol{\beta}' = K_i \theta_i (1-\theta_i)(1 - 2\theta_i) \boldsymbol{\beta} \mathbf{x}_i'.$$

For the zero inflated model,

$$\log L = \sum_{y_i=0} \log\left[(1-\Lambda_i) + \Lambda_i (1-\theta_i)^{K_i}\right]$$
$$+\sum_{y_i>0} \; \log \Lambda_i + \log \frac{\Gamma(K_i+1)}{\Gamma(y_i+1)\Gamma(K_i - y_i + 1)} + y_i \log \theta_i + (K_i - y_i) \log(1-\theta_i)$$

For convenience, call the bracketed term in the first part P_0. Then,

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{y_i=0} \; \left[\frac{-\Lambda_i (1-\theta_i)^{K_i} \theta_i K_i}{P_0}\right] \mathbf{x}_i + \sum_{y_i>0} \; \left[y_i(1-\theta_i) - (K_i - y_i)\theta_i\right] \mathbf{x}_i$$

$$\frac{\partial \log L}{\partial \boldsymbol{\gamma}} = \sum_{y_i=0} \; \left[\frac{\Lambda_i (1-\Lambda_i)\left[(1-\theta_i)^{K_i} - 1\right]}{P_0}\right] \mathbf{z}_i + \sum_{y_i>0} \; (1-\Lambda_i) \mathbf{z}_i$$

The Jacobian for the marginal effects is tedious, but derivable based on earlier results.

Application

To illustrate the binomial regression model estimator, we will simulate a data set that satisfies the assumptions of the model. We begin with the regressors, a continuously (normally) distributed variable and a binary (dummy) variable. The 'regression' model is

$$\lambda_i = \exp(-.5 + 1x_{1i} + 1x_{2i}).$$

The success probabilities are generated as logistic probabilities, $\theta_i = \Lambda(\boldsymbol{\beta}'\mathbf{x}_i)$. We then generate the number of trials, K_i, for each individual, using a random draw from the integers 3, 4, 5 and 6. With the number of trials and the success probabilities in hand, we use the built in random number generators to obtain a sample from the observation specific binomial distribution. The last three commands estimate the model, then use a Lagrange multiplier test to test for the joint significance of the two regressors. (The model with only a constant term converges without iterating, because the starting values for the iterations are the MLEs for a model with only a constant term. These results are omitted below.)

The commands are:

```
CALC    ; Ran(12345) $
CREATE  ; x1 = Rnn(0,1) ; x2 = Rnu(0,1)>.5 $
CREATE  ; bx = -.5 + x1 + x2 $
CREATE  ; thetai = Lgp(bx) $
CREATE  ; ki = Rnd(4)+2 $
CREATE  ; y = Rnb(ki,thetai) $
GLIM    ; Lhs = y ; Rhs = one,x1,x2 ; Model = Binomial ; Trials = ki $
GLIM    ; Lhs = y ; Rhs = one ; Model = Binomial ; Trials = ki $
GLIM    ; Lhs = y ; Rhs = one,x1,x2 ; Model = Binomial ; Trials = ki
        ; Start = b,0,0  ; Maxit = 0 $
```

Based on the LM statistic, the hypothesis that the two coefficients are zero is rejected. This might have been expected, given the 't statistics' shown with the first set of results.

E49.3.4 Number of Trials Until Success – The Geometric Regression Model

This model is suitable for a discrete random variable whose values decay geometrically. For example, using the health care data analyzed earlier, the following histogram shows the pattern of the dependent variable, number of doctor visits. Though these data are appropriately modeled using a count model such as the Poisson, the pattern in the histogram is that of a variable that is generated by one with a geometric distribution.

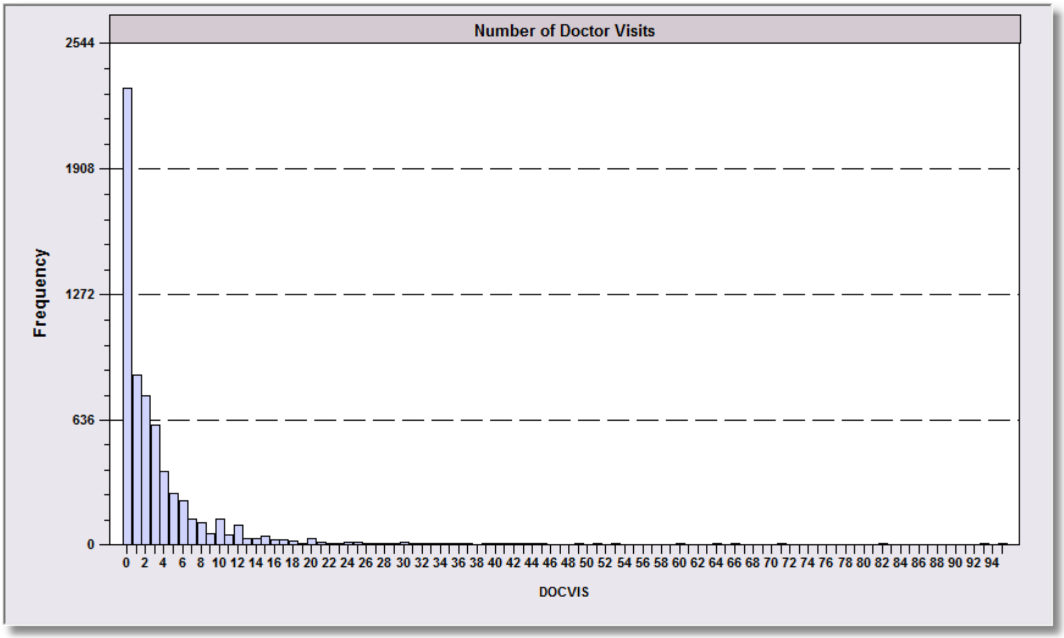

Figure E49.3 Histogram for Doctor Visits

The geometric regression model characterizes a sequences of Bernoulli trials in which the random variable y is the number of failures that occur until the first success occurs. The density is

$$f(y) = \theta(1-\theta)^y$$

where θ is the assumed constant probability of success on each trial. We parameterize the model for regression analysis with

$$\theta_i = \frac{1}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)} = \frac{1}{1+\lambda_i}.$$

Then $\text{Prob}(Y = y_i) = \lambda_i^{y_i}(1+\lambda_i)^{-(1+y_i)},\ y_i = 0,1,..$

This variable has $E[y_i|\mathbf{x}_i] = \lambda_i$ and $Var[y_i|\mathbf{x}_i] = \lambda_i(1 + \lambda_i)$.

In this model, the conditional mean function is λ_i, so the marginal effects are $\boldsymbol{\delta}_i = \lambda_i\boldsymbol{\beta}$.

The model is requested with

LOGLINEAR ; Lhs = y
; Rhs = variables in x
; Model = Geometric $

Marginal effects, fitted values, restrictions, the cluster estimator, robust covariance matrices, residuals, etc. for all other program features operate as usual.

In the application below, the geometric and Poisson regression models are found to give similar results for the panel of data on hospital visits. However, the Vuong test based on the likelihood functions seems strongly to favor the geometric model.

Technical Details

The log likelihood function is

$$\log L = \sum_{i=1}^{N} y_i \log \lambda_i - (y_i + 1)\log(1+\lambda_i)$$

The derivatives are

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{N} \left[y_i - \frac{\lambda_i (y_i+1)}{(1+\lambda_i)} \right] \mathbf{x}_i = \sum_{i=1}^{N} \left[y_i - (y_i+1)(1-\theta_i) \right] \mathbf{x}_i$$

and

$$\frac{\partial^2 \log L}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'} = \sum_{i=1}^{N} -\left[(y_i+1)\theta_i (1-\theta_i) \right] \mathbf{x}_i \mathbf{x}_i' .$$

Since $E[y_i|\mathbf{x}_i] = \lambda_i$, the partial effects are $\lambda_i \boldsymbol{\beta}$ and the Jacobian is $\mathbf{G}_i = \lambda_i[\mathbf{I} + \boldsymbol{\beta}\mathbf{x}_i']$.

E50: Generalized Linear Models – 2: Continuous

E50.1 Introduction

This chapter presents a group of ‘generalized linear models’ (GLMs) that can be used for dependent variables whose range is generally restricted, either because they are discrete (such as a binary variable) or because they naturally vary over only a restricted range (such as variables that are only nonnegative). The class of generalized linear models was defined in the pioneering works of Nelder and Wedderburn (1972) and McCullagh and Nelder (1983). As shown below, many of these are models that *LIMDEP* fits under a different heading, but it is convenient to group them here. Formally, as defined in the recent literature, the class of models is a group in which the conditional mean function is of the form $E[y|\mathbf{x}] = h(\boldsymbol{\beta}'\mathbf{x})$ for some continuous function $h(.)$. (McCullagh and Nelder and others since have focused on ‘exponential families,’ but we take some license here, and broaden their class.) This class includes all of the single index function models already considered, such as the binary choice models, censored regression, truncated regression, and all of the count models considered in Chapters E24-E26. This chapter will present a group of models not already considered and also organize several from earlier chapters for the convenience of the user interested in this class of models.

The basic command for estimation of the models described in this chapter is

GLIM ; Lhs = dependent variable
; Rhs = independent variables
; Model = type of model $

where ‘**type of model**’ is one of the generalized linear models presented here.

E50.2 Generalized Linear Models for Continuous Variables

As noted earlier, many of the single index function models described in the preceding chapters fall under the definition of GLMs in that the conditional mean function is a function of the linear index. However, in some of these cases, such as the censored regression, the inverse transformation to the index will be difficult to obtain. Table E50.1 lists most of *LIMDEP*’s GLMs – some not listed here are documented elsewhere in the manual, though perhaps not specifically identified as GLMs. The table also indicates the subset of the indicated families that are typically analyzed in the formal literature on GLMs. As can be seen, we have extended the class a bit. The third column defines the one ‘link function’ used in each of these cases. As discussed earlier, typical tabulations in the literature provide a menu of link functions. However, in most cases, only a single link function makes sense in any particular context. Moreover, in actual practical terms, except where they impose a strong inappropriate restrictions on the model – such as using a probability as the conditional mean in a count or regression model – different link functions will produce similar empirical results.

As many of the models have already been documented in earlier chapters. All of the models may be requested with the command

GLIM ; Lhs = ... ; Rhs = ... ; Model = the model name given above $

The models may all be invoked with the **GLIM** command. For the models documented in this chapter, the command **GLIM** is also synonymous with **LOGLINEAR**. So, for example, the following two commands are identical:

GLIM ; Lhs = y ; Rhs = x ; Model = Beta $
LOGLINEAR ; Lhs = y ; Rhs = x ; Model = Beta $

Tables E50.1 and E50.2 list the loglinear models for continuous data described in this chapter.

Model	Dependent Variable	Conditional Mean	Command
Beta	Bounded in (0,1)	$\exp(t_a)/[\exp(t_a)+\exp(t_b)]$	
Power	Bounded in (0,1)	$[\exp(t)+1]/[\exp(t)+2]$	
Normal (Loglinear)	Continuous	$\exp(t)$	
Gamma	Nonnegative	$P\exp(-t)$	
Weibull	Nonnegative	$[\exp(-t)]^{1/P}\Gamma[(P+1)/P]$	
Exponential[b]	Nonnegative	$\exp(-t)$	
Rayleigh	Nonnegative	$[\pi\exp(-t)/2)]^{1/2}$	
Inverse Gaussian[b]	Nonnegative	$P\exp(-t)$	

[a] In all models, $t = \boldsymbol{\beta}'\mathbf{x}$.
[b] Exponential families typically included in analysis of 'Generalized Linear Models'

Table E50.1 Generalized Linear Models[a]

Model	Conditional Mean	Conditional Variance
Beta	$\lambda_a/(\lambda_a + \lambda_b)$	$\lambda_a\lambda_b/[(\lambda_a+\lambda_b+1)(\lambda_a+\lambda_b)^2]$
Power	$(\lambda+1)/(\lambda+2)$	$(\lambda+1)/(\lambda+3) - [(\lambda+1)/(\lambda+2)]^2$
Normal (Loglinear)	λ	σ^2
Gamma	P/λ	P/λ^2
Weibull	$(1/\lambda)^{1/P}\Gamma[(P+1)/P)]$	$(1/\lambda)^{2/P}\{\Gamma[(P+2)/P)] - \Gamma^2[(P+1)/P]\}$
Exponential	$1/\lambda$	$1/\lambda^2$
Rayleigh	$[\pi/(2\lambda)]^{1/2}$	$(4 - \pi)/(2\lambda)$
Inverse Gaussian	P/λ	P/λ^3

[a] In all results given, $t = \boldsymbol{\beta}'\mathbf{x}$ and $\lambda = \exp(t) = \exp(\boldsymbol{\beta}'\mathbf{x})$.
[b] Mean and variance for the gamma count model are approximate based on increasing event window. See Winkelmann (2003, p. 55).

Table E50.2 Means and Variances of Variables in Generalized Linear Models[a]

E50.2.1 Standard Model Specifications for the Loglinear Regression Models

This is the full list of general specifications that are applicable to this group of model estimators.

Controlling Output from Model Commands

; Par keeps ancillary parameter *p* in main results vector *b*.
; Margin displays marginal effects.
; OLS displays least squares starting values when (and if) they are computed.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Cluster = spec requests computation of the cluster form of corrected covariance estimator. (**; Stratum = specification** for stratified clustered data).
; Robust requests a ‘sandwich’ estimator or robust covariance matrix for TSCS and several discrete choice models.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level ‘**n**’ is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E50.2.2 Estimated Results for Loglinear Models

The following are the estimated results for the models in Table E50.1:

Matrices:	*b*	= estimates of $\boldsymbol{\beta}$, or
	b	= estimates of $\boldsymbol{\alpha}$ followed by $\boldsymbol{\beta}$ for the beta model
	varb	= estimated asymptotic covariance matrix for MLE of *b*
Scalars:	*logl*	= log likelihood
	kreg	= number of variables in Rhs
	nreg	= number of observations
	pgamma	= *P* for the gamma model
	pweibull	= *P* for the Weibull model
	pinverse	= *P* for the inverse Gaussian model
	s	= σ for the normal (exponential regression) model, or
	s	= σ for the lognormal regression model
	exitcode	

Last Model: For the **WALD** command using *b_name* for the parts of *b*

Last Function: Conditional mean function

E50.3 Variables with Unrestricted Range

The simplest form of generalized linear model is the linear regression,

$$\begin{aligned} y_i &= \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i \\ &= \log(\lambda_i) + \varepsilon_i,\ \varepsilon_i \sim N[0,\sigma^2]. \end{aligned}$$

The linear regression model is discussed in detail in Chapters E7 and E8 and in a variety of specifications. One extension might be to use distributions other than the normal for the distribution family. While this does not represent an extension of the model, there are several ways one might proceed. First, least squares in this model is robust to distributional assumptions, so in some sense, the point of the distribution is moot. The Gauss Markov assumptions are met, so without a specific distributional alternative, least squares with a robust covariance matrix would be the estimator of choice. Alternatively, one might want to use a semiparametric method, such as least absolute deviations. Finally, one might be interested in using a specific alternative distribution. The **MAXIMIZE** command can be used to construct the particular maximum likelihood estimator. Alternatively, by treating y_i as if it were the log of a survival time, one can use one of the parametric survival models described in Chapter E60. A variety of panel data treatments for the linear model are presented in Chapter E51.

An alternative form of the normal regression model that remains in the loglinear class of models considered here is

$$\begin{aligned} y_i &= \exp(\boldsymbol{\beta}'\mathbf{x}_i) + \varepsilon_i \\ &= \lambda_i + \varepsilon_i,\ \varepsilon_i \sim N[0,\sigma^2]. \end{aligned}$$

This is a nonlinear regression model that can be fit by nonlinear least squares, using **NLSQ**. The commands could be

NAMELIST ; x = ... the list of variables $
CALC ; k = Col(x) $
NLSQ ; Lhs = y ; Fcn = Exp(b1'x) ; Labels = k_b ; Start = k_0 $

This nonlinear regression may also be fit as a loglinear model with the command

LOGLINEAR ; Lhs = dependent variable
; Rhs = independent variables
; Model = Normal $

All other options described in this chapter for the loglinear models may be used as well. This model is fit by maximum likelihood, which for the normal distribution is nonlinear least squares. If you use **NLSQ**, the estimator will use the Gauss-Marquardt method. The BFGS algorithm is used here, instead.

Of course, you can use a different functional form in **NLSQ**, and the exponential does not have any particularly attractive features. Moreover, perhaps less noted than it might be, one tends to get similar answers for the different functional forms when marginal effects are compared. For the linear model, $\boldsymbol{\beta}$ gives the partial effects. In the loglinear form, $\lambda_i\boldsymbol{\beta}$ gives the marginal effects. The example below compares these for a model of household income using the German health care data.

NAMELIST ; x = one,age,educ,female,married,hhkids $
REGRESS ; Lhs = hhninc ; Rhs = x $
LOGLINEAR ; Lhs = hhninc ; Rhs = x ; Partial Effects ; Model = Normal $

E50.4 Nonnegative Random Variables

This section presents estimators for five models for nonnegative variables, the exponential, gamma, Weibull, Rayleigh and inverse Gaussian. A sixth, the lognormal regression, is considered in the next section. In all of these loglinear models, we parameterize the regression using $\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$.

E50.4.1 Exponential Regression Model

The exponential model is a single index model with density

$$f(y_i) \;=\; \lambda_i \exp(-\lambda_i y_i)\,,\; y_i \geq 0,$$

$$\lambda_i \;=\; \exp(\boldsymbol{\beta}'\mathbf{x}_i)$$

The regression function has

$$E[y_i \mid \mathbf{x}_i] \;=\; 1/\lambda_i \text{ and } \mathrm{Var}[y_i \mid \mathbf{x}_i] \;=\; 1/\lambda_i^2$$

so the slopes of conditional mean are

$$\boldsymbol{\delta}_i \;=\; -\partial \mathrm{E}[y_i|\mathbf{x}_i]/\partial \mathbf{x}_i \;=\; -\lambda_i\,\beta.$$

(Note that the slopes have the opposite signs from the coefficients.) The exponential model forms the most basic (restrictive) model in the group considered here.

E50.4.2 Gamma Regression Model

The gamma and Weibull models both extend the exponential model by allowing a shape parameter to change the model form. The gamma model is

$$f(y_i) = \frac{\lambda_i^P}{\Gamma(P)}\exp(-\lambda_i y_i) y_i^{P-1},\ y_i \geq 0,$$

with conditional mean and variance functions

$$\mathrm{E}[y_i \mid \mathbf{x}_i] = \mathrm{P}/\lambda_i \text{ and } \mathrm{Var}[y_i \mid \mathbf{x}_i] = \mathrm{P}/\lambda_i^2.$$

The vector of slopes is

$$\boldsymbol{\delta}_i = -(\mathrm{P}/\lambda_i)\,\boldsymbol{\beta} = -\,\mathrm{E}[y_i \mid \mathbf{x}_i]\boldsymbol{\beta}.$$

The exponential model results from the gamma model if $P = 1$.

E50.4.3 Weibull Regression Model

The Weibull model is similar to the gamma. The density is

$$f(y_i) = P\lambda_i y_i^{P-1}\exp(-\lambda_i y_i^P),\ y_i \geq 0.$$

The conditional mean is found by integrating this form of the gamma function to obtain

$$\mathrm{E}[y_i \mid \mathbf{x}_i] = \left(\frac{1}{\lambda_i}\right)\Gamma\left(\frac{P+1}{P}\right)$$

and variance

$$\mathrm{Var}[y_i \mid \mathbf{x}_i] = \left(\frac{1}{\lambda_i}\right)^2\left[\Gamma\left(\frac{P+2}{P}\right)-\Gamma^2\left(\frac{P+1}{P}\right)\right]$$

which produces slope vector

$$\boldsymbol{\delta}_i = -\mathrm{E}[y_i \mid \mathbf{x}_i]\boldsymbol{\beta}.$$

Once again, the exponential model is the special case with $P = 1$.

E50.4.4 Rayleigh Regression Model

The Rayleigh distribution applies to a variable that is the square root of twice an exponential variable (i.e., a simple transformation). The density (parameterized to be consistent with our general formulation) is

$$f(y_i) = \lambda_i y_i \exp\left(-\tfrac{1}{2}\lambda_i y_i^2\right), y_i > 0,\ \lambda_i > 0.$$

Precisely, in this form, the variable $z_i = y_i^2/2$ has an exponential density with parameter λ_i. (That is how the model is estimated – we simply transform your Lhs variable during the iterations and use the simpler exponential density to form the likelihood function to estimate the parameters.) The conditional mean and variance functions are

$$E[y_i \mid \mathbf{x}_i] = \sqrt{\frac{\pi}{2\lambda_i}} \text{ and } \mathrm{Var}[y_i \mid \mathbf{x}_i] = \frac{4-\pi}{2\lambda_i}$$

The vector of partial effects is

$$\boldsymbol{\delta}_i = \left[-\left(\frac{1}{2}\sqrt{\frac{\pi}{2}}\right)\frac{1}{\sqrt{\lambda_i}}\right]\boldsymbol{\beta} = -(1/2)\mathrm{E}[y_i \mid \mathbf{x}_i]\boldsymbol{\beta}.$$

The Rayleigh form is a substantial extension of the model, since it has the shapes of the gamma function depending on the value of λ_i.

E50.4.5 Inverse Gaussian Regression Model

The inverse Gaussian model appears in survival modeling and other types of reliability analysis. The standard functional form, where for the present, we omit the covariates is

$$f(y_i) = \left[\frac{\alpha}{2\pi y_i^3}\right]^{1/2} \exp\left[\frac{-\alpha(y_i-\mu)^2}{2\mu^2 y_i}\right], y_i > 0,\ \mu > 0,\ \lambda > 0.$$

In this formulation, $\mathrm{E}[y_i] = \mu$. In order to estimate the parameters of the model, we reparameterize it using

$$P = \sqrt{\alpha}$$

and

$$\lambda = \frac{\sqrt{\alpha}}{\mu}$$

(This is a slight departure from standard references which often replace α with λ in the original form. This is done here to maintain consistency with the other models presented in this section.) The density is now

$$f(y_i) \quad = \quad \frac{P}{\sqrt{2\pi y_i^3}} \exp\left[-\frac{1}{2}\frac{(\lambda_i y_i - P)^2}{y_i}\right], \; y_i > 0, P > 0, \lambda > 0.$$

and the mean is **P**/λ. Finally, to introduce the individual heterogeneity in the parameters, we write

$$\lambda_i \quad = \quad \exp(\boldsymbol{\beta}'\mathbf{x}_i)$$

which produces the conditional density just by substitution, while

$$E[y_i|\mathbf{x}_i] = P/\lambda_i. \text{ and } Var[y_i|\mathbf{x}_i] = P/\lambda_i^3$$

The slopes of the conditional mean are

$$\boldsymbol{\delta}_i \quad = \quad (-P/\lambda_i)\boldsymbol{\beta} = -E[y_i|\mathbf{x}_i]\,\boldsymbol{\beta}.$$

E50.4.6 Comparison of Loglinear Models

The first four functional forms differ partly through the shape parameter, P (which equals 1 for the exponential model, which is this special case of the other functions.) The precise shapes of the gamma and Weibull depends on P and whether P is larger than or smaller than 1. The Rayleigh, however, is strictly a function of the exponential, as it does not have a separate shape parameter. The figure below shows the three densities for $\lambda = 1$ and $P = 1.5$.

```
SAMPLE    ; 1-401 $
CREATE    ; y = Trn(0,.01) $

          ; Vaxis = Density ; Fill ; Grid $
```

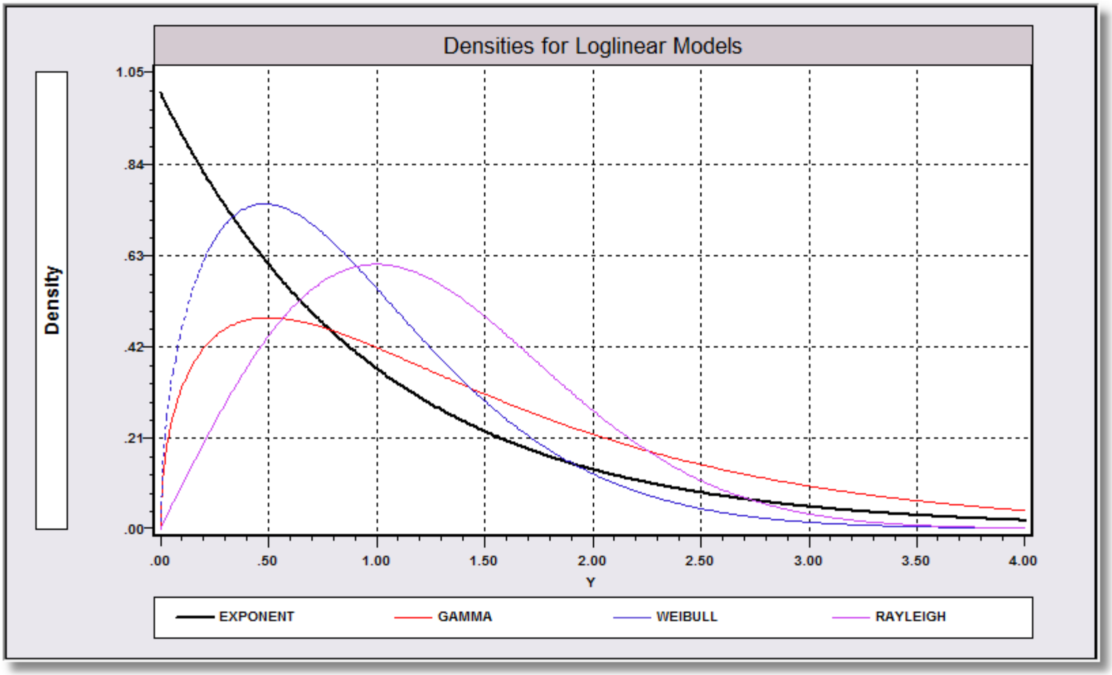

Figure E50.1 Densities for Loglinear Models

E50.4.7 Commands

The estimator is maximum likelihood in all cases. To request these models, use

```
LOGLINEAR ; Lhs = dependent variable (must be nonnegative)
          ; Rhs = one list of independent variables
          ; Model = Rayleigh, Exponential, Gamma, Weibull
                    or Inverse Gaussian $
```

E50.4.8 Applications

To illustrate the different estimators, we have used two of the five distributions to fit a loglinear model to the distribution of incomes. The partial effects at the means and averaged over the sample observations are shown with each model.

```

E50.5 Technical Details for the Loglinear Models

All five models are parameterized in terms of

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i).$$

The five densities, gradients of the log densities, and Hessians of the log densities are as follows:

E50.5.1 Exponential

For the exponential model,

$$f(y_i) = \lambda_i \exp(-\lambda_i y_i),\ \ y_i \geq 0,$$

$$\partial \log f(y_i)/\partial\lambda_i = (1 - y_i\lambda_i)\,/\,\lambda_i$$

$$\partial \log f(y_i)/\partial\boldsymbol{\beta} = (1 - y_i\lambda_i)\mathbf{x}_i$$

$$\partial^2 \log f(y_i)/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' = -(y_i\,\lambda_i)\mathbf{x}_i\mathbf{x}_i'$$

These terms then define the log likelihood function. The actual Hessian is used for the asymptotic covariance matrix. In this model, the conditional mean function is just $1/\lambda_i$, so the partial effects are

$$\partial \mathrm{E}[y_i|\mathbf{x}_i] = -\lambda_i\boldsymbol{\beta} = -\mathrm{E}[y|\mathbf{x}]\boldsymbol{\beta} = \boldsymbol{\delta}_i$$

which is computed at the means of the data. Standard errors are computed using the delta method. (Note the sign reversal in the marginal effects.) The derivatives matrix for this computation is

$$\partial\boldsymbol{\delta}_i/\partial\boldsymbol{\beta}' \;=\; \mathbf{G}_i \;=\; -\lambda_i[\mathbf{I} \;+\; \boldsymbol{\beta}\mathbf{x}_i']$$

once again, computed at the means of the data.

E50.5.2 Gamma

For the gamma model,

$$f(y_i) \;=\; \frac{\lambda_i^P}{\Gamma(P)}\exp(-\lambda_i y_i)y_i^{P-1},\;\; y_i \geq 0,$$

$$\log f(y_i) \;=\; P\log\lambda_i \;-\; \log\Gamma(P) \;-\; \lambda_i y_i \;+\; (P\text{-}1)\log y_i$$

$$\partial\log f(y_i)/\partial\lambda_i \;=\; P/\lambda_i \;-\; \mathrm{y}_i$$

$$\partial\log f(y_i)/\partial\boldsymbol{\beta} \;=\; (P - \lambda_i y_i)\mathbf{x}_i$$

$$\partial\log f(y_i)/\partial P \;=\; \log\lambda_i \;-\; \Psi(P) \;+\; \log y_i$$

The terms in the Hessian are

$$\partial^2\log f(y_i)/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' \;=\; -(\mathrm{y}_i\,\lambda_\mathrm{i})\mathbf{x}_i\mathbf{x}_i'$$

$$\partial^2\log f(y_i)/\partial P^2 \;=\; -\,\Psi'(P) \;+\; \log y_i$$

$$\partial^2\log f(y_i)/\partial\boldsymbol{\beta}\partial P \;=\; \mathbf{x}_i$$

The conditional mean function in the gamma model is

$$\mathrm{E}[y_i|\mathbf{x}_i] \;=\; P\,/\,\lambda_i$$

so, the partial effects are

$$\boldsymbol{\delta}_i \;=\; -P/\lambda_i\,\boldsymbol{\beta} \;=\; -\mathrm{E}[y|\mathbf{x}]\boldsymbol{\beta}$$

For computing standard errors of the partial effects,

$$\partial\boldsymbol{\delta}_i/\partial\boldsymbol{\beta}' \;=\; \mathbf{G}_{i\beta} \;=\; -P/\lambda_i[\mathbf{I} \;-\; \boldsymbol{\beta}\mathbf{x}_i']$$

$$\partial\boldsymbol{\delta}_i/\partial P \;=\; \mathbf{G}_{iP} \;=\; -(1/\lambda_i)\boldsymbol{\beta}$$

E50.5.3 Weibull

For the Weibull model,

$$f(y_i) = P\lambda_i y_i^{P-1}\exp(-\lambda_i y_i^P),\ y_i \geq 0,$$

$$\log f(y_i) = \log P + \log\lambda_i + (P\text{-}1)\log y_i - \lambda_i y_i^P$$

$$\partial\log f(y_i)/\partial\lambda_i = 1/\lambda_i - y_i^P$$

$$\partial \log f(y_i)/\partial\boldsymbol{\beta} = (1 - \lambda_i y_i^P)\mathbf{x}_i$$

$$\partial^2\log f(y_i)/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' = -(y_i\ \lambda_i^P)\mathbf{x}_i\mathbf{x}_i'$$

$$\partial \log f(y_i)/\partial P = 1/P + \log y_i - \lambda_i y_i^P \log y_i$$

$$\partial^2\log f(y_i)/\partial P^2 = -1/P^2 - \lambda_i y_i^P(\log y_i)^2$$

$$\partial^2\log f(y_i)/\partial\boldsymbol{\beta}\partial P = - \lambda_i y_i^P(\log y_i)\,\mathbf{x}_i$$

The conditional mean function in the Weibull model is

$$\text{E}[y_i \mid \mathbf{x}_i] = \left(\frac{1}{\lambda_i}\right)\Gamma\left(\frac{P+1}{P}\right).$$

The partial effects are

$$\boldsymbol{\delta}_i = -\left(\frac{1}{\lambda_i}\right)\boldsymbol{\Gamma}\left(\frac{P+1}{P}\right)\boldsymbol{\beta} = -\text{E}[y_i|\mathbf{x}_i]\ \boldsymbol{\beta}$$

For computing marginal effects,

$$\partial\boldsymbol{\delta}_i/\partial\boldsymbol{\beta}' = \mathbf{G}_{i\beta} = -\text{E}[y_i|\mathbf{x}_i]\ [\mathbf{I} - (1/P)\boldsymbol{\beta}\mathbf{x}_i']$$

$$\partial\boldsymbol{\delta}_i/\partial P = \mathbf{G}_{iP} = -\boldsymbol{\delta}_i\ [\Psi((\text{P}+1)/\text{P}) \times 1/\text{P}^2]$$

(We make use of the fact that $\Gamma'(t) = \Gamma(t)\Psi(t)$.)

E50.5.4 Rayleigh Distribution

The actual density for the Rayleigh distribution is

$$f(y_i) = \lambda_i y_i \exp\left(-\tfrac{1}{2}\lambda_i y_i^2\right), y_i > 0,\ \lambda_i > 0.$$

However, rather than manipulate this distribution for estimation purposes, internally, we create $z_i = y_i^2/2$, which has an exponential distribution based on the same parameter λ_i. Thus, we use the exponential model to estimate the parameters.

The marginal effects are

$$\boldsymbol{\delta}_{\mathrm{i}} = \left(\frac{-1}{2}\sqrt{\frac{\pi}{2\lambda_i}}\right)\boldsymbol{\beta}\,.$$

The derivative matrix for computing the asymptotic covariance for the marginal effects is

$$\mathbf{G}_i = \left(\frac{-1}{2}\sqrt{\frac{\pi}{2\lambda_i}}\right)[\mathrm{I} - (1/2)\boldsymbol{\beta}\mathbf{x}'].$$

E50.5.5 Inverse Gaussian

For the inverse Gaussian model,

$$f(y_i) = \frac{P}{\sqrt{2\pi y_i^{\,3}}}\exp\left[-\frac{1}{2}\frac{(\lambda_i y_i - P)^2}{y_i}\right],\ y_i > 0,\ P > 0,\ \lambda > 0.$$

$$\log f(y_i) = \log P \ - ½ \log(2\pi\, y_i^{3}) - ½\, (\lambda_i y_i - P)^2/y_i$$

$$\partial \log f(y_i)/\partial\lambda_i = -e_i \ \text{ where } e_i = \lambda_i y_i - P$$

$$\partial \log f(y_i)/\partial\boldsymbol{\beta} = -e_i\lambda_i\mathbf{x}_i$$

$$\partial^2 \log f(y_i)/\partial\boldsymbol{\beta}\partial\boldsymbol{\beta}' = -\,\lambda_i(e_i + \lambda_i y_i)\mathbf{x}i\mathbf{x}i'$$

$$\partial \log f(y_i)/\partial P = 1/P \ + \ e_i/y_i$$

$$\partial^2 \log f(y_i)/\partial P^2 = -1/P^2 - 1/y_i$$

$$\partial^2 \log f(y_i)/\partial\boldsymbol{\beta}\partial P = \lambda_i\mathbf{x}_i$$

The mean in the inverse Gaussian model in the original form is μ. Therefore, as reparameterized, the conditional mean in this model is

$$\mathrm{E}[y_i|\mathbf{x}_i] = P/\lambda_i$$

(note the similarity to the other models, which is what motivated this reparameterization). The partial effects are

$$\boldsymbol{\delta}_i = -P/\lambda_i\, \boldsymbol{\beta}$$

(note, again, the sign reversal). For computing standard errors of the marginal effects,

$$\partial\boldsymbol{\delta}_i/\partial\boldsymbol{\beta}' = \mathbf{G}_{i\beta} = -P/\lambda_i[\mathbf{I} \ - \ \boldsymbol{\beta}\mathbf{x}_i']$$

$$\partial\boldsymbol{\delta}_i/\partial P = \mathbf{G}_{iP} = -(1/\lambda_i)\boldsymbol{\beta}.$$

E50.6 The Lognormal Regression Model

The lognormal regression model is specified to include a particular type of heteroscedasticity as well as to deal explicitly with the nonnegative values of certain variables. (See Amemiya (1973).) If y has a lognormal distribution, then its variance is proportional to the square of its mean. The general form of the underlying regression is

$$y = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,$$

where y is positive, $$E[y] = \boldsymbol{\beta}'\mathbf{x}$$

and, $$\text{Var}[y] = \sigma^2[\boldsymbol{\beta}'\mathbf{x}]^2.$$

In this model, $$E[\log y] = \log(\boldsymbol{\beta}'\mathbf{x}) - 2\sigma^2$$

and $$\text{Var}[\log y] = \sigma^2.$$

The lognormal regression also allows censoring. (In the literature on this model, this variant is erroneously called truncation.) In this case, censoring may only be on the right. This model has been applied to the length of program participation, in which y must be positive and does not exceed the length of the program. Another natural application is the distribution of incomes, as in the application below.

The command is

LOGNORMAL ; Lhs = dependent variable
(or GLIM) ; Rhs = regressors $

The censored form of the model can be specified by adding the specification

; Limit = limit value

where limit is a fixed value or a variable. The limit must always be positive, as it is an upper limit.

The model parameters are ($\boldsymbol{\beta}$,σ^2). Estimation parameters are $\boldsymbol{\beta}$ and $\theta^2 = \log(1 + \sigma^2)$. Finally, for the lognormal regression model, the predicted value is just the mean, $\boldsymbol{\beta}'\mathbf{x}$. The other values displayed by **; List** are the residual, $\boldsymbol{\beta}'\mathbf{x}$ again, and the probability that y_i would exceed the limit value. The latter is zero if the data are not censored. This model, save for these considerations, is the same as the tobit model discussed in Chapter E45. All other options and specifications are identical. Note, however, that since the conditional mean is linear, **; Partial Effects** does not produce additional results.

There are no panel data forms of the lognormal model. For modeling in this context with panel data, the truncated regression or the loglinear models, Weibull, gamma, inverse Gaussian or Rayleigh should provide satisfactory alternatives. (The exponential model is likely to be too restrictive.)

E50.6.1 Application

In the results below, we fit a lognormal distribution to the income variable *hhninc*, in the German health care data analyzed earlier. The first model illustrates the truncated lognormal estimator. The second and third estimates compare the uncensored lognormal distribution to an ordinary truncated regression model with the same data. These two models are roughly comparable. The commands are:

SAMPLE ; All $
REJECT ; _groupti < 7 $
NAMELIST ; x = one,educ,hhkids,female,married,age $
LOGNORMAL ; Lhs = hhnins ; Rhs = x ; Limit = 2 $
LOGNORMAL ; Lhs = hhninc ; Rhs = x $
TRUNCATION ; Lhs = hhninc ; Rhs = x $

Note that in comparing the models, the parameter ‘σ’ is completely different; in the lognormal model it is a scale factor in the scedastic function while in the truncation model, it carries the scale of the dependent variable. Also, for comparing the estimated effects, the comparison would be between the coefficients in the lognormal model and the marginal effects in the truncation model, which, as can be seen below, are fairly similar. The differences arise because of the intrinsic differences in the functional forms.

E50.6.2 Technical Details for the Lognormal Regression Model

The log likelihood function is

$$\log L = -\tfrac{1}{2}\, \Sigma_{nonlimit\ observations} \{\log\theta^2 + \log 2\pi + (1/\theta^2)[\log y_i - \log(\boldsymbol{\beta}'\mathbf{x}_i) + \theta^2/2]^2\}$$

$$+ \Sigma_{limit\ observations} \log\Phi[-(1/\theta)(\log(\boldsymbol{\beta}'\mathbf{x}_i) - \log U_i - \theta^2/2)],$$

where $\theta^2 = \log(1 + \sigma^2)$

and U_i = upper censoring point or $+\infty$, in which case, there are no limit values.

The function and derivatives are the same as those for the tobit model with upper censoring at $\log U_i$, where we would use the analogy

$$\log y_i = \log(\boldsymbol{\beta}'\mathbf{x}_i) - \theta^2/2 + \varepsilon_i.$$

Let $$\varepsilon_i = \log y_i - \log(\boldsymbol{\beta}'\mathbf{x}_i) + \theta^2/2.$$

Thus, $$\partial\log L/\partial\boldsymbol{\beta} = (1/\theta^2)\Sigma_{nonlimit}[\varepsilon_i/(\boldsymbol{\beta}'\mathbf{x}_i)]\mathbf{x}_i - \Sigma_{limit}[(\phi/\Phi)\, 1/(\theta\boldsymbol{\beta}'\mathbf{x}_i)]\mathbf{x}_i$$

and $$\partial\log L/\partial\theta^2 = 1/(2\theta^2)\Sigma_{nonlimit}[(\varepsilon_i/\theta)^2 - \varepsilon_i - 1] + \Sigma_{limit}[(\phi/\Phi)/(2\theta)](1 + \varepsilon_i^2/\theta^2).$$

The BHHH estimator is used to estimate the asymptotic covariance matrix of the coefficient estimates.

An aspect of the model should be noted. The model implies the log of a linear function enters the log likelihood. Since a linear function cannot be directly constrained, there is the possibility that the function can become noncomputable. If the data and the model are well matched, this should be unusual. Users are warned of this possibility, however. The program cannot restrict the estimates in any way to prevent this. A value of $\boldsymbol{\beta}'\mathbf{x}$ that is nonpositive is fixed at a small positive value so that estimation can continue. However, if the problem occurs many times, the estimation is likely to break down at some point, claiming to be unable to maximize the function.

E50.7 Variable Limited to the (0,1) Interval

These models are defined for a random variable with range of variation restricted to an interval (L,U) which is usually (0,1) but may be any fixed interval. To use this model, you will need to rescale your variable if (0,1) is not the range of variation by dividing it by U-L by using a **CREATE** command. As such, we assume from this point on that y ranges in the unit interval. The distributions for y are the beta distribution and the power distribution.

The beta distribution is defined by two parameters, a and b, such that

$$f(y|a,b) = \frac{\Gamma(a+b)}{\Gamma(a)\Gamma(b)} y^{a-1}(1-y)^{b-1}, 0 \le y \le 1.$$

We parameterize this distribution by assuming

$$a = \exp(\boldsymbol{\alpha}'\mathbf{x}) = \lambda_a$$

and $$b = \exp(\boldsymbol{\beta}'\mathbf{x}) = \lambda_b.$$

This defines the conditional density, $f(y_i|\mathbf{x}_i,\boldsymbol{\alpha},\boldsymbol{\beta})$ as well as the log likelihood function needed for parameter estimation. The mean and variance of the beta distributed random variable are

$$E[y|\mathbf{x}] = \frac{\lambda_a}{\lambda_a + \lambda_b} \text{ and } \mathrm{Var}[y|\mathbf{x}] = \frac{\lambda_a\lambda_b}{(\lambda_a + \lambda_b + 1)(\lambda_a + \lambda_b)^2}.$$

Therefore, by differentiation, the marginal effects in this model are

$$\boldsymbol{\delta} = \frac{\partial E[y\,|\,\mathbf{x}]}{\partial \mathbf{x}} = \{E[y|\mathbf{x}] \times (1 - E[y|\mathbf{x}])\}(\boldsymbol{\alpha} - \boldsymbol{\beta}) = d(\boldsymbol{\alpha},\boldsymbol{\beta}) \times (\boldsymbol{\alpha} - \boldsymbol{\beta}).$$

Note that the signs of the individual coefficients are not necessarily indicative of the signs of the marginal effects.

The power model is also used to analyze a variable whose range is (0,1). The density for the random variable (as formulated in *LIMDEP*) is

$$f(y\,|\,\lambda) = (\lambda + 1)\, y^{\lambda},\ 0 < y < 1.$$

We parameterize the model by setting

$$\lambda = \exp(\boldsymbol{\beta}'\mathbf{x}).$$

For this model,

$$E[y|\mathbf{x}] = \frac{\lambda+1}{\lambda+2} \text{ and } \mathrm{Var}[y|\mathbf{x}] = \frac{\lambda+1}{\lambda+3} - \left(\frac{\lambda+1}{\lambda+2}\right)^2.$$

The marginal effects are

$$\boldsymbol{\delta} = \frac{\partial E[y\,|\,\mathbf{x}]}{\partial \mathbf{x}} = \left(\frac{\lambda}{(\lambda+2)^2}\right)\boldsymbol{\beta}.$$

We note, this model is a bit volatile, but it generally works. For analyzing a variable which is a proportion or is simply bounded by zero and one, one could use this formulation, or any of the binary choice models (probit, logit, complementary log log, Gompertz). These estimators automatically detect and adjust the estimation procedure for a proportions variable.

The model request for these models is

LOGLINEAR ; Lhs = dependent variable (must be in the range (0,1))
; Rhs = list of independent variables
; Model = Beta or Power $

All other options available for loglinear models are extended to this one. This model allows cross section analysis as above and all three panel data treatments, random parameters (**; RPM**), latent class (**; LCM**) and fixed effects (**; FEM**) as discussed below. Standard errors for the marginal effects are computed using the delta method. The models are fit by maximum likelihood. For the beta model, two vectors of parameters are produced. There is no obvious connection between them, nor any priority in their entry into the conditional mean function. The differences between the corresponding parameters feeds into the shape of the distribution. Note, for example, if $\boldsymbol{\alpha} = \boldsymbol{\beta}$, regardless of the values, the distribution is standard uniform between zero and one. Other configurations produce different shapes of the distribution.

E50.7.2 Technical Details

The log likelihood for the beta model is

$$\log L = \sum_{i=1}^{N} \log\Gamma(\lambda_{a,i}+\lambda_{b,i}) - \log\Gamma(\lambda_{a,i}) - \log\Gamma(\lambda_{b,i}) + (\lambda_{a,i}-1)\log y_i + (\lambda_{b,i}-1)\log(1-y_i)\,.$$

The derivatives are

$$\begin{aligned}\frac{\partial \log L}{\partial \boldsymbol{\alpha}} &= \sum_{i=1}^{N} [\Psi(\lambda_{a,i}+\lambda_{b,i}) - \Psi(\lambda_{a,i}) + \log y_i]\lambda_{a,i}\mathbf{x}_i \\ \frac{\partial \log L}{\partial \boldsymbol{\beta}} &= \sum_{i=1}^{N} [\Psi(\lambda_{a,i}+\lambda_{b,i}) - \Psi(\lambda_{b,i}) + \log(1-y_i)]\lambda_{b,i}\mathbf{x}_i\end{aligned}.$$

The BHHH estimator is used for the asymptotic covariance matrix. The conditional mean function is

$$E[y|\mathbf{x}] \;=\; \frac{\lambda_a}{\lambda_a+\lambda_b} \;=\; \mu$$

The partial effects are

$$\boldsymbol{\delta} \;=\; \frac{\partial E[y\,|\,\mathbf{x}]}{\partial \mathbf{x}} \;=\; [\mu(1\text{-}\mu)](\boldsymbol{\alpha} - \boldsymbol{\beta}).$$

To find the derivatives to use the delta method for the asymptotic covariance matrix for the estimated marginal effects, we require

$$\mathbf{G} \;=\; [\partial\boldsymbol{\delta}/\partial\boldsymbol{\alpha}',\, \partial\boldsymbol{\delta}/\partial\boldsymbol{\beta}'] \;=\; [\mathbf{G}_\alpha,\mathbf{G}_\beta].$$

By a tedious application of the chain rule, we find

$$\partial[\mu(1\text{-}\mu)]/\partial\lambda_a = (1/\lambda_a)\mu(1\text{-}\mu)(1 - 2\mu)$$

and by symmetry $\quad \partial[\mu(1\text{-}\mu)]/\partial\lambda_b = (1/\lambda_b)\mu(1\text{-}\mu)(1 - 2\mu).$

Therefore,

$$\begin{aligned}\mathbf{G}_\alpha &= \mu(1\text{-}\mu)\mathbf{I} \;+\; [(1/\lambda_b)\mu(1\text{-}\mu)(1 - 2\mu)]\boldsymbol{\alpha}\,[\lambda_a\mathbf{x}'] \\ &= \mu(1\text{-}\mu)[\mathbf{I} + (1 - 2\mu)\boldsymbol{\alpha}\mathbf{x}'].\end{aligned}$$

By the symmetry of the function, we can deduce

$$\mathbf{G}_\beta = \mu(1\text{-}\mu)[\mathbf{I} + (1 - 2\mu)\boldsymbol{\beta}\mathbf{x}'].$$

For the power model, the density is

$$f(\text{y} \mid \lambda) = (\lambda + 1)\, y^{\lambda},\ 0 < y < 1$$

$$\lambda = \exp(\boldsymbol{\beta}'\mathbf{x}).$$

so the log likelihood and its derivatives are

$$\log L = \sum_{i=1}^{N} \log(1+\lambda_i) + \lambda_i \log y_i$$

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{i=1}^{N} \left[\frac{\lambda_i}{1+\lambda_i} + \lambda_i \log y_i\right] \mathbf{x}_i$$

$$\frac{\partial^2 \log L}{\partial \boldsymbol{\beta}\partial \boldsymbol{\beta}'} = \sum_{i=1}^{N} \left[\frac{\lambda_i}{(1+\lambda_i)^2} + \lambda_i \log y_i\right] \mathbf{x}_i\mathbf{x}_i'$$

The marginal effects are

$$\boldsymbol{\delta} = \left(\frac{\lambda}{(\lambda+2)^2}\right)\boldsymbol{\beta}$$

so,

$$\mathbf{G} = \frac{\partial \boldsymbol{\delta}}{\partial \boldsymbol{\beta}'} = \frac{\lambda}{(\lambda+2)^2}\mathbf{I} + \frac{\lambda(2-\lambda)}{(\lambda+2)^3}\boldsymbol{\beta}\mathbf{x}'$$

$$= \frac{\lambda}{(\lambda+2)^2}\left[\mathbf{I} + \frac{2-\lambda}{2+\lambda}\boldsymbol{\beta}\mathbf{x}'\right]$$

E51: Generalized Linear and Fractional Response Models for Panel Data

E51.1 Introduction

This chapter presents the panel data estimators for the generalized linear models (GLMs) described in Chapters E49 and E50.

The basic command for estimation of the models described in this chapter is

GLIM ; Lhs = dependent variable
; Rhs = independent variables
; Model = type of model
; Panel
; Panel model specification $

where ‘**type of model**’ is one of the generalized linear models presented here. The panel model specification indicates the form of the stochastic specification, fixed or random effects, random parameters, or latent class.

The models listed in Table E51.1 provide specific extensions for panel data methods.

Model	Type of Random Variable
Lognormal	Nonnegative
Binomial	Count of successes
Geometric	Count until success
Power	Bounded in (0,1)
Normal (Loglinear)	Continuous
Gamma	Nonnegative
Weibull	Nonnegative
Exponential	Nonnegative
Rayleigh	Nonnegative
Inverse Gaussian	Nonnegative

Table E51.1 Loglinear Models with Supported Panel Data Treatments

There are no panel data estimators supported for the lognormal or beta models. The full set of panel data treatments, fixed effects, random effects, random parameters, and latent class, are supported for these nine models.

An additional modeling framework that is similar to the ones listed above is Papke and Wooldridge’s (2008) *fractional response model* for panel data, which is presented in Section E51.8.

E51.2 GEE Modeling

The four panel data treatments noted above provide the most common applications of longitudinal, or repeated measures methods to microeconomic data of the sort of interest here. A widely cited development in the statistics literature, generalized equation estimation (GEE) modeling appears to be yet another form of estimator. (See Liang and Zeger (1986) and Diggle, Liang and Zeger, (1994).) This is an extension of the GLM framework to panel data applications. The GEE estimator is not explicitly supported in *LIMDEP* directly as a preprogrammed routine. However, most of the internally consistent forms of GLM/GEE models are actually contained in the random parameters model package in *LIMDEP*. As this is a frequently asked question, we consider it in detail.

The GEE approach adds what is essentially a random effects form to a panel data treatment in the preceding GLM models. We redefine the link function as

$$f(\mathrm{E}[y_{it}|\,\mathbf{x}_{it}]) \;=\; \boldsymbol{\beta}'\mathbf{x}_{it} \;+\; \varepsilon_{it},\ t = 1,...,T_i.$$

Now, consider some different approaches to formulating the $T_i \times T_i$ covariance matrix for the heterogeneity: (We borrow the nomenclature from the GEE literature):

Independent:	$\mathrm{Corr}[\varepsilon_{it}, \varepsilon_{is}] \;=\; 0,\ t \neq s$
Exchangeable:	$\mathrm{Corr}[\varepsilon_{it}, \varepsilon_{is}] \;=\; \rho,\ t \neq s$
AR(1):	$\mathrm{Corr}[\varepsilon_{it}, \varepsilon_{is}] \;=\; \rho^{\lvert t-s \rvert},\ t \neq s$
Nonstationary:	$\mathrm{Corr}[\varepsilon_{it}, \varepsilon_{is}] \;=\; \rho_{ts},\ t \neq s,\ \lvert t-s \rvert \leq g$
Unstructured:	$\mathrm{Corr}[\varepsilon_{it}, \varepsilon_{is}] \;=\; \rho_{ts},\ t \neq s.$

The GEE approach to estimation is a form of generalized method of moments. Most of these models are already available in other forms in *LIMDEP*. The first one is obvious – this is just the pooled estimator ignoring any group effects – we considered this model in Chapters E49 and E50. The second is the random effects model. We have noted a large number of models, including most of those in the valid set of GLIMs that *LIMDEP* can fit in the random effects form. In addition, all models that are available in the random parameters form can be fit with just a random constant term to provide this random effects model. This includes most of the GLM models and some others, such as the tobit model. This model is produced simply by writing the random constants model as

$$f(\mathrm{E}[y_{it}|\,\mathbf{x}_{it}]) \;=\; \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} \;+\; u_{it},\ t = 1,...,T_i$$

$$\alpha_i \;=\; \alpha \;+\; w_i,\ i = 1,...,N.$$

Thus, the random constants model is functionally equivalent to the GEE model/estimator with the ‘exchangeable’ form of the covariance matrix. There is, however, an important difference in the treatment. The GEE estimator is a type of method of moments estimator. (See Diggle et al. (1994) for documentation.) The estimator in *LIMDEP* is maximum simulated likelihood. In addition, the random parameters model allows an AR(1) format for the random constant term, so all the models that fit in the exchangeable case can also be fit as in the AR(1) case. (See Chapter R24 for details on random parameters estimation.)

The nonstationary covariance matrix is a restricted form of the of the unstructured covariance matrix, in which covariances are restricted to be zero after a certain lag. It is possible to obtain both of these forms by using freely correlated random period specific constant terms (i.e., time dummy variables) in the model. It might also be desired to force the means of the variables to be equal, so as to match exactly the structure above. We do note, however, these sorts of models are very weakly identified in any estimation setting, owing to the large number of parameters that must be estimated to characterize the distribution of an unobserved random vector. A fully unstructured correlation matrix, for example, is nearly inestimable as an ancillary parameter in a model fit by maximum likelihood, because the log likelihood becomes quite flat in the space of the correlations. If the panel is at all large, users should not be optimistic about fitting models such as the unstructured one above using GEE, MSL or any other technique. (For example, *LIMDEP*'s multinomial probit and multivariate probit models face this difficulty.)

LIMDEP can estimate most GEE models. The estimation technique however, is simulated maximum likelihood, not the method of moments. By construction, *LIMDEP*'s estimator will be more efficient asymptotically, though in the sizes typical of panel data sets, this will probably be a minor consideration. We note, finally, ability to structure the random parameters model with random coefficients on all variables, rather than just the constant term, makes this estimator, in fact, far more general than the GEE estimator. The end result would be, in answer to the frequently asked question, yes, *LIMDEP* does do GLIM and GEE estimation, and considerably more with the random parameters model.

E51.3 Panel Data Models

There are several general formulations for extensions of the regression models to a panel data setting. These include, where $f(.)$ denotes the density for the observed random variable (i.e., the model),

- **Fixed effects:** $f(y_{it}) = f(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i)$; α_i may be correlated with $\mathbf{x}_{it}$,
- **Random effects:** $f(y_{it}) = f(\boldsymbol{\beta}'\mathbf{x}_{it} + u_i)$; u_i is uncorrelated with $\mathbf{x}_{it}$,
- **Random parameters:** $f(y_{it}) = f(\boldsymbol{\beta}_i'\mathbf{x}_{it})$, $\boldsymbol{\beta}|i \sim h(\boldsymbol{\beta}|i)$ with mean vector $\boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i$ and covariance matrix $\boldsymbol{\Sigma}$
- **Latent class:** $f(y_{it}|\text{class } j) = f(\boldsymbol{\beta}_j'\mathbf{x}_{it})$, $\text{Prob}[\text{class} = j] = F_j(\boldsymbol{\theta})$

NOTE: The inverse Gaussian regression model is extremely volatile, particularly with fixed effects. It is essential to have a good set of starting values, and even with these, the model is still often difficult to fit. To fit this model in any of the panel data forms, you must precede your command with estimation of the same model with no heterogeneity. That is, the immediately preceding command (each time you use it) must be

LOGLINEAR ; Lhs = ... ; Rhs = ... ; Model = Inverse Gaussian $

There is no natural starting value for the exponential regression model, other than the one fit to the pooled sample, as developed above. You must provide the values in the same way for this generalized regression model, with

LOGLINEAR ; Lhs = ... ; Rhs = ... ; Model = Normal $

Once again, the model specification must be otherwise identical in the pooled and panel data estimators.

The same features, options, and panel data treatments are provided for all ten models listed in Table E51.1. For convenience, the relevant specifications and restrictions for all of them are listed below. In all cases, the basic random effects model can be estimated by using the random parameters model with only a random constant term. The binomial regression model (only) also supports a quadrature based (Butler and Moffitt estimator) for the random effects model. This is noted again below.

Standard Model Specifications for the Panel Data Loglinear Models

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par keeps individual specific parameter estimates.
; Margin displays marginal effects.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm (not available for FEM).
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator (not for FEM).
; Rst = list specifies equality and fixed value restrictions (not for FEM).

E51.4 Fixed Effects Models

The fixed effects model assumes a group specific effect:

$$f(y_{it}) = f(\lambda_{it})$$

where $\lambda_{it} = \exp(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i)$

where α_i is the parameter to be estimated. You may also fit a two way fixed effects model

$$\lambda_{it} = \exp(\boldsymbol{\beta}'\mathbf{x}_{it} + \alpha_i + \gamma_t)$$

where γ_t is an additional, time (period) specific effect. This model is fit (in principle) as a dummy variable with separate dummy variables in the model for each individual (and group for the two way model).

The command for estimation of the fixed effects models is

LOGLINEAR ; Lhs = dependent variable
; Rhs = independent variables
; Model = Binomial, Geometric, Power, Exponential, Gamma, Weibull,
Inverse Gaussian, Rayleigh, Power, Geometric, Binomial
; Pds = panel specification
; FEM (for fixed effects model) $

(See the earlier note about the command for the inverse Gaussian regression model. The fixed effects form is not supported for the normal model.) You may request residuals, fitted values, marginal effects, and all other optional features with this model. Restrictions, with **; Rst**, however, must be built into the model at the outset. The algorithm does not accommodate restrictions. Full details on estimating fixed effects models appear in Section R23.2.

NOTE: Your Rhs list should not include a constant term, as the fixed effects model fits a complete set of constants for the set of groups. If you do include *one* in your Rhs list, it is removed prior to beginning estimation.

The fixed effects models are estimated by maximum likelihood. The time specific effect is requested by adding

; Time

to the command if the panel is balanced, and

; Time = variable name

if the panel is unbalanced.

For the unbalanced panel, we assume that overall, the sample observation period is

$$t = 1,2,..., T_{max}$$

and that the time variable gives for the specific group, the particular values of t that apply to the observations. Thus, suppose your overall sample is five periods. The first group is three observations, periods 1, 2, 4, while the second group is four observations, 2, 3, 4, 5. Then, your panel specification would be

; Pds = Ti, for example, where *Ti* = 3, 3, 3, 4, 4, 4, 4
and **; Time = Pd**, for example, where *Pd* = 1, 2, 4, 2, 3, 4, 5.

Results that are kept for this model are

Matrices: *b* = estimate of β
varb = asymptotic covariance matrix for estimate of β
alphafe = estimated fixed effects

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variables*

Last Function: None

The upper limit on the number of groups is 100,000.

To illustrate the fixed effects estimator, we fit a Weibull model to the distribution of income in the health care data. The model is somewhat limited, since it cannot accommodate time invariant regressors. We use health satisfaction, marital status, presence of children and working status. (It would be natural to include age and education. This produces perfect collinearity in the two way fixed effects model – age can be expressed as a linear combination of the time dummy variables and any other nonzero variable.) The results below compare a pooled model, the fixed effects model, and a two way model with time effects. One household with zero income is also removed from the sample.

E51.5 Random Effects Models

The random effects model also assumes a group specific effect:

$$f(y_{it}) = f(\lambda_{it})$$

where $$\lambda_{it} = \exp(\boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_u u_i),\ \mathrm{u_i} \sim N[0,1],$$

where σ_u is the one additional parameter to be estimated. This differs from the fixed effects model in the assumption that u_i is uncorrelated with $\mathbf{x}_{it}$. For example, the binomial regression with this formulation would have

$$\pi_{it} = \exp(\boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_u u_i)/[1+ \exp(\boldsymbol{\beta}'\mathbf{x}_{it} + \sigma_u u_i)] \text{ where } \sigma_u u_i \sim N[0,\sigma_u^2].$$

The Butler and Moffitt procedure for estimating this model has been incorporated in many random effects estimators, including many models in *LIMDEP*. A full listing of the frameworks appears in Section R23.3. The approach uses Hermite quadrature to evaluate the one dimensional normal integral in the conditional log likelihood. An alternative method of estimating one factor random effects models is via maximum simulated likelihood in a random parameters model with only a random constant term. This is described in Chapter R24, and in the next section below.

Random effects estimators for the loglinear models identified in Table E51.1 are obtained by using the random parameters approach. The generic command would be

```
LOGLINEAR ; Lhs = the dependent variable
          ; Rhs = one,... the remaining independent variables
          ; ... any other model specifications
          ; Pds = the panel data specification
          ; RPM ; Fcn = one(n) [; Halton ; Pts = the desired number]
          ; Model = one of Normal, Exponential, Gamma, Weibull, Rayleigh,
                    Inverse Gaussian, Power, Geometric, Binomial $
```

An example appears below. In addition, (only) one of these models, the binomial model, may be fit with the Butler and Moffitt estimator. The command would be

```
LOGLINEAR ; Lhs = the dependent variable
          ; Rhs = one,... the remaining independent variables
          ; Trials = the specification
          ; Pds = the panel data specification ; Normal
          ; Model = Binomial $
```

To illustrate, the following estimates a Weibull model for the distribution of incomes in the health care data. Note that a pooled exponential regression (P = 1) (not shown) is used to obtain the starting values. The likelihood ratio statistic of over 8,000 firmly rejects this hypothesis. Whether this is from the random parameters part of the model or the shape of the distribution remains to be determined. Strictly within the Weibull results, we find the null hypothesis of P = 1, can be firmly rejected based on a Wald (t) statistic of (2.24607 – 1)/0.01378 = 90.36.

E51.6 Random Parameters Models

The random parameters model may be specified for all nine loglinear models. The structure of the random parameters model is based on the conditional density

$$f(y_{it}|\, \mathbf{x}_{it}, \boldsymbol{\beta}_i) \;=\; f(\boldsymbol{\beta}_i{}'\mathbf{x}_{it}),\; i = 1,...,N,\; t = 1,...,T_i.$$

where $f(.)$ is the density for the particular model. The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals) means

$$\text{E}[\boldsymbol{\beta}_i|\, \mathbf{z}_i] \;=\; \boldsymbol{\beta} \;+\; \boldsymbol{\Delta}\mathbf{z}_i.$$

(The second term is optional – the mean may be constant.)

$$\text{Var}[\boldsymbol{\beta}_i|\, \mathbf{z}_i] \;=\; \boldsymbol{\Sigma}.$$

The model is operationalized by writing

$$\boldsymbol{\beta}_i \;=\; \boldsymbol{\beta} \;+\; \boldsymbol{\Delta}\mathbf{z}_i \;+\; \boldsymbol{\Gamma}\mathbf{v}_i.$$

As noted earlier, the heterogeneity term is optional. In addition, it may be assumed that some of the parameters are nonrandom. It is convenient to analyze the model in this fully general form here. One could easily accommodate nonrandom parameters just by placing rows of zeros in the appropriate places in $\boldsymbol{\Delta}$ and $\boldsymbol{\Gamma}$.

NOTE: If there is no heterogeneity in the mean, and only the constant term is considered random – the model may specify that some parameters are nonrandom – then this model is equivalent to the random effects model.

E51.6.1 Command for the Random Parameters Model

The basic model command for this form of the model is

LOGLINEAR ; Lhs = dependent variable
; Rhs = independent variables
; Model = Exponential, Gamma, Weibull, Inverse Gaussian,
Rayleigh, Power, Normal, Geometric, Binomial
; Pds = panel specification
; RPM (or ; RPM = list of variables in z)
; Fcn = specifications of the random parameters
[; Pts = number of replications and ; Halton are optional] $

(See the earlier note about the command for the inverse Gaussian regression and normal exponential models.)

NOTE: For this model, your Rhs list should include a constant term.

NOTE: The **; Pds** specification is optional. You may fit these models with cross section data. There is nothing inherent in the model that limits it to a panel data application.

Specifying Random Parameters

The **; Fcn = specification** is used to define the random parameters. It is constructed from the list of Rhs names as follows: Suppose your model is specified by

; Rhs = one, x1, x2, x3, x4

This involves five coefficients. Any or all of them may be random; any not specified as random are assumed to be constant. For those that you wish to specify as random, use

; Fcn = variable name (distribution), variable name (distribution), ...

Three distributions may be specified. All random variables have mean zero.

n = standard normal distribution, variance = 1,
t = triangular (tent shaped) distribution in [-1,+1], variance = 1/6,
u = standard uniform distribution [-1,1], variance = 1/3.

(Several other available distributions are listed in Section R24.3.) Note that each of these is scaled as it enters the distribution, so the variance is only that of the random draw before multiplication. The latter two distributions are provided as one may wish to reduce the amount of variation in the tails of the distribution of the parameters across individuals and to limit the range of variation. (See Train (2010) for discussion.). To specify that the constant term and the coefficient on *x*1 are normally distributed with fixed mean and variance, use

; Fcn = one(n), x1(n)

This specifies that the first and second coefficients are not random while the remainder are. The parameters estimated will be the mean and standard deviations of the distributions of these two parameters and the fixed values of the other three.

NOTE: The model with only a random constant term (**; Fcn = one(n)**) is precisely equivalent to a 'random effects' model.

Correlated Random Parameters

The preceding defines an estimator for a model in which the covariance matrix of the random parameters is diagonal. To extend it to a model in which the parameters are freely correlated, add

; Correlation (or just ; Cor)

to the command.

Heterogeneity in the Means

The preceding examples have specified that the mean of the random variable is fixed over individuals. If there is measured heterogeneity in the means, in the form of

$$E[\beta_{ki}] = \beta_k + \Sigma_m \delta_{km} z_{mi}$$

where z_m is a variable that is measured for each individual, then the command may be modified to

; RPM = list of variables in z

In the data set, these variables must be repeated for each observation in the group.

The Parameter Vector and Starting Values

The parameter vector is laid out as follows, in this order:

$\alpha_1, ..., \alpha_K$	are the K nonrandom parameters,
$\beta_1,...,\beta_M$	are the M means of the distributions of the random parameters,
$\sigma_1,\sigma_2,...,\sigma_M$	are the M scale parameters for the distributions of the random parameters,
P	is the shape parameter in the gamma, inverse Gauss or Weibull model (last parameter).

These are the essential parameters. If you have specified that parameters are to be correlated, then the σs are followed by the below diagonal elements of **Γ**. (The σs are the diagonal elements.) If you have specified heterogeneity variables, **z**, then the preceding are followed by the rows of **Δ**. Consider an example: The model specifies:

; Model = Weibull
; RPM = z1,z2
; Rhs = one,x1,x2,x3,x4 ? The base parameters are β_1, β_2, β_3, β_4, β_5.
; Fcn = one(n),x2(n),x4(n)
; Correlated

Then, after rearranging, the model becomes

Variable	**Parameter**
$x1$	α_1
$x3$	α_2
one	$\beta_1 + \sigma_1 v_{i1} + \delta_{11} z_{i1} + \delta_{12} z_{i2}$
$x2$	$\beta_2 + \sigma_2 v_{i2} + \gamma_{21} v_{i1} + \delta_{11} z_{i1} + \delta_{12} z_{i2}$
$x4$	$\beta_3 + \sigma_3 v_{i3} + \gamma_{31} v_{i1} + \gamma_{32} v_{i2} + \delta_{11} z_{i1} + \delta_{12} z_{i2}$

and the parameter vector would be

$$\theta = \alpha_1, \alpha_2, \beta_1, \beta_2, \beta_3, \sigma_1, \sigma_2, \sigma_3, \gamma_{21}, \gamma_{31}, \gamma_{32}, \delta_{11}, \delta_{12}, \delta_{21}, \delta_{22}, \delta_{31}, \delta_{32}, P$$

You may use **; Rst** and **; CML** to impose restrictions on the parameters. Use the preceding as a guide to the arrangement of the parameter vector.

Results saved by this estimator are:

Matrices: *b* = estimate of $\boldsymbol{\theta}$
varb = asymptotic covariance matrix for estimate of $\boldsymbol{\theta}$
beta_i = individual specific parameters, if **; Par** is requested
sdbeta_i = estimated standard deviations of conditional distributions

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variables*

Last Function: None

E51.6.2 Application

The example below continues the application shown in the preceding sections. Here, we fit the model with two random parameters, both heterogeneous and heteroscedastic. The specification for the random coefficient on *working*, for example, is

$$\beta_{working,i} = \beta_{working} + \delta Female_i + \sigma_{working,i,} w_{working,i}$$

$$\sigma_{working,i} = \sigma_{working} + \theta_{working} age_i$$

$$w_{working,i} \sim \text{N}[0,1].$$

The value used for age_i is the observation in the first period of the observation.

The command set is:

SAMPLE ; **All $**
REJECT ; **hhninc = 0 $** (There are four bad observations in the data set)
SETPANEL ; **Group = id ; Pds = ti $**
REJECT ; **ti # 7 $**

E51.7 Latent Class Loglinear Regression Models

The model for a panel of data, $i = 1,...,N$, $t = 1,...,T_i$ is

$$f(y_{it}|\,\mathbf{x}_{it}) = f(y_{it},\boldsymbol{\beta}'\mathbf{x}_{it}) = f(i,t).$$

Henceforth, we use the term 'group' to indicate the T_i observations on respondent i in periods $t = 1,...,T_i$. Unobserved heterogeneity in the distribution of y_{it} is assumed to impact the density in the form of a random effect. The continuous distribution of the heterogeneity is approximated by using a finite number of 'points of support.' The distribution is approximated by estimating the location of the support points and the mass (probability) in each interval. In implementation, it is convenient and useful to interpret this discrete approximation as producing a sorting of individuals (by heterogeneity) into J classes, $j = 1,...,J$. (Since this is an approximation, J is chosen by the analyst.)

Thus, we modify the model for a latent sorting of y_{it} into J 'classes' with a model which allows for heterogeneity as follows: The density of the observed y_{it} given that regime j applies is

$$f(y_{i,t}|j) = f(y_{it}|\,\mathbf{x}_{it}, j)$$

where the density is now specific to the group. The analyst does not observe directly which class, $j = 1,...,J$ generated observation $y_{it}|j$, and class membership must be estimated. Heckman and Singer (1984) suggest a simple form of the class variation in which only the constant term varies across the classes. This would produce the model

$$f(y_{i,t}\,|j) = f(y_{it},\,\boldsymbol{\beta}'\mathbf{x}_{it} + \delta_j),\ \text{Prob}(\text{class} = j) = F_j.$$

We formulate this approximation more generally as,

$$f(y_{i,t}\,|j) = f[y_{it}\,|\,\boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}_j'\mathbf{x}_{it},\,P_j)$$

$$F_j = \exp(\theta_j) / \Sigma_j \exp(\theta_j),\ \text{with } \theta_J = 0.$$

If the prior class probabilities are functions of observed variables, then they may be extended in the form of a multinomial logit model, with

$$\theta_{ij} = \boldsymbol{\theta}_j'\mathbf{z}_i.$$

This is done by adding the specification of **z** to the command as shown below. In this formulation, each group has its own parameter vector, $(\boldsymbol{\beta}_j',\sigma_j) = (\boldsymbol{\beta} + \boldsymbol{\delta}_j,P_j)$ though the variables that enter the mean are assumed to be the same. (This can be changed by imposing restrictions on the full parameter vector, as described below.) This allows the Heckman and Singer formulation as a special case by imposing restrictions on the parameters.

The estimation command for this model is

```
LOGLINEAR ; Lhs = dependent variable
          ; Rhs = independent variables
          ; Model = Exponential, Gamma, Weibull, Inverse Gaussian,
                    Rayleigh, Power, Normal, Geometric, Binomial
          ; Pds = panel specification
          ; LCM (or ; LCM = list of variables in z)
          ; Pts = number of classes $
```

The default number of support points is five. But, this is fairly high. You may set J to 2, 3, ...,9 with

; Pts = the value you wish

Some particular values computed for the latent class model are

; Group = the index of the most likely latent class
; Cprob = estimated probability for the most likely latent class

You can obtain a listing of these two results by using

; List

An example appears below. Computation of these values is described in the technical details in Chapter R25.

You can use the **; Rst = list** option to structure the latent class model so that different variables appear in different classes. For example, the following would restrict a model so that $x1$ appears in one class and $x2$ in the other:

; Rst = a1,bx1,0, a2,0,bx2,theta1,theta2.

Alternatively, you can use this device to construct the Heckman and Singer form of the model as follows, where we use a three class model as an example:

```
NAMELIST  ; x = ... one, list of variables $
CALC      ; kx1 =  Col(x) - 1 $
LOGLINEAR ; Lhs = ... ; Rhs = x ; LCM ; Pts = 3
          ; Model = Exponential, Gamma, Weibull, etc.
          ; Rst =  d1,kx1_b, pshape1,
                   d2,kx1_b, pshape2,
                   d3,kx1_b, pshape3, t1,t2,t3 $
```

Estimates retained by this model include

Matrices:	*b*	= full parameter vector, $[\boldsymbol{\beta}_1', P_1, \boldsymbol{\beta}_2', P_2, \ldots F_1, \ldots, F_J]$
	varb	= full covariance matrix
	beta_i	= individual specific parameters, if **; Par** requested
	classp_i	= individual specific posterior class probabilities if **; Par** requested

Note that *b* and *varb* involve $J\times(K+2)$ estimates. Two additional matrices are created,

	b_class	= a $J\times K$ matrix with each row equal to the corresponding $\boldsymbol{\beta}_j$
	class_pr	= a $J\times 1$ vector containing the estimated class probabilities

Scalars:	*kreg*	= number of variables in Rhs list
	nreg	= total number of observations used for estimation
	logl	= maximized value of the log likelihood function
	exitcode	= exit status of the estimation procedure

Last Function: None

Application

The following repeats the earlier example in the latent class framework. We fit the model with three latent classes, and allow the prior class probabilities to depend on *female*. The general formulation is as follows:

```
SAMPLE      ; All $
REJECT      ; hhninc = 0 $
SETPANEL    ; Group = id ; Pds = ti $
REJECT      ; ti # 7 $
LOGLINEAR   ; Lhs = hhninc
            ; Rhs = one,hsat,married,hhkids,working
            ; Model = Weibull ; Partial Effects
            ; LCM = female ; Panel ; Pts = 3 ; Par $
```

The model requests that the posterior class probabilities be retained in the matrix *classp_i*. This is an 886×3 matrix, shown below. The average class probabilities are shown below the model results. The matrix command,

```
MATRIX      ; List ; 1/886 * 1'classp_i $
```

verifies the computation.

A restriction that the coefficients on *hhkids* and *working* and the shape parameter, *P*, be equal in all three classes is imposed by adding

```
; Rst = a1,a2,a3,b1,b2,pw,c1,c2,c3,b1,b2,pw,d1,d2,d3,b1,b2,pw,t1,t2,t3
```

to the command.

The results for this model are shown below. This and the general model are nested, and we can use a likelihood ratio to test the restriction as a hypothesis. The log likelihoods for the unrestricted and restricted models are 4615.52967 and 4476.74896, respectively. The chi squared likelihood ratio statistic would be twice the difference, or 277.56 with 6 degrees of freedom (3 restrictions times (3-1) classes). The hypothesis would be rejected. The restriction for producing the Heckman and Singer model would be

; Rst = a1,4_b,pw,a2,4_b,pw,a3,4_b,pw,t1,t2,t3

```

E51.8 Fractional Responses

Papke and Wooldridge (2998) panel data model for a fractional response is

$$E[y_{it}|\ \mathbf{x}_{it},a_i]\ =\ \Phi(\boldsymbol{\beta}'\mathbf{x}_{it} + a_i),\ \ 0 \leq y_{it} \leq 1$$

where a_i is unobserved heterogeneity. The model is completed with the assumption about the heterogeneity,

$$a_i|\ \mathbf{X}_i \ \sim\ \ N[\alpha + \delta'\overline{\mathbf{x}}, \sigma^2]$$

where $\mathbf{X}_i$ is the $T_i{\times}K$ matrix of data on $\mathbf{x}_{it}$ for the T_i periods. After integrating out the heterogeneity, the conditional mean function in terms of the observables is

$$E[y_{it}\mid \mathbf{X}_i] = \Phi\left(\frac{\boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}'\overline{\mathbf{x}}_i + \alpha}{\sqrt{1+\sigma^2}}\right) = \Phi\left(\boldsymbol{\beta}_a'\mathbf{x}_{it} + \boldsymbol{\delta}_a'\overline{\mathbf{x}}_i + \alpha_a\right).$$

The second result provides the useable model in terms of the scaled coefficients. Since the parameter σ^2 is not identified, estimation and inference is based on the scaled coefficients. The model should contain a constant term. Note that if $\boldsymbol{\beta}$ contains a constant to begin with, β_0, the parameter estimated is $(\beta_0 + \alpha)/(1 + \sigma^2)^{1/2}$. We extend the model specification slightly to allow time invariant variables, $\mathbf{z}_i$, so

$$E[y_{it}\mid \mathbf{X}_i, \mathbf{z}_i] = \Phi\left(\boldsymbol{\beta}_a'\mathbf{x}_{it} + \boldsymbol{\delta}_a'\overline{\mathbf{x}}_i + \alpha_a + \gamma_a'\mathbf{z}_i\right).$$

The estimator for this model is obtained with command

FRACTIONAL ; Lhs = dependent variable
; Rhs = independent variables
; Panel (or ; Pds = name) $

The group means of the Rhs variables are added to the model during estimation – the Rhs list should not contain the means. The constant term, *one*, is automatically created, as it is part of the structure of the latent common effect. All of the standard options are available. Average partial effects based on the scaled coefficients are requested with

; Partial effects.

Estimation and computation of the partial effects are developed further in the technical details in Section E51.8.4. Predictions and residuals are retained with

; Keep = name
and **; Res = name**.

E51.8.1 Standard Model Specifications for the Fractional Response Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Partials displays marginal effects.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm (not available for FEM).
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator (not for FEM).
; Rst = list specifies equality and fixed value restrictions (not for FEM).

E51.8.2 Application

To illustrate the estimator, we have constructed the fractional variable *frac* which, for each household in the sample equals the proportion of the total income for the T_i years that is reported in each period, t. Thus, $frac_{it} = hhninc_{it}/(\Sigma_t hhninc_{it})$. For a few households, this equals zero in a few periods. The estimated fractional response model appears below.

```
SAMPLE       ; All $
SETPANEL     ; Group = id ; Pds = ti $
REJECT       ; ti < 7 $
CREATE       ; sums = Group Sums(hhninc, Pds = ti) $
CREATE       ; frac = hhninc/sums $
FRACTIONAL   ; Lhs = frac ; Rhs = one,age,educ,female,hhkids,married
             ; Panel ; Partial Effects $
```

E51.8.3 Endogenous Explanatory Variables

The possibility of accommodating endogenous variables on the right hand side of the equation is raised in Papke and Wooldridge (2008). Their application involves an endogenous continuous variable. Since the estimator is not based on a likelihood function, the sort of full information maximum likelihood estimator proposed, for example, for the count model with sample selection, or other two part models, will not be appropriate. The authors suggest, instead, the control function approach developed by Rivers and Vuong (1988) and investigated further by Terza, Basu and Rathouz (2008).

Consistent estimation is suggested by adding the residual from a reduced form equation for the endogenous variable to the fractional response model. For example, assume that one of the variables in $\mathbf{x}_{it}$ is $x_{it,e}$, a continuous endogenous variable such as 'spending,' that depends on a $\mathbf{z}_{it}$ that contains at least one variable that is not contained in $\mathbf{x}_{it}$. Then, consistent estimation of the parameters of the fractional response model is achieved by adding v_{it}, the residual in the linear regression of $x_{it,e}$ on $\mathbf{z}$. (Note, it is not suggested that predictions of $x_{it,e}$ be placed in the equation in place of the original data – rather, the residual is *added* to the equation.) Three issues remain:

1. If there is more than one endogenous variable, then a residual is added to the fractional response for each of them. Identification requires that each equation be uniquely identified by its own exogenous variable(s).

2. If the endogenous variables are not continuous, there may be an ambiguity as to how the residual is to be computed. We suggest Chesher and Irish's (1987) generalized residuals. For the single index models that are very likely to be behind the endogenous variables, the generalized residual is the derivative of the log density with respect to the constant term in the model. For a linear model, this would be e_{it}/s^2. For a binary choice (probit) model, this would be the signed inverse Mills ratio. For a count data model, this would be $y_{it} - \lambda_{it}$ where λ_{it} is the conditional mean. And so on.

3. There is no obvious approach suggested for obtaining the appropriate asymptotic covariance matrix for this estimator. The Murphy and Topel (2002) two step approach seems like the natural candidate, but is likely to be cumbersome in the extreme. Papke and Wooldridge mention bootstrapping in passing – this seems like an attractive alternative to the tedious development of a Murphy and Topel estimator.

The following general template could be used to incorporate these steps:

```
SETPANEL      ; Group = the variable ; Pds = ti $
PROCEDURE = FracResp(y1,x,y2,z,model2) $
MODEL2        ; Lhs = y2 ; Rhs = z $
CREATE        ; ey2 = _genres $
FRACTIONAL    ; Lhs = y1 ; Rhs = x, ey2 ; Panel $
ENDPROC $
EXEC          ; Proc = FracResp(y1,x,y2,z,model2) ; Bootstrap = b
              ; Panel ; N = number of bootstrap reps $
```

The following contrived example supposes that work status is endogenous in the fractional response model, and is determined by a probit model for the data generating process. We use a panel bootstrap method to do the estimation. In order to speed up the estimation, we have restricted the sample to groups with seven periods. The program illustrates several features. The procedure uses adjustable parameters, so it can be used with different model specifications. Note one of the parameters in the parameter list is the model command name, '*model2*.' The **EXECUTE** command that calls this procedure below requests *model2* to be a **PROBIT** command. The program also illustrates use of the panel bootstrap – bootstrap replications sample groups of observations defined by the **SETPANEL** command. Finally, the estimator that is constructed is a two step MLE/NLSQ estimator with an endogenous right hand side variable, working, in the second equation. The last command below computes the covariance matrix for the estimator without using the bootstrapping procedure. The **; Maxit = 0** specification just reuses the previous estimates.

```

E51.8.4 Technical Details

Full technical details of this model are given in Papke and Wooldridge (2008). We will provide a sketch of the main results here. The structure of the model is

$$E[y_{it}|\,\mathbf{x}_{it},a_i] \;=\; \Phi(\boldsymbol{\beta}'\mathbf{x}_{it} + a_i),\;\; 0 \leq y_{it} \leq 1$$

where a_i is unobserved heterogeneity with projection onto the group means of the data approximated with,

$$a_i|\,\mathbf{X}_i \sim \;\; N[\alpha+\delta'\overline{\mathbf{x}},\sigma^2]\,.$$

The reduced form is

$$E[y_{it}\,|\,\mathbf{X}_i] = \Phi\left(\frac{\boldsymbol{\beta}'\mathbf{x}_{it}+\boldsymbol{\delta}'\overline{\mathbf{x}}_i+\alpha}{\sqrt{1+\sigma^2}}\right) = \Phi\left(\boldsymbol{\beta}_a'\mathbf{x}_{it}+\boldsymbol{\delta}_a'\overline{\mathbf{x}}_i+\alpha_a\right).$$

Objects of estimation are β_a, δ_a and α_a. We estimate average partial effects as the partial derivatives of $E[y_{it}|X_i]$ and use the delta method to obtain the asymptotic standard errors for these. The average is taken over all the sample observations.

The estimator is based on nonlinear multivariate least squares. First step estimates of $(\beta_a,\delta_a,\alpha_a)$ are obtained by a pooled grouped probit estimator, which maximizes the log likelihood

$$\log L = \sum_{i=1}^{n}\sum_{t=1}^{T_i} \begin{matrix} y_{it}\log\Phi(\boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}'\overline{\mathbf{x}}_i + \alpha) + \\ (1-y_{it})\log[1-\Phi(\boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}'\overline{\mathbf{x}}_i + \alpha)] \end{matrix}$$

This initial estimator of the parameters, $\boldsymbol{\gamma}^0$, is used in construction of the weighting matrix for generalized least squares. The criterion function for estimation is, then

$$\text{Min}_{\gamma}\, S(\boldsymbol{\gamma}) = \Sigma_i\, (\mathbf{y}_i - E[\mathbf{y}_i|\mathbf{X}_i])'\, [\mathbf{V}(\mathbf{X}_i,\boldsymbol{\gamma}^0]^{-1}\, (\mathbf{y}_i - E[\mathbf{y}_i|\mathbf{X}_i])$$

where $\mathbf{y}_i = (y_{i1},y_{i2},\ldots,y_{i,Ti})'$ and the T_i conditional means are stacked in $E[\mathbf{y}_i|\mathbf{X}_i]$. The asymptotic covariance matrix for the estimator is computed using (3.8) in Papke and Wooldridge (2008). Partial effects are based on their (3.11) and (3.12), for the entire sample.

E52: Linear Sample Selection Models

E52.1 Introduction

Many variants of the 'sample selection' model can be estimated with *LIMDEP*. (See Heckman (1979), Maddala (1983) and Greene (2011) for further discussion.) Most of them share the following structure: A specified model, denoted **A**, applies to the underlying data. However, the observed data are not sampled randomly from this population. Rather, a related variable z^* is such that an observation is drawn from **A** only when z^* crosses some threshold. If the observed data are treated as having been randomly sampled from **A** instead of from the subpopulation of **A** associated with the 'selected' values of z^*, potentially serious biases result. The general solution to the selectivity problem relies upon an auxiliary model of the process generating z^*. Information about this process is incorporated in the estimation of **A**.

Several of the forms of this model which can be estimated with *LIMDEP* depart from Heckman's now canonical form, a linear regression with a binary probit selection criterion model:

$$y = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,$$

$$z^* = \boldsymbol{\alpha}'\mathbf{w} + u,$$

$$\varepsilon,u \sim N[0,0,\sigma_\varepsilon^2, \sigma_u^2, \rho].$$

A bivariate classical (seemingly unrelated) regressions model applies to the structural equations. The standard deviations are σ_ε and σ_u, and the covariance is $\rho\sigma_\varepsilon\sigma_u$. If the data were randomly sampled from this bivariate population, the parameters could be estimated by least squares, or GLS combining the two equations. However, z^* is not observed. Its observed counterpart is z, which is determined by

$$z = 1 \text{ if } z^* > 0$$

and

$$z = 0 \text{ if } z^* \le 0.$$

Values of y and **x** are only observed when z equals one. The essential feature of the model is that under the sampling rule, $E[y|\mathbf{x},z=1]$ is not a linear regression in **x**, or **x** and z. The development below presents estimators for the class of essentially nonlinear models that emerge from this specification.

The basic command structure for the models described in this chapter is

```
PROBIT     ; Lhs = variable z ; Rhs = variables in w ; Hold $
SELECT     ; Lhs = variable y ; Rhs = variables in x $
```

Note that two commands are required for estimation of the sample selection model, one for each structural equation.

This is the simplest form of this model. In this chapter, we consider estimation by two step least squares and maximum likelihood. In addition, we provide a large number of different forms and associated estimation techniques. Because there are so many different models considered here, this chapter will depart from our usual format. Rather than gather material by function (theoretical background, command, application, mathematical details), we will gather the material on sample selection by model. This chapter will develop the two step and ML estimators for sample selection models using cross section data. Chapter E53 presents panel data formulations of the sample selection models. These two chapters are concerned with variations on the binary selection mechanism with linear primary equation. Chapters E54 and E55 develop a variety of models that involve different types of equations and different types of selection mechanisms, respectively.

E52.2 Regression Model with Sample Selection

The models described in this section are based on a dichotomous selection mechanism. Heckman's approach to estimation is based on the following observations: In the selected sample,

$$\begin{aligned} \mathrm{E}[y_i|\mathbf{x}_i, \text{in sample}] &= \mathrm{E}[y_i \mid \mathbf{x}_i, z_i = 1] \\ &= \mathrm{E}[y_i \mid \mathbf{x}_i, \boldsymbol{\alpha}'\mathbf{w}_i + u_i > 0] \\ &= \boldsymbol{\beta}'\mathbf{x}_i + \mathrm{E}[\varepsilon_i \mid u_i > -\boldsymbol{\alpha}'\mathbf{w}_i] \\ &= \boldsymbol{\beta}'\mathbf{x}_i + (\rho\sigma_\varepsilon\sigma_u)\{\phi(-\boldsymbol{\alpha}'\mathbf{w}_i)/[1 - \Phi(-\boldsymbol{\alpha}'\mathbf{w}_i)]\} \\ &= \boldsymbol{\beta}'\mathbf{x}_i + (\rho\sigma_\varepsilon\sigma_u)[\phi(\boldsymbol{\alpha}'\mathbf{w}_i)/\Phi(\boldsymbol{\alpha}'\mathbf{w}_i)]. \end{aligned}$$

Given the structure of the model and the nature of the observed data, σ_u cannot be estimated, so it is normalized to 1.0. (We observe the same values of z_i regardless of the value of σ_u.) Then,

$$\begin{aligned} \mathrm{E}[y_i \mid \mathbf{x}_i, \text{in sample}] &= \boldsymbol{\beta}'\mathbf{x}_i + (\rho\sigma_\varepsilon)\lambda_i \\ &= \boldsymbol{\beta}'\mathbf{x}_i + \theta\lambda_i\,. \end{aligned}$$

There are some subtle ambiguities in the received applications of this model. First, it is unclear whether the index function, $\boldsymbol{\beta}'\mathbf{x}_i$, or the conditional mean is really the function of interest. If the model is to be used to analyze the behavior of the selected group, then it is the latter. If not, it is unclear. The index function would be of interest if attention were to be applied to the entire population, rather than those expected to be selected. This is application specific. Second, the partial effects in this model are complicated as well. For the moment, assume that $\mathbf{x}_i$ and $\mathbf{w}_i$ are the same variables. Then,

$$\frac{\partial E[y_i \mid \mathbf{x}_i, z_i = 1]}{\partial \mathbf{x}_i} = \boldsymbol{\beta} + \theta(-\lambda_i\boldsymbol{\alpha}'\mathbf{x}_i - \lambda_i^2)\boldsymbol{\alpha}$$

For any variable x_k which appears in both the selection equation (for z_i) and the regression equation, the partial effect consists of both the direct part (β_k) and the indirect part, which is of opposite sign – the term in parentheses is always negative; $\theta(-\lambda_i\boldsymbol{\alpha}'\mathbf{x}_i - \lambda_i^2)\alpha_k$. It is not obvious which part will dominate. Most applications have at least some variables that appear in both equations, so this is an important consideration. Note also that variables which do not appear in the index function still affect the conditional mean function through their affect on the inverse Mills ratio (the 'selection variable'). (We note the risk of conflict in the notation used here for the selection term, λ_i, and the loglinear term in the conditional mean functions of the generalized linear models in the preceding chapters. There is no relationship between the two. The two uses of 'lambda' are so common in the received literature as to have become part of the common parlance and as such, the risk of ambiguity is worse if we try to change the notation used here for clarity.)

LIMDEP contains three estimators for this model, Heckman's two step (or 'Heckit') estimator, full information maximum likelihood, and two step maximum likelihood (which is, more or less, a limited information maximum likelihood estimator). The first is presented in Section E52.2. The MLEs are presented in the Sections E52.2.3 and E52.3.3. The latter develops a model with heteroscedasticity, and uses the limited information maximum likelihood estimator.

E52.2.1 Defining Limit Observations and Control Observations

Limit Observations

The default specification for the selection model is to select on the value one for z. If you wish, instead, to select on zero use

; Limits

to define observations with $z = 1$ as 'limit' observations in the commands. In this case, λ is computed using the appropriate formula,

$$\lambda = -\phi(\boldsymbol{\alpha}'\mathbf{w})/[1 - \Phi(\boldsymbol{\alpha}'\mathbf{w})]$$

instead of $\phi(\boldsymbol{\alpha}'\mathbf{w})/\Phi(\boldsymbol{\alpha}'\mathbf{w})$. An application is suggested by the mover stayer model discussed in Section E56.2. This brings no other changes in the model or results. However, if you select on zero, *LIMDEP* saves *sigma*0 and *bsr*0 instead *sigma*1 and *bsr*1 when it retains the results. This is noted again below. Once again, these have relevance to the mover stayer model presented later.

Control Observations

In some experimental situations, some observations might actually be randomly selected from the full population, not the selected one. These might be controls, included by the experimental design. For any such observation, the correct value of λ to include in the equation is zero. You can indicate that there are control observations in your sample with a binary indicator included as a second Lhs variable in the command. Observations for which the variable is zero are given a value of 0.0 for λ; observations for which it is one will get the appropriate value computed by the formulas given earlier.

NOTE: This option is not used with the maximum likelihood estimators.

This variable, d_i must be coded 0/1. When it is present, the value of λ_i that is inserted in the equation is $d_i\lambda_i^*$, where λ_i^* is computed as prescribed earlier. As such, if you do not use a binary variable, the results may be seriously distorted.

E52.2.2 Two Step Estimation of the Standard Model

Heckman's two step, or 'Heckit' estimation method, is based on the method of moments. It is a consistent, but not efficient two step estimator.

Step 1. Use a probit model for z_i to estimate $\boldsymbol{\alpha}$.
For each observation, compute $\lambda_i = \phi(\boldsymbol{\alpha}'\mathbf{w}_i)/\Phi(\boldsymbol{\alpha}'\mathbf{w}_i)$ using the probit coefficients.

Step 2. Linearly regress y_i on $\mathbf{x}_i$ and λ_i to estimate $\boldsymbol{\beta}$ and $\theta = \rho\sigma_\varepsilon$.
Adjust the standard errors and the estimate of σ_ε^2, which is inconsistent.

The corrected asymptotic covariance matrix for the two step estimator, $(\mathbf{b},c)$, is

$$\text{Asy.Var}[\mathbf{b},c] = \sigma_\varepsilon^2(\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}[\mathbf{X}^{*\prime}(\mathbf{I} - \rho^2\boldsymbol{\Delta})\mathbf{X}^* + \rho^2(\mathbf{X}^{*\prime}\boldsymbol{\Delta}\mathbf{W})\boldsymbol{\Sigma}(\mathbf{W}'\boldsymbol{\Delta}\mathbf{X}^*)](\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}$$

where $\mathbf{X}^* = [\mathbf{X} : \boldsymbol{\lambda}]$,

$\boldsymbol{\Delta} = \text{diag}[\boldsymbol{\delta}]$,

$\boldsymbol{\delta}_i = -\lambda_i(\boldsymbol{\alpha}'\mathbf{w}_i + \lambda_i)$ $(-1 \le \delta_i \le 0)$,

and $\boldsymbol{\Sigma}$ = asymptotic covariance matrix for the estimator of $\boldsymbol{\alpha}$.

A consistent estimator of σ_ε^2 is $\hat{\sigma}_\varepsilon^2 = \mathbf{e}'\mathbf{e}/n - \hat{\theta}^2\bar{\hat{\delta}}$. The remaining parameters are estimated using the least squares coefficients. The computations used in the estimation procedure are those discussed in Heckman (1979) and in Greene (1981).

NOTE: (This is one of our frequently asked questions.) *LIMDEP* always computes the corrected asymptotic covariance matrix, for all variants of selection models in all model frameworks.

The estimator of the correlation coefficient, ρ, is $\text{sign}(\hat{\theta})\sqrt{\hat{\theta}^2/\hat{\sigma}_\varepsilon^2}$. This is the ratio of a regression coefficient (the coefficient on λ_i) and the variance estimator above. Note that it is not a sample moment estimator of the correlation of two variables. This ratio is not guaranteed to be between -1 and +1. (See Greene (1981), which is about this result.) But, note also that an estimate of ρ is needed to compute the asymptotic covariance matrix above, so this is a potential complication. When this occurs, *LIMDEP* uses either +1 or -1, and continues. We emphasize, this is not an error, nor is it a program failure. It is a characteristic of the data. (It may signal some problems with the model.) When this condition occurs, the model results will contain the diagnostic

```
Estimated correlation is outside the range -1 < r < 1. Using 1.0
```

If the estimate of ρ is invalid, so that the polar value must be used, the corrected standard errors can be negative. If this happens, a warning is given and the OLS standard errors for the estimates are used instead. This condition is specific to the two step regression estimators. The maximum likelihood estimators discussed below force the coefficient to lie in the unit interval – ρ is estimated directly, not by the method of moments.

To estimate this model with *LIMDEP*, it is necessary first to estimate the probit model, then request the selection model. The pair of commands is

PROBIT ; Lhs = name of z ; Rhs = list for w ; Hold results $
SELECT ; Lhs = name of y ; Rhs = list for x $

For this simplest case, **; Hold ...** may be abbreviated to **; Hold**. All of the earlier discussion for the probit model applies. This application differs only in the fact the **; Hold** requests that the model specification and results be saved to be used later. Otherwise, they disappear with the next model command. The **PROBIT** command is exactly as described in Chapter E26. The selection model is completely self contained. You do not need to compute or save λ_i.

Standard Model Specifications for the Sample Selection Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Partial Effects displays marginal effects, same as **; Marginal Effects**.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

None

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.

Predictions for this model are computed according to the formula given above for the conditional mean, including λ_i. The other variables listed are the residual computed as usual, $\boldsymbol{\beta}'\mathbf{x}$, and λ_i. The optional specifications

; Keep = name
; Res = name
; List

are the same as for the linear regression model, **REGRESS**.

You may also specify weights for the regression with

; Wts = weighting variable

LIMDEP recomputes the scale factor for the weights so that the weights used in estimation sum to the number of observations in the selected sample, not the number in the full data set.

In most cases, it is not necessary for you to compute the selection variable, λ; this is taken care of internally. Nonetheless, you may have occasion to use this variable for some other purpose. If so, change the **; Hold** specification in the **PROBIT** command to

; Hold (IMR = name)

(IMR stands for Inverse Mill's Ratio.) This places λ_i in your data array as variable *name* and you can use it for any other purpose or write it to a data file for later use.

NOTE: The *imr* variable is computed as $\lambda = \phi/\Phi$ if $z = 1$ and $\lambda = -\phi/(1-\Phi)$ if $z = 0$. Note that the data saved are determined by the current sample. This means that if you have partitioned the sample before giving the **PROBIT** command, after it is executed, the data array may have some cells which are undefined. The variable is only computed for observations used to fit the probit model.

The retrievable results saved by the estimator are

Matrices:	*b*	contains $(\boldsymbol{\beta},\theta)$
	v*arb*	contains the corrected VC matrix
	*bsr*1	contains $[\boldsymbol{\beta},\sigma_\varepsilon,\rho]$ (Used with the mover stayer model.)

Scalars:	*sy* and *ybar*	for the dependent variable
	x	= $\sigma_{,}$ (this is also saved in *sigma*1)
	ssqrd	= $\mathbf{e}'\mathbf{e}/N$
	sumsqdev	= $\mathbf{e}'\mathbf{e}$
	rsqrd	= R^2 in the linear regression
	rho	= ρ
	degfrdm	= $N - K - 1$
	kreg	= $K + 1$
	nreg	= number of observations in selected sample

Last Model: *b_variables*, *theta*

Last Function: Conditional mean function, $\beta'x + \theta\lambda_i$

The conditional mean function given above is used in the **SIMULATE** and **PARTIAL EFFECTS** commands when computing predictions and partial effects.

The estimate of ρ needed to compute the appropriate standard errors for the estimates is the square root of

$$\hat{\rho}^2 = \hat{\theta}^2 / \left(\mathbf{e}'\mathbf{e}/N \ - \ \hat{\theta}^2\bar{\delta}\right).$$

The output for the sample selection model consists of a short summary similar to the results for a least squares regression, with some additional information about the selection model.

To illustrate the estimator, we use one of the most familiar data sets used in the pedagogical segment of this literature, Mroz's (1987) female labor supply data. The data are described in detail in Section E45.7. The variables in the data set are

lfp	=	a dummy variable = 1 if woman worked in 1975, else 0
whrs	=	wife's hours of work in 1975
kl6	=	number of children less than 6 years old in household
k618	=	number of children between ages 6 and 18 in household
wa	=	wife's age
we	=	wife's educational attainment, in years
ww	=	wife's average hourly earnings, in 1975 dollars
rpwg	=	wife's wage reported at the time of the 1976 interview
hhrs	=	husband's hours worked in 1975
ha	=	husband's age
he	=	husband's educational attainment, in years
hw	=	husband's wage, in 1975 dollars
faminc	=	family income, in 1975 dollars
mtr	=	marginal tax rate facing the wife
wmed	=	wife's mother's educational attainment, in years
wfed	=	wife's father's educational attainment, in years
un	=	unemployment rate in county of residence, in percentage points
cit	=	dummy variable = 1 if live in large city (SMSA), else 0
ax	=	actual years of wife's previous labor market experience
prin	=	*faminc* - (*whrs***ww*) = wife's property income

We will use the two step estimator to build the selection model:

$$lfp \ = \ f(kl6,\ k618,\ prin,\ un,\ hinc)$$

$$winc \ = \ g(wa,\ wa^2,\ we,\ cit,\ ax)$$

where *hinc* = husband's income = $hhrs \times hw$, and *winc* = wife's wage income = $ww \times whrs$. The estimates also compare the corrected results to uncorrected ordinary least squares.

The commands are:

CREATE ; prin = faminc - ww*whrs $
CREATE ; hinc = hw*hhrs $
CREATE ; winc = ww*whrs $
CREATE ; wasq = wa*wa $
NAMELIST ; w = one,kl6,k618,prin,un,hinc $
NAMELIST ; x = one,wa,wasq,we,cit,ax $
PROBIT ; Lhs = lfp ; Rhs = w ; Hold $
SELECTION ; Lhs = winc ; Rhs = x ; Partial Effects $
REGRESS ; Lhs = winc ; Rhs = x $

E52.2.3 Maximum Likelihood Estimation

The full log likelihood for the sample selection model is built up from

Prob(Selection) × density|selection for selected observations

and Prob(Nonselection) for nonselected observations.

Combining the various parts, this produces the following log likelihood function for the sample selection model:

$$\log L \;=\; \sum\nolimits_{z=1} \log\left[\frac{\exp\left(-(1/2)\varepsilon_i^2/\sigma_\varepsilon^2\right)}{\sigma\sqrt{2\pi}}\Phi\left(\frac{\rho\varepsilon_i/\sigma_e+\boldsymbol{\alpha}'\mathbf{w}_i}{\sqrt{1-\rho^2}}\right)\right] \;+\; \sum\nolimits_{z=0} \log\Phi(-\boldsymbol{\alpha}'\mathbf{w}_i)$$

where $\varepsilon_i \;=\; y_i - \boldsymbol{\beta}'\mathbf{x}_i$.

NOTE: There are two (only apparent) inconsistencies between this and the statement of the counterpart in Maddala’s (1983) widely used reference on his page 266. First, he appears to multiply the first term by $1/\Phi(\boldsymbol{\alpha}'\mathbf{w}_i)$. The reason for this is that his result gives the conditional density for the selected observations whereas the likelihood function is built up from the unconditional densities for the entire sample. Thus, the log likelihood function above results from the construction,

density = Prob(selected) × Maddala’s result

which gives our result. The second inconsistency appears to be the sign on the residual term in the second function above, which is -ρ... in Maddala. The reason for this is the inexplicable negative sign on ε_1 in his statement (9.17) as opposed to our positive sign on u in our statement of the model. Since ε is normally (symmetrically) distributed, the formulations are equivalent. There is no obvious reason for the sign reversal in Maddala’s treatment – at this juncture, the literature has settled on the slightly simpler formulation adopted herein.

Maximum likelihood estimates of the model parameters can be obtained by adding the specification

; MLE

to the **SELECTION** command described earlier. This activates a number of the standard optional features, as shown in the revised listing below. It is still necessary to precede this estimator with the probit model in order to provide starting values for the MLE. The full set of output for the earlier methodology is produced as well. The final values from the Heckman procedure are used as the starting values for the maximum likelihood procedure. The method is that of BFGS.

NOTE: Although this model computes an estimate of α, it does *not* replace the estimates that have been retained with the **; Hold** instruction in the preceding **PROBIT** command.

Standard Model Specifications for the Sample Selection MLE

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par keeps ancillary parameter σ with main parameter **β** vector in *b*.
; Partial Effects displays marginal effects, same as **; Marginal Effects**.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Cluster = spec requests computation of the cluster form of corrected covariance estimator. (includes **; Stratum** as well for stratified and clustered data sets).
; Robust requests a sandwich estimator or robust VC for TSCS and some discrete choice models (uses **; Cluster = 1**).

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg [= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb [= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level ‘**n**’ is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.
; Fill fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

Once the model has been estimated by maximum likelihood, all remaining computations are the same as for the earlier treatment with estimation by two step least squares. But, in this case, fewer scalars are saved. In particular, only *ybar*, *sy*, *nreg*, as before, plus *logl*, *sigma*1, *rho*, and *varrho* for the MLE are added. The matrix *bsr*1 is as described above and *b* and *varb* contain $\boldsymbol{\beta}, \sigma_\varepsilon$, and ρ.

NOTE: When the parameters are estimated by maximum likelihood, there is no 'λ_i' variable in the equation. (See the technical details below.) Therefore, there is one fewer parameter in *b* for the regression.

TECHNICAL NOTE: During the optimization process, the parameter ρ is replaced by the transformation of $\tau = \log[(1+\rho)/(1-\rho)]$, so that $\rho = [\exp(\tau)-1]/[\exp(\tau)+1]$. By this reparameterization, τ may be estimated as an unrestricted parameter – its range is unbounded. This circumvents problems of ρ straying outside the allowable range of (-1,+1).

The model estimated earlier is shown below using the maximum likelihood approach, instead.

```
CREATE      ; prin = faminc - ww*whrs $
CREATE      ; hinc = hw*hhrs $
CREATE      ; winc = ww*whrs $
CREATE      ; wasq  = wa*wa $
NAMELIST    ; w = one,kl6,k618,prin,un,hinc $
NAMELIST    ; x  = one,wa,wasq,we,cit,ax $
PROBIT      ; Lhs = lfp ; Rhs = w ; Hold $
SELECTION   ; Lhs = winc ; Rhs = x ; Partial Effects ; MLE $
```

Two sets of partial effects are reported. The first set are the partial effects based on the maximum likelihood estimator. The second set are those estimated earlier based on the two step estimator.

E52.2.4 A Selection Model with Heteroscedasticity

We extend the sample selection model to incorporate heteroscedasticity in the regression variance with the usual loglinear formulation,

$$\sigma_{\varepsilon i} = \sigma_\varepsilon \exp(\boldsymbol{\gamma}'\mathbf{v}_i).$$

This adds a considerable complication to the model. The full structure becomes

$$\begin{aligned} y_i &= \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, \\ z_i^* &= \boldsymbol{\alpha}'\mathbf{w}_i + u_i, \\ \varepsilon_i, u_i &\sim N[0,0,\sigma_{\varepsilon i}^2, 1, \rho], \\ z &= 1 \text{ if } z^* > 0 \text{ and } z = 0 \text{ if } z^* \le 0, \end{aligned}$$

Values of y_i and $\mathbf{x}_i$ are only observed when z_i equals one. The major complication arises because

$$\begin{aligned} E[y_i \mid \mathbf{x}_i, \text{in sample}] &= \boldsymbol{\beta}'\mathbf{x}_i + (\rho\sigma_{\varepsilon i})\lambda_i \\ &= \boldsymbol{\beta}'\mathbf{x}_i + \theta_i\lambda_i\,. \end{aligned}$$

Note that the heterogeneity in the variance now shows up in the mean. The interesting effects in this model now come in three parts. As we did earlier, assume for the moment that all three data vectors in the model are the same. Then,

$$\frac{\partial E[y_i \mid \mathbf{x}_i, z_i = 1]}{\partial \mathbf{x}_i} = \boldsymbol{\beta} + [\theta_i(-\lambda_i\boldsymbol{\alpha}'\mathbf{x}_i - \lambda_i^2)[\boldsymbol{\alpha} + [\sigma_{\varepsilon i}\lambda_i\rho]\boldsymbol{\gamma}.$$

It is not unlikely that a variable would appear in all three parts, so the marginal effect in this model is extremely complicated. The example below and the technical details present further details.

The preceding implies that conventional least squares based estimation, such as Heckman's estimator, will no longer be consistent. In order to use Heckman's approach, one would require a consistent estimator of $\boldsymbol{\gamma}$ before the least squares step, and it is unclear where that would come from. *LIMDEP* uses a two step, maximum likelihood estimator for this model. The command for this model is

PROBIT ; Lhs = z ; Rhs = variables in w ; Hold $
SELECT ; Lhs = y ; Rhs = variables in x ; Hfn = variables in v $

Do not include *one* in the Hfn list. The constant term in the variance model is already included (implicitly) as $\log\sigma_\varepsilon$, so if you include one of your own, the model will become inestimable.

Estimates of the heteroscedastic model are obtained in three steps. First, the two step least squares estimator is obtained ignoring the heteroscedasticity. Second, the full maximum likelihood estimator is obtained, again ignoring the heteroscedasticity. This is done to obtain the starting values for the parameters, under the assumption that $\boldsymbol{\gamma} = \mathbf{0}$. Finally, the maximum likelihood estimates for the heteroscedasticity model are obtained, allowing $\boldsymbol{\gamma}$ to be unrestricted. The parameter vector in this final model is $[\boldsymbol{\beta}, \boldsymbol{\gamma}, \sigma, \rho]$. The estimator of α is not recomputed – this is a limited information maximum likelihood estimator.

Other optional features for this model are the same as for the maximum likelihood estimator of the model with homoscedastic disturbances. (The list of standard model specifications is identical, so it is not repeated here.) If you provide starting values or impose constraints, use this arrangement of the parameters. Starting values are computed in two steps for this model. First, the sample selection model is computed using Heckman's method and ignoring the heteroscedasticity. Second, the MLE, once again ignoring the heteroscedasticity is computed, to sharpen the starting values of ρ and σ. Then, the starting values for $\boldsymbol{\beta}$, σ, and ρ from the MLE and a vector of zeros for γ are used as the start values for this estimator. Therefore, your model results for this model will contain all three sets of estimates.

The estimation results retained are

Matrices:	*b*	= $[\boldsymbol{\beta}, \boldsymbol{\gamma}, \sigma, \rho]$ (all parameters are retained)
	varb	= the full asymptotic covariance matrix
Scalars:	*s*	= estimate of σ
	rho	= estimate of ρ
	varrho	= estimated asymptotic variance for estimated ρ
	ybar, sy	= descriptive statistics for dependent variable
	nreg	= number of observations in selected sample
	logl	= log likelihood
	exitcode	

To illustrate the model, we will layer heteroscedasticity on the earnings equation based on our previous application. The probit equation is omitted from the results below, as it was estimated earlier.) We note, as happens frequently in models with heteroscedasticity, the parameter estimates differ from those in the model with homoscedasticity, but the total marginal effects are very similar.

Technical Details on Estimation of the Heteroscedasticity Model

The full log likelihood function for the full sample is

$$\log L \;=\; \sum\nolimits_{z=1} \log\left[\frac{\exp\left(-(1/2)\varepsilon_i^2/\sigma_{\varepsilon i}^2\right)}{\sigma\sqrt{2\pi}}\Phi\left(\frac{\rho\varepsilon_i/\sigma_{\varepsilon i}+\boldsymbol{\alpha}'\mathbf{w}_i}{\sqrt{1-\rho^2}}\right)\right] \;+\; \sum\nolimits_{z=0} \log\Phi(-\boldsymbol{\alpha}'\mathbf{w}_i)$$

where the parameter vector is [$\boldsymbol{\beta},\boldsymbol{\alpha},\boldsymbol{\gamma},\sigma_\varepsilon,\rho$.] The parameters of the probit selection equation can be estimated consistently in isolation using the probit model. We do so, and insert the estimated $\boldsymbol{\alpha}$ in the model, to obtain

$$\log L\,|\,\hat{\boldsymbol{\alpha}} \;=\; \sum\nolimits_{z=0} \log\Phi\left(-\hat{\boldsymbol{\alpha}}'\mathbf{w}_i\right) \;+\; \sum\nolimits_{z=1} \log\left[\frac{\exp\left(-(1/2)\varepsilon_i^2/\sigma_{\varepsilon i}^2\right)}{\sigma\sqrt{2\pi}}\Phi\left(\frac{\rho\varepsilon_i/\sigma_{\varepsilon i}+\hat{\boldsymbol{\alpha}}'\mathbf{w}_i}{\sqrt{1-\rho^2}}\right)\right]$$

Conditioned on $\hat{\boldsymbol{\alpha}}$, we may now maximize the likelihood with respect to the remaining parameters, [$\boldsymbol{\beta},\boldsymbol{\gamma},\sigma,\rho$]. Any terms involving $\hat{\boldsymbol{\alpha}}$ are irrelevant to the solution. To simplify the process, we make the following substitutions:

$$q_i \;=\; \hat{\boldsymbol{\alpha}}'\mathbf{w}_i$$

$$\eta \;=\; 1/\sigma_\varepsilon$$

$$\tau \;=\; \rho/\sqrt{1-\rho^2}$$

$$\boldsymbol{\delta} \;=\; -\boldsymbol{\gamma}$$

$$\boldsymbol{\mu} \;=\; \boldsymbol{\beta}/\sigma_\varepsilon$$

(Note, we are using the Olsen transformation.) Then, the log likelihood becomes

$$\log L \mid \hat{\boldsymbol{\alpha}} = \sum_{z=0} \log\Phi(-q_i) + \sum_{z=1} \log\eta + \boldsymbol{\delta}'\mathbf{v}_i - \frac{\log 2\pi}{2} - \frac{1}{2}\left(\exp(\boldsymbol{\delta}'\mathbf{v}_i)\right)^2 (\eta y_i - \boldsymbol{\mu}'\mathbf{x}_i)^2 + \log\Phi\left[\tau\left(\exp(\boldsymbol{\delta}'\mathbf{v}_i)\right)(\eta y_i - \boldsymbol{\mu}'\mathbf{x}_i) + q_i\sqrt{1+\tau^2}\right]$$

In spite of its length, this is not a particularly difficult log likelihood to maximize, and estimation of this model is fairly routine.

The derivatives of the log likelihood are as follows, where we give the result for a single observation: Let

$$\varepsilon_i = \eta y_i - \boldsymbol{\mu}'\mathbf{x}_i,$$

$$\kappa_i = \exp(\boldsymbol{\delta}'\mathbf{v}_i),$$

$A_i = \phi(\,.\,) / \Phi(\,.)$ based on the $\log\Phi(.)$ term in $\log L$.

Then,

$$\frac{\partial \log L_i}{\partial \boldsymbol{\mu}} = [\kappa_i^2\, \varepsilon_i - A_i\, \tau\, \kappa_i\,]\mathbf{x}_i,$$

$$\frac{\partial \log L_i}{\partial \boldsymbol{\delta}} = [1 - \kappa_i^2\varepsilon_i^2 + A_i\tau\, \kappa_i\, \varepsilon_i]\mathbf{v}_i,$$

$$\frac{\partial \log L_i}{\partial \eta} = \frac{1}{\eta} - [\kappa_i^2\varepsilon_i - A_i\, \tau\, \kappa_i]y_{,i,}$$

$$\frac{\partial \log L_i}{\partial \tau} = A_i\, [\kappa_i\, \varepsilon_i + q_i\, \tau \,/\, \sqrt{1+\tau^2}\,].$$

The BHHH estimator is used for the asymptotic covariance matrix.

Since this is a two step estimator, we now make the Murphy and Topel correction. Let the vector of derivatives given above, evaluated at the maximum likelihood estimators, be denoted $\mathbf{g}_i$. The transpose of this vector forms the ith row of the matrix **G**, and the BHHH estimator noted above is

$$\mathbf{V}_2 = (\mathbf{G}'\mathbf{G})^{-1}.$$

Now, let

$$\mathbf{m}_i = \frac{\partial \log L_i}{\partial \boldsymbol{\alpha}}$$

$$= -\mathbf{1}(z_i = 0)[\phi(q_i) / \Phi(-q_i)]\mathbf{w}_i + \mathbf{1}(z_i = 1)[\mathrm{A}_i\tau \,/\, \sqrt{1+\tau^2}\,]\,\mathbf{w}_i$$

$$\mathbf{d}_i = \{(2z_i - 1)\phi(q_i) / \Phi[(2z_i - 1)q_i]\}\mathbf{w}_i$$

and define matrices **M** and **D** in the same manner as **G**. Finally, let $\mathbf{V}_1$ denote the estimated asymptotic covariance matrix for the first round estimator of $\boldsymbol{\alpha}$. (This could be the BHHH estimator, $(\mathbf{D}'\mathbf{D})^{-1}$, but *LIMDEP* uses the Hessian for this purpose, instead.) The corrected covariance matrix is

$$\mathbf{V}_2^* = \mathbf{V}_2 + \mathbf{V}_2\, [(\mathbf{G}'\mathbf{M})\mathbf{V}_1(\mathbf{M}'\mathbf{G}) - (\mathbf{G}'\mathbf{D})\mathbf{V}_1(\mathbf{M}'\mathbf{G}) - (\mathbf{G}'\mathbf{M})\mathbf{V}_1(\mathbf{D}'\mathbf{G})\,]\,\mathbf{V}_2.$$

E52.3 Treatment Effects – Using All Observations

If you wish to use the entire sample, that is, not select out any observations, use the specification

; All

in the **SELECTION** command, and otherwise, set it up in the usual manner. In this instance, all computations are exactly as described earlier, save that in the calculations,

$$\lambda_i = (2z_i - 1)\,\phi(\boldsymbol{\alpha}'\mathbf{w}_i) / \Phi[(2z_i - 1)\boldsymbol{\alpha}'\mathbf{w}_i].$$

The model of an endogenous binary variable is an example that would use this formulation. A specification of the selection, known as a 'treatment effects model,' has been used, for example, in the returns to education literature (see Barnow, Cain, and Goldberger (1981));

$$y = \boldsymbol{\beta}'\mathbf{x} + \delta z + \varepsilon,$$

$$z^* = \boldsymbol{\alpha}'\mathbf{w} + u,$$

$$z = 1 \text{ if } z^* > 0 \text{ and } z = 0 \text{ if } z^* \leq 0.$$

The indicator, z is assumed to indicate the presence or absence of some treatment, for example, participation in an experiment or going to college. This is the same as the selectivity model discussed earlier except that z itself appears in the primary equation. Thus, there is an endogenous variable in the regression equation. On the other hand, note that conditioned on z (i.e., the 'selection') this is the same model we have been examining so far. There are three approaches to estimation.

E52.3.1 Two Step Estimation

Barnow, et. al. suggest two methods of estimating this model. The simplest method is to use the selection model exactly as before. It is still necessary to estimate the probit equation for z and pass the results to **SELECT**. If z is now simply included among the Rhs variables in the **SELECT** command, consistent estimates of $\boldsymbol{\beta}$ and δ are obtained. It is necessary, however, in this case, to use the entire sample of data, so the additional specification **; All** is necessary. All other output, saved results, options, etc. for the **SELECT** command are the same. The initial results for the model will indicate that the entire sample is in use, as in the following:

```
+------------------------------------------------------------+
| Sample Selection Model                                     |
| Probit selection equation based on LFP                     |
| Sample is all observations.                                |
| Results of selection:                                      |
|                       Data points     Sum of weights       |
| Data set                   753             753.0           |
| Selected sample            753             753.0           |
+------------------------------------------------------------+
```

E52.3.2 Two Stage Least Squares – Instrumental Variable Estimation

A second means of estimating the model is with two stage least squares. The problem with ordinary least squares estimates of the model based on the observed data is the correlation between z and ε. A solution to the inconsistency of OLS is to use 2SLS, using as the instrumental variable for z the predicted probabilities from the probit equation. It is not necessary to **; Hold** the results of the probit in this case. The set of commands would be

```
NAMELIST   ; w = ...  ; x = ... $
PROBIT     ; Lhs = z ; Rhs = w ; Prob = zfit $
2SLS       ; Lhs = y ; Rhs = x,z
           ; Inst = x,zfit $
```

We note, there is a tendency in the literature to equate the simple replacement of z_i in the regression with the fitted probability as an instrumental variable estimator. Ordinary least squares is then used to estimate the parameters. We emphasize, this is not 2SLS for this model and the replacement variable is not an instrument, it is a proxy. Whether the estimator so constructed is even consistent is debatable. The following, developed below in the application, illustrates use of 2SLS to fit the treatment model. In the main equation, we fit an hours equation for the husband, where the 'treatment' is whether the wife is in the labor force.

```
NAMELIST   ; x  = one,ha,he,hw,faminc $
NAMELIST   ; w = one,we,age,agesq,kl6,k618 $
PROBIT     ; Lhs = lfp ; Rhs = w
           ; Prob  = pfit $
2SLS       ; Lhs = hhrs ; Rhs = x,lfp
           ; Inst = x,pfit $
```

E52.3.3 Maximum Likelihood Estimation

Finally, a third approach is full information maximum likelihood. The log likelihood for the treatment effects model is

$$\log L = \sum_{i=1}^{N} \log\left[\frac{\exp\left(-(1/2)\varepsilon_i^2/\sigma_\varepsilon^2\right)}{\sigma\sqrt{2\pi}}\Phi\left(\frac{(2z_i-1)(\rho\varepsilon_i/\sigma_e + \boldsymbol{\alpha}'\mathbf{w}_i)}{\sqrt{1-\rho^2}}\right)\right]$$

where $\varepsilon_i = y_i - \boldsymbol{\beta}'\mathbf{x}_i - \delta z_i$.

This is a straightforward modification of the estimator developed earlier for the selection model. To fit the treatment effects model, just add **; MLE** to the two step estimator. The commands are

```
PROBIT     ; Lhs = variable z ; Rhs = variables in w ; Hold $
SELECT     ; Lhs = variable y ; Rhs = variables in x, variable z ; All ; MLE $
```

E52.3.4 Application

In the following, we fit a 'treatment model' for the husband's hours, where the endogenous dummy variable is the wife's labor force participation. The following uses all three estimators.

```
NAMELIST    ; x  = one,ha,he,hw,faminc $
NAMELIST    ; w = one,we,age,agesq,kl6,k618 $
PROBIT      ; Lhs = lfp    ; Rhs = w ; Hold ; Prob = pfit $
SELECT      ; Lhs = hhrs ; Rhs = x,lfp ; All $
2SLS        ; Lhs = hhrs ; Rhs = x,lfp ; Inst = x,pfit $
SELECT      ; Lhs = hhrs ; Rhs = x,lfp ; All ; MLE $
```

These are the two step estimators using Heckman's method.

```

E52.4 Simultaneous Equations Models with Selectivity

A simultaneous equations model which is 'selected' is estimated in exactly the same fashion as a single equation, using a form of two stage least squares. (See Lee, Maddala, and Trost (1980).) We consider a simple three equation case; the extensions to other cases would be analogous. The assumed model is:

$$y_1 = \alpha_1 + \beta_{1,1}x_1 + \beta_{1,2}x_2 + \beta_{1,3}x_3 + \gamma_{1,2}y_2 + \varepsilon_1,$$

$$y_2 = \alpha_2 + \beta_{2,1}x_1 + \beta_{2,3}x_3 + \beta_{2,4}x_4 + \gamma_{2,1}y_1 + \varepsilon_2,$$

$$y_3 = \alpha_3 + \beta_{3,5}x_5 + \gamma_{3,1}y_1 + \gamma_{3,2}y_2 + \varepsilon_1 .$$

This structure is observed if $z = 1$; some other if $z = 0$. The general procedure would be:

Step 1. Estimate the probit selection equation.

Step 2. Estimate each equation of the reduced form and keep the fitted values.

Step 3. Estimate the structural equations using **SELECT**, using fitted instead of actual values on the right hand side of each equation.

Step 4. As in a conventional simultaneous equations model, it is necessary to use the original data, not the predicted values, when computing the estimate of the disturbance variance. (Step 4 is done automatically, internally.)

To accommodate the last of these, in order to estimate a simultaneous equations model with selectivity, after obtaining the predicted values at Step 3, the **SELECT** commands should be the same as the usual **2SLS** commands. That is,

```
SELECT      ; Lhs  = left hand side variable
            ; Rhs  = original variables including endogenous
            ; Inst = instruments, with fitted values in place of actual $
```

For the model shown above, the commands would be

```
NAMELIST    ; x = one,x1,x2,x3,x4,x5 $
PROBIT      ; Lhs = z   ; Rhs = list of variables in w ; Hold $
SELECT      ; Lhs = y1 ; Rhs = x ; Keep = y1fit $
SELECT      ; Lhs = y2 ; Rhs = x ; Keep = y2fit $
SELECT      ; Lhs = y3 ; Rhs = x ; Keep = y3fit $
SELECT      ; Lhs = y1 ; Rhs = one,x1,x2,x3,y2
            ; Inst = one,x1,x2,x3,y2fit $
SELECT      ; Lhs = y2 ; Rhs = one,x1,x3,x4,y1
            ; Inst = one,x1,x3,x4,y1fit $
SELECT      ; Lhs = y3 ; Rhs = one,x5,y1,y2
            ; Inst = one,x5,y1fit,y2fit $
```

No mention is made in the output of the simultaneous nature of the model, but the necessary adjustments are made internally. Since it is assumed that you are generating the predicted values yourself, it follows that the number of instruments is always identical to the number of Rhs variables. If not, an error is assumed, and estimation is terminated.

A small application based on our earlier example is shown below. In this model, it is assumed that hours (*whrs*) and wage (*ww*) are simultaneously determined.

```
NAMELIST    ; x  = one,kl6,k618,wa,we,wmed $
NAMELIST    ; w = one,kl6,wa $
PROBIT      ; Lhs = lfp    ; Rhs = w ; Hold $
SELECT      ; Lhs = whrs ; Rhs = x  ; Keep = whrsfit $
SELECT      ; Lhs = ww    ; Rhs = x  ; Keep = wwfit $
SELECT      ; Lhs = whrs ; Rhs = one,kl6,k618,wa,ww
            ; Inst = one,kl6,k618,wa,wwfit $
SELECT      ; Lhs = ww    ; Rhs = one,wa,we,wmed,whrs
            ; Inst = one,wa,we,wmed,whrsfit $
```

E52.5 Incidental Truncation

In the single equation probit/selection model, if there are no observations with $z = 0$, then the probit model cannot be estimated. Bloom and Killingsworth (1985) demonstrated that the model can still be fit, by maximum likelihood. The full specification is:

$$\begin{aligned} y &= \boldsymbol{\beta}'\mathbf{x} + \varepsilon, \\ z^* &= \boldsymbol{\alpha}'\mathbf{w} + u, \\ z &= 1 \text{ if } z^* > 0,\ z = 0 \text{ if } z^* \le 0, \\ \varepsilon,u &\sim N[0,0,\sigma_\varepsilon^2,1,\rho]. \end{aligned}$$

A probit model applies to z. In the usual circumstance, the familiar selectivity model applies. However, if observations on y, z, $\mathbf{x}$, and $\mathbf{w}$ are obtained only when z equals one, then the model is no longer estimable by the method of Heckman. (The dependent variable in the probit equation is always one.) But, the model is identified as long as ρ is nonzero, and can be estimated by maximum likelihood. The paper by Bloom and Killingsworth provides the methodology.

The data consist of a set of observations on y, $\mathbf{x}$, and $\mathbf{v}$, with which it is known at every observation that z equals one. (Observations on z are unnecessary.) The model command is

```
INCIDENTAL  ; Lhs  = y
            ; Rh1 = x
            ; Rh2 = w $
```

The only internal starting value for this model which seems viable is a pair of least squares estimators. Thus, starting values are obtained by regressing y on $\mathbf{x}$ to estimate $\boldsymbol{\beta}$ and y on $\mathbf{w}$ to estimate $\boldsymbol{\alpha}$. Admittedly, these starting values are inconsistent. The second set are particularly problematic. We use them only to provide some information on the relative scales of the coefficients in the second equation. The first variable in $\mathbf{w}$ must be the constant term, *one*. The starting value for ρ is the ratio of the first coefficient in the second equation to the estimate of σ from the first. (This is computed internally.) We assume that the constant term is first in the second equation.

The model parameters are $\boldsymbol{\theta} = [\boldsymbol{\beta},\boldsymbol{\alpha},\sigma,\rho]$. Use this ordering if you provide your own starting values for the iterations or use **; Rst** to impose restrictions. The retrievable results are

Matrices: *b* and *varb* include $[\boldsymbol{\beta},\boldsymbol{\alpha}]$. **; Par** adds (σ,ρ) to the parameter vector.

Scalars: *ybar, sy, nreg, kreg, logl, rho, varrho, exitcode*

Last Model: *b_variables in x, a_variables in v , sigma, reu*.

Last Function: None

All options for nonlinear models are available. In particular, the **; Test:** specification can be used to test the equality of coefficients across equations, and **; Rst** can be used to impose fixed value and within or cross equation equality restrictions. Predictions are computed using the formula given earlier for the standard selection model – once the parameters are in hand, the observed data can be treated as if the standard model applies.

Standard Model Specifications for the Incidental Truncation Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps ancillary parameters σ and ρ with main parameter $\boldsymbol{\beta}$ vector in *b*.
; Partial Effects	displays marginal effects, same as **; Marginal Effects**.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix	displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Cluster = spec	requests computation of the cluster form of corrected covariance estimator.
; Robust	requests a ‘sandwich’ estimator or robust covariance matrix for TSCS and some discrete choice models (uses **; Cluster = 1**).

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg [= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb [= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level ‘**n**’ is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E53: Sample Selection Models for Panel Data

E53.1 Introduction

Heckman's now canonical form of the sample selection model is a linear regression with a binary probit selection criterion model:

$$
\begin{aligned}
y &= \boldsymbol{\beta}'\mathbf{x} + \varepsilon, \\
z^* &= \boldsymbol{\alpha}'\mathbf{w} + u, \\
\varepsilon, u &\sim N[0,0,\sigma_\varepsilon^2, \sigma_u^2, \rho].
\end{aligned}
$$

A bivariate classical (seemingly unrelated) regressions model applies to the structural equations. The standard deviations are σ_ε and σ_u, and the covariance is $\rho\sigma_\varepsilon\sigma_u$. If the data were randomly sampled from this bivariate population, the parameters could be estimated by least squares, or GLS combining the two equations. However, z^* is not observed. Its observed counterpart is z, which is determined by

$$z = 1 \text{ if } z^* > 0$$

and

$$z = 0 \text{ if } z^* \leq 0.$$

Values of y and $\mathbf{x}$ are only observed when z equals one. The essential feature of the model is that under the sampling rule, $E[y|\mathbf{x},z=1]$ is not a linear regression in $\mathbf{x}$, or $\mathbf{x}$ and z. The development below presents estimators for the class of essentially nonlinear models that emerge from this specification.

The basic command structure for the models described in this chapter is

PROBIT ; Lhs = variable z ; Rhs = variables in w ; Hold $
SELECT ; Lhs = variable y ; Rhs = variables in x $

Note that two commands are required for estimation of the sample selection model, one for each structural equation. Chapter E52 defined several estimators appropriate for cross sectional treatment of the model. This chapter will develop some panel data approaches.

E53.2 Panel Data Treatments

The literature on panel data models for the sample selection is rather incomplete and ambiguous. Applications are relatively sparse, and few useable general modeling frameworks have been proposed. The earliest contribution appears to be Hausman and Wise's (1979) paper on attrition (see Section E53.7 for the estimator) which is a contemporary of Heckman's seminal paper on cross sections. The Hausman and Wise model is a two period fully parametric model. The literature has come nearly full circle since then, in that some of the later work (Kyriazidou (1997) focuses once again on the two period framework. (In Hausman and Wise's case, two periods was a natural application, as their interest lay in the beginning (baseline) and ending point of a study, whereas in the more recent analyses, two periods is often assumed of necessity to make the analysis tractable.)

Fixed and random effects, and hybrid models have been suggested by Verbeek (1990), Zabel (1992) and Verbeek and Nijman (1992). The estimators suggested here build on the suggestions by these authors, and extend them in several directions. The following modeling frameworks are provided:

Fixed Effects

$$y_{it} = \theta_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it},\ [u_{it}, \varepsilon_{it}] \sim \text{BVN}[(0,0),1,\sigma,\rho]$$

$$z_{it}^* = \alpha_i + \boldsymbol{\delta}'\mathbf{w}_{it} + u_{it}$$

$$z_{it} = \mathbf{1}(z_{it}^* > 0)$$

y_{it}, $\mathbf{x}_{it}$ observed only when $z_{it} = 1$.

Random Effects

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + c_i,\ \varepsilon_{it} \sim \text{N}[0,\sigma^2],\ c_i \sim \text{N}[0,\sigma_c^2]$$

$$z_{it}^* = \boldsymbol{\alpha}'\mathbf{w}_{it} + u_{it} + d_i$$

$$z_{it} = 1(z_{it}^* > 0),\ u_{it} \sim \text{N}[0,1],\ d_i \sim \text{N}[0,\sigma_d^2]$$

y_{it}, $\mathbf{x}_{it}$ observed only when $z_{it} = 1$,

$$\text{Corr}[\varepsilon_{it},u_{it}] = \rho$$

$$\text{Corr}[c_i, d_i] = \theta$$

Random Parameters

$$y_{it} = \boldsymbol{\beta}_i'\mathbf{x}_{it} + \varepsilon_{it}\ \ \varepsilon_{it} \sim \text{N}[0,\sigma^2], \qquad \boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}_\beta\mathbf{f}_i + \boldsymbol{\Gamma}_\beta\mathbf{v}_i$$

$$z_{it}^* = \boldsymbol{\alpha}_i'\mathbf{w}_{it} + u_{it},\ u_{it} \sim \text{N}[0,1], \qquad \boldsymbol{\alpha}_i = \boldsymbol{\alpha} + \boldsymbol{\Delta}_\alpha\mathbf{g}_i + \boldsymbol{\Gamma}_\alpha\mathbf{h}_i,$$

$$z_{it} = 1(z_{it}^* > 0)$$

y_{it}, $\mathbf{x}_{it}$ observed when $z_{it} = 1$

$$\text{Corr}[\varepsilon_{it},u_{it}] = \rho$$

Hausman and Wise's Attrition Model

$$y_{i1} = \mathbf{x}_{i1}'\boldsymbol{\beta} + \varepsilon_{i1} + u_i,\ \sigma^2 = \text{Var}[\varepsilon_{i1} + u_i] \qquad \text{(first period regression)}$$

$$y_{i2} = \mathbf{x}_{i2}'\boldsymbol{\beta} + \varepsilon_{i2} + u_i \qquad \text{(second period regression, same } u_i\text{)}$$

$$z_{i2}^* = \delta y_{i2} + \mathbf{x}_{i2}'\boldsymbol{\theta} + \mathbf{w}_{i2}'\boldsymbol{\alpha} + v_{i2} \qquad \text{(attrition mechanism)}$$

$$z_{i2}^* = \mathbf{x}_{i2}'(\delta\boldsymbol{\beta} + \boldsymbol{\theta}) + \mathbf{w}_{i2}'\boldsymbol{\alpha} + \delta\varepsilon_{i2} + v_{i2} = \mathbf{r}_{i2}'\boldsymbol{\gamma} + h_{i2}.$$

$$z_{i2} = 1(z_{i2}^* > 0) \qquad \text{(attrition indicator observed in period 2)}$$

$$\rho_{12} = \text{Corr}[\varepsilon_{i1} + u_i, \varepsilon_{i2} + u_i] = \text{Var}[u_i] / \sigma^2$$

$$\rho_{23} = \text{Corr}[h_{i2}, \varepsilon_{i2} + u_i]$$

In each case, there are several different forms of the model which may be specified.

E53.3 Sample Selection Models with Fixed Effects

A sample selection model with fixed effects would appear as follows: The structural probit model would be

$$z_{it}^* = \alpha_i + \boldsymbol{\delta}'\mathbf{w}_{it} + u_{it}$$

$$z_{it} = \mathbf{1}(z_{it}^* > 0)$$

The primary regression equation is, then

$$y_{it} = \theta_i + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it},\ [u_{it}, \varepsilon_{it}] \sim \text{BVN}[(0,0),1,\sigma,\rho]$$

y_{it}, $\mathbf{x}_{it}$ are observed only when $z_{it} = 1$.

Thus, the familiar selection model applies for each person in each period. This model is fit by a hybrid two step maximum likelihood procedure described below.

NOTE: If you wish to include time effects in this model, you must create them separately as dummy variables and include them in the model specifications. In order to implement the procedure described below, it is necessary to disable the automatic creation of the time dummies in this model.

The command for this model is completely self contained. Use

```
SELECT    ; Lhs = y, z (specify both dependent variables)
          ; Rhs = list of variables in x
          ; Rh2 = list of variables in w
          ; FEM
          ; Pds = specification of the panel $
```

It is not necessary to precede this with a **PROBIT** command, as the probit equation is fit at the same time as the selection model. The 'treatment effects' model, in which z_{it} appears in the regression and all observations are used,

$$y_{it} = \theta_i + \mu z_{it} + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it},\ [u_{it}, \varepsilon_{it}] \sim \text{BVN}[(0,0),1,\sigma,\rho],$$

may be requested as in the cross section case by just including z in the Rhs list for the regression (if appropriate) and adding the request to the command:

; All

A special case in the data must be considered when fitting this model. If the probit model for individual i cannot be fit because z_{it} is always zero or one in every period, then the selection model cannot be either. Such groups must be skipped over in estimation of the model. This is the same condition that must be met for the probit model, but it is more likely to be a problem in this setting, as the selection is likely to be the same in every period. One possibility might be a model extension which treats selection as observation of the entire group or not, instead of period by period. This remains to be developed – the nature of the underlying correlation is complicated by this modification.

Results that are kept for this model are

Matrices:	*b*	= estimate of **β**
	varb	= asymptotic covariance matrix for estimate of **β**.
	alphafe	= estimated fixed effects
Scalars:	*kreg*	= number of variables in Rhs
	nreg	= number of observations
	logl	= log likelihood function

Last Model: *b_variables*

Last Function: None

Asymptotic standard errors for the estimator in this model are computed by using bootstrapping. In order to request the computation of bootstrapped standard errors, add

; Nbt = the desired number of replications

Computation of the model is not always possible. As such, some of the bootstrap replications may fail. A trace of the replications appears in the model results. The example below illustrates. To compute the asymptotic standard errors without bootstrapping, use

; Nbt = 1

In this instance, the standard errors are computed as if the probit model estimates were known – that is, as if this were not a two step estimator.

E53.3.1 Standard Model Specifications

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Partial Effects displays marginal effects, same as **; Marginal Effects**.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Prob = name	saves probabilities as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.

E53.3.2 Application

The following illustrates this estimator with a random sample drawn so that there are 200 individuals and 15 periods of observation:

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-3000 $
MATRIX      ; ai = Rndm(200) ; ci = Rndm(200) $
CREATE      ; i = Trn(15,0) ; u = Rnn(0,1) ; e = .5*u+.5*Rnn(0,1) $
CREATE      ; z1 = Rnn(0,1) ; z2 = Rnn(0,1)
            ; d = (.5*z1+.5*z2+ai(i)+u) > 0 $
CREATE      ; x1 = Rnn(0,1) ; x2 = Rnn(0,1)  ; y = x1+x2+ci(i)+e $
SELECT      ; Lhs = y,d
            ; Rh1 = x1,x2 ; Rh2 = z1,z2
            ; FEM ; Pds = 15 ; Nbt = 10 $
```

These are the initial probit estimates computed to obtain the initial values.

```

E53.3.3 Technical Details on FE Selection Models

The log likelihood function for this model including all parameters, for the *i*th individual in the sample is as follows:

$$\log L_i = \sum_{z_{it}=0} \log \boldsymbol{\Phi}\left(-\alpha_i - \boldsymbol{\delta}'\mathbf{w}_{it}\right) +$$

$$\sum_{z_{it}=1} \left[\begin{array}{l} \dfrac{-\log 2\pi}{2} - \log\sigma - \dfrac{(y_{it} - \theta_i - \boldsymbol{\beta}'\mathbf{x}_{it})^2}{2\sigma^2} + \\ \log \boldsymbol{\Phi}\left[\dfrac{(\alpha_i + \boldsymbol{\delta}'\mathbf{w}_{it}) + (\rho/\sigma)(y_{it} - \theta_i - \boldsymbol{\beta}'\mathbf{x}_{it})}{\sqrt{1-\rho^2}} \right] \end{array} \right]$$

The full log likelihood is then summed over all individuals. We first make the following reparameterizations:

$$\eta = 1/\sigma$$

$$\boldsymbol{\gamma} = (1/\sigma)\boldsymbol{\beta}$$

$$\kappa_i = \theta_i / \sigma$$

$$\tau = \rho/\sqrt{1-\rho^2}$$

This greatly simplifies the log likelihood:

$$\log L_i = \sum_{z_{it}=0} \log \boldsymbol{\Phi}\left(-\alpha_i - \delta'\mathbf{w}_{it}\right) +$$

$$\sum_{z_{it}=1} \left[\begin{array}{l} \dfrac{-\log 2\pi}{2} + \log\eta - (\eta y_{it} - \kappa_i - \boldsymbol{\gamma}'\mathbf{x}_{it})^2 + \\ \log \boldsymbol{\Phi}\left[\left(\sqrt{1+\tau^2}\right)(\alpha_i + \boldsymbol{\delta}'\mathbf{w}_{it}) + \tau(\eta y_{it} - \kappa_i - \boldsymbol{\gamma}'\mathbf{x}_{it}) \right] \end{array} \right]$$

In principle, this can now be maximized to provide fully efficient maximum likelihood estimates of the model's parameters. However, this would entail simultaneous estimation of two sets of fixed effects parameters. We do this in two steps instead, in a fashion similar to the Heckman style two step estimator for the cross section counterpart.

Step 1. The fixed effects probit estimator is estimated using the method described in Section R23.2.3. The model estimates are retained for Step 2.

Step 2. The log likelihood function is now conditioned on the probit estimates obtained at Step 1.

Let

$$\mu_{it} = \alpha_i + \delta' w_{it}$$

and let m_{it} denote the estimate of μ_{it} obtained by computing it at the Step 1 probit estimates. The conditional log likelihood is

$$\log L_C = \sum_{z_{it}=0} \log \boldsymbol{\Phi}\left(-m_{it}\right) \quad +$$

$$\sum_{z_{it}=1} \left[\begin{array}{l} \dfrac{-\log 2\pi}{2} + \log \eta - (\eta y_{it} - \kappa_i - \boldsymbol{\gamma}'\mathbf{x}_{it})^2 \\ + \log \boldsymbol{\Phi}\left[\left(\sqrt{1+\tau^2}\right) m_{it} + \tau(\eta y_{it} - \kappa_i - \boldsymbol{\gamma}'\mathbf{x}_{it}) \right] \end{array} \right]$$

At this step, the conditional log likelihood function is maximized with respect to the remaining parameters, η, κ_i, $\boldsymbol{\gamma}$, and τ. Note that the $z_{it} = 0$ observations are not used in obtaining this solution. In the treatment effects model, once again, only terms from the second part of the function are included, but the sign and form of the argument in $\Phi(.)$ is changed appropriately. If the treatment effects model is requested, then the sign of the term in the second part of the log likelihood is also changed accordingly, observation by observation. No other changes are needed internally.

Aside from the aforementioned incidental parameters problem, these estimates are consistent, albeit inefficient. However, since it is a two step estimator, the estimated asymptotic covariance matrix is inappropriate as it does not account for the randomness induced by estimation of the probit parameters used to compute m_{it}. In other applications we have used the Murphy and Topel estimator to complete this computation. In this case, however, that would require a full covariance matrix for the fixed effects parameters in the probit model and, moreover, require an exorbitant amount of computation. With contemporary computers, the latter consideration is generally going to be minor, but the former remains problematic.

As an alternative, we use the bootstrap method of obtaining an estimator of the asymptotic covariance matrix. Our approach is as follows: The number of bootstrap replications is set either at 20 or with

; Nbt = desired number of replications.

Within each replication, the bootstrap is drawn over the set of *N* individuals, not over the full sample. Suppose, for example, the sample contains 200 people, each observed 15 times (our earlier application). The bootstrap samples are then drawn from these 200 individuals, each with their 15 observations. Then, the entire two step procedure is computed for each replication – both the probit model and the selection model.

There is an additional complication. The log likelihood for the sample selection model is not globally concave. As a consequence, the iterations at Step 2 occasionally break down because the Hessian becomes indefinite. If this occurs during the initial estimation, the process is halted. However, if this occurs during a bootstrap replication the program tries again with a new bootstrap sample. This 'retry' is repeated up to 10 times. If after 10 tries it remains impossible to obtain a set of estimates, the routine gives up.

E53.4 Sample Selection Models with Random Effects

There is a lengthy literature on fixed and random effects in sample selection models. The fixed effects model was presented in the preceding section. The random effects model is cast in its simplest terms in Verbeek (1990), Zabel (1992) and Verbeek and Nijman (1992). The structural equations are:

Regression

$$y_{it} = \beta' \mathrm{x}_{it} + \varepsilon_{it} + c_i, \ \varepsilon_{it} \sim N[0,\sigma^2], \text{ nonautocorrelated}$$

Selection Mechanism

$$z_{it}^* = \boldsymbol{\alpha}'\mathbf{w}_{it} + u_{it} + d_i$$

$$z_{it} = 1(z_{it}^* > 0), \ u_{it} \sim N[0,1]$$

Selection

$$y_{it}, \mathrm{x}_{it} \quad \text{observed only when } z_{it} = 1,$$

$$\mathrm{Corr}[\varepsilon_{it},u_{it}] = \rho$$

The random effects, (c_i, d_i) are assumed to be bivariate normally distributed with zero means, standard deviations σ_c and σ_d and correlation θ. 'Selectivity' comes in two forms here, through the correlation of the unique components, ε_{it} and u_{it}, and the correlation of the group specific components, c_i and d_i. Estimable parameters in this model are the slope parameters, $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$, variance parameters σ_c and σ_d and the two correlation parameters.

NOTE: This model is fit by maximum simulated likelihood, not by two step least squares. There is no 'lambda' variable, $\phi(...)/\Phi(...)$ created or used during the estimation, so no coefficient for this variable will appear in the results.

E53.4.1 Including Group Means

A standard criticism of the random effects approach is that the group effects are likely to be correlated with the included variables. Zabel (1992) suggests that this can be remedied by including the group means of the variables in the models. The modified specification is

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}'\overline{\mathbf{x}}_i + \varepsilon_{it} + c_i, \ \varepsilon_{it} \sim N[0,\sigma^2], \text{ nonautocorrelated}$$

$$z_{it}^* = \boldsymbol{\alpha}'\mathbf{w}_{it} + \boldsymbol{\gamma}'\overline{\mathbf{w}}_i + u_{it} + d_i$$

with the same stochastic specification.

E53.4.2 Treatment Effects

The 'treatment effects' model, in which z_{it} appears in the regression and all observations are used,

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \boldsymbol{\delta}'\overline{\mathbf{x}}_i + \gamma z_{it} + \varepsilon_{it} + c_i, \ \varepsilon_{it} \sim N[0,\sigma^2], \text{ nonautocorrelated}$$

is requested as in the cross section case by just including z in the Rhs list for the regression (if appropriate) and adding the request to the command:

; All

E53.4.3 Commands

This model is fit as a random parameters model, using simulation rather than quadrature to do the estimation. It must be fit in three steps as shown below

Step 1. Compute the probit model to define selection mechanism

PROBIT ; Lhs = variable zit ; Rhs = one,... ; Hold $

Step 2. Selection model to produce good starting values

SELECT ; Lhs = variable yit ; Rhs = one,... ; MLE $

Step 3. Random effects model

SELECT ; Lhs = variable zit ; Rhs = one,...
; RPM ; Pds = panel specification
; Fcn = REM $

NOTE: Both equations must include a constant term, *one*.

The model part of the second **SELECT** command is the same as that in the first one. Zabel's modification is requested by adding

; Means

to the **SELECT** command. The default specification is uncorrelated group effects ($\theta = 0$). This may be relaxed by adding

; Correlated

to the command. Our experience suggests that the identification of θ is a bit weak. In the experiment below, in a large sample of $N = 300$, $T = 15$, in which the correlation is zero by construction in the original data, the estimate of it is, nonetheless, large and highly significant. However, convergence of the iterations could not be reached; the likelihood surface became quite flat in the dimension of θ in a range in which the derivatives with respect to the other parameters were fairly far from zero.

E53.4.4 Other Model Specifications

This model is estimated as a random parameters model with two random coefficients, the constants in the two equations. The set of options for the model specification are the same as for other random parameters models. See Chapter R24 for discussion. The results retained by this estimator are

Matrices:	*b*	= full coefficient vector
	varb	= full estimated asymptotic covariance matrix
Scalars:	*nreg*	= total number of observations
	kreg	= number of parameters estimated
	logl	= log likelihood
	s	= estimate of σ
	rho	= estimate of ρ

E53.4.5 Application

The model is applied to the data used to illustrate the fixed effects model. By construction, these data actually conform to the random effects model without the means included and with uncorrelated effects. Each formulation begins with the initial **PROBIT** followed by **SELECT**.

Basic Random Effects Formulation

```
PROBIT    ; Lhs = d ; Rhs = one,z1,z2 ; Hold $
SELECT    ; Lhs = y ; Rhs = one,x1,x2 ; MLE ; Par $
SELECT    ; Lhs = y ; Rhs = one,x1,x2
          ; RPM ; Pds = 15 ; Fcn = REM $
```

Random Effects with Group Means (First SELECT is the same)

```
SELECT    ; Lhs = y ; Rhs = one, x1,x2
          ; RPM ; Pds = 15 ; Fcn = REM ; Means $
```

Correlated Random Effects (First SELECT is the same)

```
SELECT    ; Lhs = y ; Rhs = one,x1,x2
          ; RPM ; Pds = 15 ; Fcn = REM ; Correlated ; Halton $
```

Group Means and Correlated Random Effects (First SELECT is the same)

```
SELECT    ; Lhs = y ; Rhs = one,x1,x2
          ; RPM ; Pds = 15 ; Fcn = REM ; Means ; Correlated ; Halton $
```

We show the full set of results for the second model, the REM with group means.

E53.4.6 Technical Details on RE Selection Models

The log likelihood function for one group for the sample selection model is built up from the structure

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + c_i,\ \ \varepsilon_{it} \sim N[0,\sigma^2], \text{ nonautocorrelated}$$

$$z_{it}^* = \boldsymbol{\alpha}'\mathbf{w}_{it} + u_{it} + d_i$$

$$z_{it} = 1(z_{it}^* > 0),\ u_{it} \sim N[0,1]$$

The contribution of the ith group to the log likelihood (which is then summed) is

$$\log L_i \mid c_i,d_i = \sum\nolimits_{z_{it}=0} \log \boldsymbol{\Phi}\left(-d_i - \boldsymbol{\alpha}'\mathbf{w}_{it}\right) + \sum\nolimits_{z_{it}=1} \left[\begin{array}{l} \dfrac{-\log 2\pi}{2} - \log\sigma - \dfrac{(y_{it} - c_i - \boldsymbol{\beta}'\mathbf{x}_{it})^2}{2\sigma^2} + \\ \log\boldsymbol{\Phi}\left[\dfrac{(d_i + \boldsymbol{\alpha}'\mathbf{w}_{it}) + (\rho/\sigma)(y_{it} - c_i - \boldsymbol{\beta}'\mathbf{x}_{it})}{\sqrt{1-\rho^2}}\right] \end{array}\right]$$

We reparameterize the log likelihood as follows:

$$\theta = 1/\sigma$$

$$\boldsymbol{\gamma} = (1/\sigma)\boldsymbol{\beta}$$

$$\tau = \rho / \sqrt{1-\rho^2}$$

We also isolate the two constant terms, α_0 and β_0 (γ_0 after the Olsen normalization) so that in the formulation below, the slope vectors do not contain constant terms. We also allow the group means for the nonconstant variables in **w** and **x** to appear in the vectors below, but there is no need to note them in particular in the derivation, so we leave them implicit. With these reparameterizations, the function becomes

$$\log L_i \mid c_i, d_i = \sum\nolimits_{z_{it}=0} \log\boldsymbol{\Phi}\left(-\alpha_0 - d_i - \boldsymbol{\alpha}'\mathbf{w}_{it}\right) + \sum\nolimits_{z_{it}=1} \left(\begin{array}{l} \dfrac{-\log 2\pi}{2} + \log\theta - \dfrac{(\theta y_{it} - (\gamma_0 + c_i) - \boldsymbol{\gamma}'\mathbf{x}_{it})^2}{2} \\ + \log\boldsymbol{\Phi}\left\{\begin{array}{l} \sqrt{1+\tau^2}\left[(\alpha_0 + d_i) + \boldsymbol{\alpha}'\mathbf{w}_{it}\right] \\ +\tau\left(\theta y_{it} - (\gamma_0 + c_i) - \boldsymbol{\gamma}'\mathbf{x}_{it}\right) \end{array}\right\} \end{array}\right)$$

The treatment effects model removes the first term and changes the sign of the argument in the CDF in the second term when $z_{it} = 0$, but no other changes are necessary. The unconditional log likelihood is found by integrating out the effects, c_i and d_i which we do with the simulation procedure described in Section R24.7. This is the form of our random parameters model as described there, in this case with exactly two random parameters. The original parameters are recovered after estimation, with standard errors obtained via the delta method.

E53.5 Random Parameters Sample Selection Models

The random parameters form of the sample selection model contains several structural equations.

Regression

$$y_{it} = \boldsymbol{\beta}_i'\mathbf{x}_{it} + \varepsilon_{it} \quad \varepsilon_{it} \sim N[0,\sigma^2], \text{ nonautocorrelated,}$$

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}_\beta \mathbf{f}_i + \boldsymbol{\Gamma}_\beta \mathbf{v}_i$$

Selection Mechanism

$$z_{it}^* = \boldsymbol{\alpha}_i'\mathbf{w}_{it} + u_{it},$$

$$\boldsymbol{\alpha}_i = \boldsymbol{\alpha} + \boldsymbol{\Delta}_\alpha \mathbf{g}_i + \boldsymbol{\Gamma}_\alpha \mathbf{h}_i,$$

$$z_{it} = 1(z_{it}^* > 0), \; u_{it} \sim N[0,1]$$

Observation Mechanism

$$y_{it}, \mathbf{x}_{it} \quad \text{observed when } z_{it} = 1$$

‘Selectivity’

$$(\varepsilon_{it},u_{it}) \sim N[(0,0),(\sigma^2,1,\rho\sigma)], \; \text{Corr}[\varepsilon_{it},u_{it}] = \rho$$

Our implementation of this model is the same as the one with all nonrandom parameters. Although the model here is fit by maximum likelihood, it is fit in two steps in the fashion of the two step least squares estimator described earlier in this chapter. In the first step, the probit model is fit and the results are stored for use by the selection model. In the second, the regression with selection is fit conditionally on the first step estimation.

NOTE: This model is fit by maximum simulated likelihood, not by two step least squares. There is no ‘lambda’ variable, $\phi(...)/\Phi(...)$ created or used during the estimation, so no coefficient for this variable will appear in the results.

E53.5.1 Treatment Effects

The ‘treatment effects’ model, in which z_{it} appears in the regression and all observations are used,

$$y_{it} = \boldsymbol{\beta}_i'\mathbf{x}_{it} + \gamma_i z_{it} + \varepsilon_{it} \quad \varepsilon_{it} \sim N[0,\sigma^2], \text{ nonautocorrelated}$$

is requested as in the cross section case by just including *z* in the Rhs list for the regression (if appropriate) and adding the request to the command:

; All

E53.5.2 Commands

This must be fit in two parts as shown below: The probit model need not be a random parameters model; it can be fit as a standard model with nonrandom parameters if desired.

PROBIT ; Lhs = ... ; Rhs = ... ; Hold
[; RPM ; Pds = ... ; Fcn = ... ; Pts = ...] $
SELECT ; Lhs = ... ; Rhs = ...
; RPM ; Pds = ... ; Fcn = ... $

Zabel's modification is requested by adding

; Means

to the **SELECT** command. All other options for the random parameters are available, including

; Correlated	to allow random parameters to be freely correlated
; AR1	for autoregressive random effects
; RPM = **list**	of variables if means of parameters are heterogeneous
; Pts = n	for the number of replications
; Halton	to use Halton draws

and so on. (Details appear in Chapter R24.) Fitted values and residuals may be computed requesting

; Par	to keep individual specific parameter estimates.
; Keep = name	to retain fitted values
; Res = name	to retain residuals

These are computed using individual specific coefficient vectors.

E53.5.3 Results

The results retained by this estimator are

Matrices:	*b*	= full coefficient vector
	varb	= full estimated asymptotic covariance matrix
	beta_i	= individual specific parameters, if **; Par** is requested.
Scalars:	*nreg*	= total number of observations
	kreg	= number of parameters estimated
	logl	= log likelihood
	s	= estimate of σ
	rho	= estimate of ρ

E53.5.4 Application

There are many possible variants of the random parameters model. The following illustrates the simplest case, in which the template sample selection model is specified and coefficients in the selection model are random and uncorrelated.

```
PROBIT    ; Lhs  = d   ; Rhs = one,z1,z2 ; Hold ; RPM
          ; Pds  = 15 ; Fcn = one(n), z1(n), z2(n) ; Pts = 25 ; Halton $
SELECT    ; Lhs  = y   ; Rhs = one,x1,x2 ; RPM
          ; Pds  = 15 ; Fcn = one(n), x1(n), x2(n) ; Pts = 25 ; Halton $
```

E53.5.5 Technical Details on the RP Selection Model

The log likelihood function for one group for the sample selection model is built up from the general random parameters structure

$$
\begin{aligned}
y_{it} &= \boldsymbol{\beta}_i'\mathbf{x}_{it} + \varepsilon_{it} \quad \varepsilon_{it} \sim \mathrm{N}[0,\sigma^2], \text{ nonautocorrelated,}\\
\boldsymbol{\beta}_i &= \boldsymbol{\beta} + \boldsymbol{\Delta}_\beta \mathbf{f}_i + \boldsymbol{\Gamma}_\beta \mathbf{v}_i\\
z_{it}^* &= \boldsymbol{\alpha}_i'\mathbf{w}_{it} + u_{it},\\
\boldsymbol{\alpha}_i &= \boldsymbol{\alpha} + \boldsymbol{\Delta}_\alpha \mathbf{g}_i + \boldsymbol{\Gamma}_\alpha \mathbf{h}_i,\\
z_{it} &= 1(z_{it}^* > 0),\ u_{it} \sim \mathrm{N}[0,1]
\end{aligned}
$$

The contribution of the *i*th group to the log likelihood (which is then summed) is

$$
\log L_i \mid \mathbf{v}_i,\mathbf{h}_i = \sum\nolimits_{z_{it}=0} \log \Phi\left(-\boldsymbol{\alpha}_i'\mathbf{w}_{it}\right) + \sum\nolimits_{z_{it}=1} \left(\begin{array}{l} \dfrac{-\log 2\pi}{2} - \log\sigma - \dfrac{(y_{it}-\boldsymbol{\beta}_i'\mathbf{x}_{it})^2}{2\sigma^2} + \\ \log\Phi\left[\dfrac{(\boldsymbol{\alpha}_i'\mathbf{w}_{it}) + (\rho/\sigma)(y_{it}-\boldsymbol{\beta}_i'\mathbf{x}_{it})}{\sqrt{1-\rho^2}}\right] \end{array} \right)
$$

The ancillary parameters, σ and ρ are assumed to be nonrandom as usual. This model is fit in two steps. In the first, the probit model is estimated as usual for the Heckman procedure or as a random parameters model. The results are retained for later use. If the probit model has been fit as a random parameters model, then the means of the parameter distributions are retained for use in the second step.

We then reparameterize the log likelihood as follows:

θ = $1/\sigma$

$\boldsymbol{\gamma}_i$ = $(1/\sigma)\boldsymbol{\beta}_i$ (this also scales $\boldsymbol{\beta}$, $\boldsymbol{\Delta}_\beta$ and $\boldsymbol{\Gamma}_\beta$)

τ = $\rho / \sqrt{1-\rho^2}$

a_{it} = $\boldsymbol{\alpha}'\mathbf{w}_{it}$ (where $\boldsymbol{\alpha}$ is the standard probit estimates or the means of the random parameters in the random parameters probit model.)

With these reparameterizations, the function becomes

$$\log L_i \mid \mathbf{v}_i,\mathbf{h}_i = \sum_{z_{it}=0} \log \boldsymbol{\Phi}\left(-a_{it}\right) + \sum_{z_{it}=1} \left(\begin{array}{l} \dfrac{-\log 2\pi}{2} + \log\theta - \dfrac{(\theta y_{it} - \boldsymbol{\gamma}_i'\mathbf{x}_{it})^2}{2} + \\ \log\boldsymbol{\Phi}\left\{\sqrt{1+\tau^2}\left[a_{it}\right] + \tau\left(\theta y_{it} - \boldsymbol{\gamma}_i'\mathbf{x}_{it}\right)\right\} \end{array} \right)$$

After the normalization, a_{it} (and the first term in the function) becomes irrelevant to the solution. The second term is then maximized using the template form of the random parameters model discussed in Chapter R24. When estimation is complete, the asymptotic covariance matrix is obtained by the delta method. Finally, the Murphy and Topel procedure is used to account for the presence of the estimated parameters in a_{it}. This particular form of the model is a fairly straightforward form of the random parameters structure.

E53.6 FIML Estimator for the RP Selection Model

The preceding section describes a two step random parameters model estimator. At the first step, the probit model is constructed. This may be a random parameters model or a fixed parameters model. At the second step, the random parameters sample selection model is estimated, taking the estimated probit model as fixed. The log likelihood that is maximized is

$$\log L_i \mid \mathbf{v}_i,\mathbf{h}_i = \sum_{z_{it}=0} \log \boldsymbol{\Phi}\left(-a_{it}\right) + \sum_{z_{it}=1} \left(\begin{array}{l} \dfrac{-\log 2\pi}{2} + \log\theta - \dfrac{(\theta y_{it} - \boldsymbol{\gamma}_i'\mathbf{x}_{it})^2}{2} + \\ \log\boldsymbol{\Phi}\left\{\sqrt{1+\tau^2}\left[a_{it}\right] + \tau\left(\theta y_{it} - \boldsymbol{\gamma}_i'\mathbf{x}_{it}\right)\right\} \end{array} \right)$$

where $a_{it} = \boldsymbol{\alpha}'\mathbf{w}_{it}$ from the probit model. Thus, a_{it} is taken as data, and α is not reestimated.

You may also estimate the full model with all parameters random simultaneously. The log likelihood function that is maximized is

$$\log L_i \mid \mathbf{v}_i,\mathbf{h}_i \;=\; \sum\nolimits_{z_{it}=0} \log\Phi\left(-\boldsymbol{\alpha}_i'\mathbf{w}_{it}\right) \;+$$

$$\sum\nolimits_{z_{it}=1}\left(\begin{array}{l}\dfrac{-\log 2\pi}{2} - \log\sigma - \dfrac{(y_{it}-\boldsymbol{\beta}_i'\mathbf{x}_{it})^2}{2\sigma^2} + \\ \log\Phi\left[\dfrac{(\boldsymbol{\alpha}_i'\mathbf{w}_{it}) + (\rho/\sigma)(y_{it}-\boldsymbol{\beta}_i'\mathbf{x}_{it})}{\sqrt{1-\rho^2}}\right]\end{array}\right)$$

All location parameters in both the probit model and in the regression model can be modeled as random. As before, we use the Olsen transformation to simplify the estimation;

$$\theta \;=\; 1/\sigma$$

$$\boldsymbol{\gamma}_i \;=\; (1/\sigma)\boldsymbol{\beta}_i \;\; \text{(this also scales } \boldsymbol{\beta}, \boldsymbol{\Delta}_\beta \text{ and } \boldsymbol{\Gamma}_\beta\text{)}$$

$$\tau \;=\; \rho \,/\, \sqrt{1-\rho^2}$$

This model is essentially the same as the one in the previous section. The difference is that the parameters of the distribution of $\boldsymbol{\alpha}_i$ are reestimated – it is a full information estimator. The command is

```
PROBIT or LOGIT ; … ; Hold $  (as usual for selection models)
SELECT          ; MLE ; Lhs = y,d
                ; Rhs = Rhs in the selection regression
                ; Rh2 = Rhs in the binary variable (probit or logit) equation
                ; RPM … as usual
                ; Pds  = setting is optional, 1 period is the default
                ; Pts  = setting if desired

```

E53.7 The Hausman and Wise Attrition Model

The recent literature on sample selection contains numerous analyses of two period models, such as Kyriazidou (1997). They tend to focus on non- and semiparametric analyses. An early parametric contribution of Hausman and Wise (1979) is considered here. The model is specifically a two period model of attrition, which would seem to characterize many of the studies suggested in the current literature (which is why we consider it here). The model formulation is a two period random effects formulation:

$$y_{i1} = \mathbf{x}_{i1}'\boldsymbol{\beta} + \varepsilon_{i1} + u_i \quad \text{(first period regression)}$$

$$y_{i2} = \mathbf{x}_{i2}'\boldsymbol{\beta} + \varepsilon_{i2} + u_i \quad \text{(second period regression).}$$

Attrition is likely in the second period (to begin the study, the individual must have been observed in the first period). The authors suggest that the probability that an observation is made in the second period varies with the value of y_{i2} as well as some other variables,

$$z_{i2}^* = \delta y_{i2} + \mathbf{x}_{i2}'\boldsymbol{\theta} + \mathbf{w}_{i2}'\boldsymbol{\alpha} + v_{i2.}$$

Attrition occurs if $z_{i2}^* \leq 0$, which produces a probit model,

$$z_{i2} = 1(z_{i2}^* > 0) \qquad \text{(attrition indicator observed in period 2).}$$

An observation is made in the second period if $z_{i2} = 1$, which makes this an early version of the familiar sample selection model. The reduced form of the observation equation is

$$\begin{aligned} z_{i2}^* &= \mathbf{x}_{i2}'(\delta\boldsymbol{\beta} + \boldsymbol{\theta}) + \mathbf{w}_{i2}'\boldsymbol{\alpha} + \delta\varepsilon_{i2} + v_{i2} \\ &= \mathbf{x}_{i2}'\boldsymbol{\pi} + \mathbf{w}_{i2}'\boldsymbol{\alpha} + h_{i2} \\ &= \mathbf{r}_{i2}'\boldsymbol{\gamma} + h_{i2}. \end{aligned}$$

The variables in the probit equation are all those in the second period regression plus any additional ones dictated by the application. The estimable parameters in this model are $\boldsymbol{\beta}$, $\boldsymbol{\gamma}$, $\sigma^2 = \text{Var}[\varepsilon_{it} + u_i]$ and two correlation coefficients,

$$\rho_{12} = \text{Corr}[\varepsilon_{i1} + u_i, \varepsilon_{i2} + u_i] = \text{Var}[u_i] / \sigma^2,$$

and

$$\rho_{23} = \text{Corr}[h_{i2}, \varepsilon_{i2} + u_i].$$

All disturbances are assumed to be normally distributed. (Readers are referred to the paper for motivation and details on this specification.)

The authors propose a full information maximum likelihood estimator. The estimator described here uses two steps. The parameters of the probit model are estimated first by maximum likelihood. Then the remaining parameters are estimated conditionally on these first step estimates. The Murphy and Topel adjustment is made after the second step. Further details are given at the end of this section.

E53.7.1 Commands

The Hausman and Wise estimator is obtained as follows: The data are not set up as a panel. All data appear on a single line, as one observation. There are three dependent variables and three sets of independent variables, as shown below.

```
PROBIT    ; Lhs = z
          ; Rhs = variables in probit and in second regression
          ; Hold $
SELECT    ; Lhs = first period y, second period y
          ; Rhs = first period regression
          ; Rh2 = second period regression $
```

NOTE: The Rhs and Rh2 lists must contain the same number of variables. These are two sets of observations on the same variables.

Data on y_{i2} and x_{i2} can be coded as missing values or anything else for observations which have attrition ($z = 0$). Values there will be ignored.

Other options are the standard ones for nonlinear optimization. There are no fitted values or marginal effects produced for this estimator, however. The results retained by the estimator are

Matrices:	*b*	= estimate of β
	varb	= estimate of asymptotic covariance matrix
Scalars:	*logl*	= log likelihood
	nreg	= number of observations
	*rho*12	= estimate of ρ_{12}
	*rho*23	= estimate of ρ_{23}
	s	= estimate of σ

E53.7.2 Application

We used the data from the previous example, and created a second period of data.

E53.7.3 Technical Details for the Hausman and Wise Attrition Model

The individual terms in the log likelihood for the model are

$$\text{Log } L_i = \frac{-\log 2\pi}{2} - \log\sigma - \frac{(y_{i1} - \mathbf{x}_{i1}'\boldsymbol{\beta})^2}{2\sigma^2} +$$

$$(z_{i2}) \times \left[\begin{array}{c} -\log\sqrt{2\pi\sigma^2(1-\rho_{12}^2)} - \dfrac{\left[(y_{i2} - \rho_{12}y_{i1}) - (\mathbf{x}_{i2} - \rho_{12}\mathbf{x}_{i1})'\boldsymbol{\beta}\right]^2}{2\sigma^2(1-\rho_{12}^2)} \\ + \log\boldsymbol{\Phi}\left[\dfrac{\mathbf{r}_{i2}'\delta + (\rho_{23}/\sigma)(y_{i2} - \mathbf{x}_{i2}'\boldsymbol{\beta})}{\sqrt{(1-\rho_{23}^2)}}\right] \end{array} \right] +$$

$$(1 - z_{i2}) \times \left[\log\left(1 - \boldsymbol{\Phi}\left[\frac{\mathbf{r}_{i2}'\boldsymbol{\delta} + (\rho_{12}\rho_{23}/\sigma((y_{i1} - \mathbf{x}_{i1}'\boldsymbol{\beta})}{\sqrt{(1-\rho_{12}\rho_{23}^2)}}\right]\right)\right]$$

Reparameterization of the log likelihood brings some large simplification. First, $\boldsymbol{\delta}$ has been estimated at the first step, so we carry only

$$a_{i2} = \mathbf{r}_{i2}'\boldsymbol{\delta}$$

in the log likelihood. Then, let c = -.5log2π and

$$\theta = 1/\sigma,$$

$$\boldsymbol{\gamma} = (1/\sigma)\boldsymbol{\beta},$$

$$T_{12} = \sqrt{1-\rho_{12}^2}\,, \qquad \tau_{12} = \rho_{12} / T_{12}$$

$$T_{23} = \sqrt{1-\rho_{23}^2}\,, \qquad \tau_{12} = \rho_{123} / T_{23}$$

$$T_{13} = \sqrt{1+\tau_{12}^2+\tau_{23}^2}\,, \quad \tau_{13} = \tau_{12}\,\tau_{23} / T_{13}$$

$$e_{i1} = \theta\, y_{i1} - \mathbf{x}_{i1}'\boldsymbol{\gamma}$$

$$e_{i2} = \theta\, y_{i2} - \mathbf{x}_{i2}'\boldsymbol{\gamma}$$

$$U_i = T_{12}\, e_{i2} - \tau_{12}\, e_{i1}$$

$$V_i = T_{23}a_{i2} + \tau_{13}e_{i2}$$

The log likelihood for observation i is now

$$\log L_i = c + \log\theta - .5e_{i1}^2 + z_{i2}(\, c + \log\theta - \log T_{12} - .5{*}U_i^2 + \log\Phi(V_i)] + (1-z_{i2})\log\Phi(-V_i)$$

This is maximized with respect to $\boldsymbol{\gamma}$, θ, τ_{12} and τ_{23}. Derivatives are complicated, but use familiar results for the normal distribution. The BHHH estimator is used for the asymptotic covariance matrix. The original parameters and their asymptotic covariance matrix are recovered using the delta method.

E54: Alternative Sample Selection Models

E54.1 Introduction

Many variants of the ‘sample selection’ model can be estimated with *LIMDEP*. (See Heckman (1979), Maddala (1983) and Greene (2011) for further discussion.) The basic structure is

$$y = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,$$

$$z^* = \boldsymbol{\alpha}'\mathbf{w} + u,$$

$$\varepsilon,u \sim N[0,0,\sigma_\varepsilon^2,\sigma_u^2,\rho].$$

A bivariate classical normal (seemingly unrelated) regressions model applies to the structural equations. The standard deviations are σ_ε and σ_u, and the covariance is $\rho\sigma_\varepsilon\sigma_u$. If the data were randomly sampled from this bivariate population, the parameters could be estimated by least squares, or GLS combining the two equations. However, z^* is not observed. Its observed counterpart is z, which is determined by

$$z = 1 \text{ if } z^* > 0$$

and

$$z = 0 \text{ if } z^* \leq 0.$$

Moreover, values of y and $\mathbf{x}$ are only observed when z equals one. Thus, the model is two steps removed from the two equations seemingly unrelated regressions which would be simple to estimate. The essential feature of the model is that under the sampling rule, $E[y|\mathbf{x},z = 1]$ is not a linear regression. The development below presents estimators for the class of essentially nonlinear models that emerge from this specification.

This is the simplest form of this model. Several variants and estimators were considered in Chapter E52. Panel data estimators were developed in Chapter E53. In this chapter, we develop a number of models in which the first, linear equation, $y = \boldsymbol{\beta}'\mathbf{x} + \varepsilon$, is replaced with a nonlinear model in which the density of the random variable, rather than its conditional mean are specified;

$$f(y|\mathbf{x},\varepsilon) = g(y,\mathbf{x}, \varepsilon,\boldsymbol{\beta}).$$

The other assumptions are the same. The model is extended to a variety of settings, such as binary and multinomial choice models, count data models and a stochastic frontier model.

E54.2 Probit Model with Selection

In the bivariate probit setting (see Section E33.2), data on y_1 might be observed only when y_2 equals one. For example, in modeling loan defaults with a sample of applicants, default will only occur among applicants who are granted loans. Thus, in a bivariate probit model for the two outcomes, the observed default data are nonrandomly selected from the set of applicants. The model that might be used is

$$
\begin{aligned}
z_{i1} &= \boldsymbol{\beta}'\mathbf{x}_{i1} + \varepsilon_{i1},\ y_{i1} = \text{sgn}(z_{i1}),\\
z_{i2} &= \boldsymbol{\beta}'\mathbf{x}_{i2} + \varepsilon_{i2},\ y_{i2} = \text{sgn}(z_{i2}),\\
\varepsilon_{i1},\varepsilon_{i2} &\sim \text{BVN}(0,0,1,1,\rho),\\
(y_{i1},\mathbf{x}_{i1}) &\ \text{is observed only when } y_{i2} = 1.
\end{aligned}
$$

This is a type of sample selectivity model. The model was proposed by Wynand and van Praag (1981). An extensive application which uses choice based sampling as well is Boyes, Hoffman, and Low (1989). (See also Greene (1992 and 2011).) The sample selection model is obtained by adding **; Selection** to the **BIVARIATE PROBIT** (or just **BIVARIATE**) command. This model is fit in a single step, using full information maximum likelihood. Use

```
BIVARIATE   ; Lhs = y1, y2   (selection variable is second)
            ; Rhs = x1       (variables in selected model)
            ; Rh2 = x2       (variables in selection equation)
            ; Selection $
```

All other options and specifications are the same as for the model without selection. Except for the diagnostic table which indicates that this model has been chosen, the results for the selection model are exactly the same as for the basic model.

E54.2.1 Choice Based Sampling

Like other discrete choice models, you may use a choice based sampling correction with this model. You must provide a weighting variable which for this model will take only three different values. In each case, the weight is

$w_i(z_{i1},z_{i2})$ = *population proportion* / *sample proportion*.

The three cells in your data set for this selection model are $z_2 = 0$, ($z_2 = 1,z_1 = 0$) and ($z_2 = 1,z_1 = 1$). Your command is modified to account for the weighting as follows:

```
BIVARIATE ; Lhs  = y1, y2     (selection variable is second)
; Rhs = x1       (variables in selected model)
; Rh2 = x2       (variables in selection equation)
; Wts = wi
; Choice Based Sampling
; Selection $
```

E54.2.2 Application

The foregoing was applied in Greene (1992). The study analyzed usage and default patterns for a sample of individuals applying for and using a major credit card. Descriptive statistics for a subset of the variables in this data set of 13,444 observations (provided as data file credit.lpj) are as follows.

Variable	Mean	Standard Deviation	Minimum	Maximum	Cases
Dummy variable for whether individual holds the credit card					
CARDHLDR|	.780943	.413623	.000000	1.00000	13444

Age in years and twelfths of a year when card was applied for					
AGE|	33.54046	10.06261	18.0	88.6667	13444
Income in $ per year – regular income and additional income					
INCOME|	30114.33	15035.36	600.0	99999.0	13444
ADDLINCM|	4126.17	9127.93	.000000	99999.0	13444
Ratio of average yearly expenditure to average total yearly income					
EXP_INC|	.070974	.103922	.0000882	2.03773	13444
Average yearly expenditure using the credit card					
AVGYREXP|	2357.658	3734.952	12.00000	121663.8	13444
Dummy variable indicates whether individual owns or rents their home					
OWNRENT |	.455965	.498076	.000000	1.00000	13444
Dummy variable indicates whether individual is self employed					
SELFEMPL|	.057944	.233646	.000000	1.00000	13444
Number of dependents in household, not including the individual					
DEPDNT |	1.01726	1.27910	.000000	9.00000	13444
Income per dependent, in $10,000 units					
INCPER |	21719.7	13591.2	362.500	150000.	13444
Months residing at current address when applied for the credit card					
CURNTADD|	55.3189	63.0897	.000000	576.000	13444
Dummy variable for whether the individual holds another major credit card					
CREDMAJR|	.813076	.389865	.000000	1.00000	13444
Number of credit accounts active at the time of card application					
TRADACCT|	6.42205	6.10691	.000000	50.0000	13444

The variable *cardhldr* is a binary variable which indicates whether the individual holds the major credit card whose vendor produced the overall data set. The probit equation is used to model *default*. The selection model that arises as the default is only observed for those with *cardhldr* = 1.

This application continues the original analysis. (The specification is different below.) The first set of estimates computes the bivariate probit model with selection. In fact, the sample is choice based. The list below shows the sample and true population proportions and the weights to be applied.

		Sample	Population	Weight
Card holder = 0		0.219	0.768	3.507
Card holder = 1	Default = 1	0.0949	0.0237	0.2497
	Default = 0	0.905	0.208	0.2298

The choice based sampling in these data is fairly drastic. The sample was constructed for the purpose of studying default, so it was heavily skewed toward defaulters, far in excess of observed rates. (We note, in the years since the study was done, the vendor has also drastically increased the acceptance rate.)

```
NAMELIST    ; card = one,age,income,ownrent,selfempl,curntadd $
NAMELIST    ; dflt  = one,income,avgyrexp,depdnt,incper,credmajr,tradacct $
BIVARIATE   ; Lhs = default,cardhldr
            ; Rh1= dflt ; Rh2 = card ; Selection
            ; Summary ; Partial Effects $
```

This set of instructions computes the weights for the choice based sampling estimator.

```
CALC        ; wc0 = 1-Xbr(cardhldr) ; pc0 = .768 $
REJECT      ; cardhldr = 0 $
CALC        ; wc11 = Xbr(default) ; pc11 = .232*.102
            ; wc10 = 1 - wc11 ; pc10 = .232*.898 $
SAMPLE      ; All $
CREATE      ; cbwt = (cardhldr = 0)*pc0 / wc0
                  + (cardhldr = 1)*(default = 1) * pc11 / wc11
                  + (cardhldr = 1)*(default = 0) * pc10 / wc10 $
```

This is the same model, now applying the weights. The results are substantially different, as might be expected.

```
BIVARIATE   ; Lhs = default,cardhldr
            ; Rh1= dflt ; Rh2 = card ; Selection
            ; Wts = cbwt ; Choice Based Sampling $
```

E54.2.3 Technical Details

The log likelihood for the bivariate probit model with selection is

$$\text{Log - }L = \sum\nolimits_{y_2=1,y_1=1} \log\Phi_2[\boldsymbol{\beta}_1'\mathbf{x}_{i1},\boldsymbol{\beta}_2'\mathbf{x}_{i2},\rho] + \sum\nolimits_{y_2=1,y_1=0} \log\Phi_2[-\boldsymbol{\beta}_1'\mathbf{x}_{i1},\boldsymbol{\beta}_2'\mathbf{x}_{i2},-\rho]$$
$$+ \sum\nolimits_{y_2=0} \log\Phi[-\boldsymbol{\beta}_2'\mathbf{x}_{i2}].$$

The necessary first and second derivatives are given in Section E33.2.9.

NOTE: This is one of several sample selection models estimated by maximum likelihood with *LIMDEP*. In this setting, there is no 'lambda' variable as there is in the regression model with sample selection. Heckman's (1979) selection correction variable applies to the linear regression model estimated with two step least squares, but not generally to models fit by maximum likelihood. For testing for selection effects, the appropriate approach is to test the hypothesis of no effects, which results if ρ equals zero.

NOTE: You may code y_1 as 0.0 for the nonselected (nonobserved) observations in this model. The correct value to use (or ignore) is determined by the program during estimation.

E54.3 Ordered Probit Model

The following describes an ordered probit counterpart to the standard sample selection model. This is only available for the ordered probit specification, not the ordered logit, Gompertz, etc. The structural equations are, first, the main equation, the ordered choice model,

$$
\begin{aligned}
y_i^* &= \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i, \ \ \varepsilon_i \sim F(\varepsilon_i\,|\boldsymbol{\theta}), E[\varepsilon_i] = 0, \text{Var}[\varepsilon_i] = 1,\\
y_i &= 0 \text{ if } y_i \le \mu_0,\\
&= 1 \text{ if } \mu_0 < y_i \le \mu_1,\\
&= 2 \text{ if } \mu_1 < y_i \le \mu_2,\\
&\ldots\\
&= J \text{ if } y_i > \mu_{J\text{-}1}.
\end{aligned}
$$

Second is the selection equation, a univariate probit model,

$$
\begin{aligned}
d_i^* &= \boldsymbol{\alpha}'\mathbf{z}_i + u_i,\\
d_i &= 1 \text{ if } d_i^* > 0 \text{ and } 0 \text{ otherwise,}
\end{aligned}
$$

The observation mechanism is

$$
\begin{aligned}
&[y_i,\mathbf{x}_i] \quad \text{is observed if and only if } d_i = 1.\\
&\varepsilon_i, u_i \sim N_2[0,0,1,1,\rho]; \text{ there is ‘selectivity’ if } \rho \text{ is not equal to zero.}
\end{aligned}
$$

This model requires two passes to estimate. In the first, you fit a probit model for the selection variable, d. You then pass these values to the ordered probit model using a standard command for this operation, the **; Hold** parameter in the probit command. The two commands would be as follows: (This model is requested in the same fashion as *LIMDEP*’s other sample selectivity models.) Estimate the first stage probit model and hold the results for next step in the estimation.

```
PROBIT      ; Rhs = z list ; Lhs = d ; Hold $
```

Second, estimate the ordered probit model with selectivity,

```
ORDERED     ; ... as usual ; Selection  $
```

You need not make any other changes in the ordered probit command.

The second step reestimates $\boldsymbol{\alpha}$ from the probit model along with $\boldsymbol{\beta}$ and $\boldsymbol{\mu}$, obtaining a FIML set of estimates for all parameters including ρ. The ordered probit command results in two full rounds of estimation. In the first round, the model is estimated as if there were no selection. This provides the remaining starting values. The starting value for ρ is zero. Then, in the second round, the FIML estimates are computed. This model is rather difficult to estimate, and it is best to allow *LIMDEP* to use its own starting values. (In spite of this, nonconvergence can be a problem. When problems arise, be sure first to check the scaling of the independent variables.)

NOTE: This model is *not* fit by computing a 'lambda' variable, $\lambda_i = \phi(\boldsymbol{\alpha}'\mathbf{z}_i)/ \Phi(\boldsymbol{\alpha}'\mathbf{z}_i)$ from the results of the first step probit and including it in the ordered probit at the second. It is estimated by maximizing the likelihood function shown at the end of this section with respect to $\boldsymbol{\beta}$, $\boldsymbol{\alpha}$, and ρ. There will be no coefficient shown for such a variable in the estimation results, though the estimated ρ is shown.

NOTE: (This is another frequently asked question.) All observations in the sample are used in fitting this model, not just the ones for which $d = 1$. The observations for which $d = 0$ contribute to the probit part of the log likelihood. The remainder contribute both to the probit and the ordered probit.

The **; Rst = ...** and **; CML:** options for imposing restrictions can be used freely with this model to constrain $\boldsymbol{\beta}$ and $\boldsymbol{\alpha}$. The parameter vector is

$$\boldsymbol{\Theta} = [\beta_1,...,\beta_K,\alpha_1,...,\alpha_L,\mu_1,...,\mu_{J-1},\rho].$$

You may also give your own starting values with **; Start = list ...**, though the internal values will usually be preferable.

All results kept for the basic model are also kept; *b* and *varb* still include only $\boldsymbol{\beta}$, but **; Par** adds all of $[\boldsymbol{\mu},\boldsymbol{\alpha},\rho]$ to the parameter vector. This model adds two additional scalars:

rho = estimate of ρ,
varrho = estimate of asymptotic variance of estimated ρ.

NOTE: The estimates of $\boldsymbol{\alpha}$ update the estimates you stored with **; Hold** when you fit the probit model. Thus, for example, if you were to follow your **ORDERED** command immediately with the identical command, the starting values used for $\boldsymbol{\alpha}$ would be the MLEs from the prior ordered probit command, not the ones from the original probit model that you fit earlier. Also, if you were to follow this model command with a selection model command, this estimate of $\boldsymbol{\alpha}$ would be used there, as well.

With the corrected estimates of $[\boldsymbol{\beta},\boldsymbol{\mu}]$ in hand, predictions for this model are computed in the same manner as for the basic model without selection. The only difference is that no prediction for y is computed in the selection model if $d = 0$.

E54.3.1 Application

The following illustrates the model with some simulated data which satisfy the assumptions of the specified model:

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-500 $
CREATE      ; x1 = Rnu(1,4) ; x2 = Rnd(2) - 1 $
CREATE      ; z1 = Rnn(0,1) ; z2 = Rnn(0,1) ; u = Rnn(0,2) $
CREATE      ; d  = (z1 + z2 + u) > 0 $
CREATE      ; e  = u + Rnn(0,3) ; y = 1 + .5 * x1 + 1.2 * x2 + e $
RECODE      ; y ; -25/2.5 = 0 ; 2.501/3 = 1 ; 3.001/4 = 2 ; 4.01/100 = 3 $
PROBIT      ; Lhs = d ; Rhs = one,z1,z2 ; Hold $
ORDERED     ; Lhs = y ; Rhs = one,x1,x2 ; Select ; Partial Effects $
```

This is the initially estimated probit equation. The coefficients below are used as the starting values for the ordered probit with selection. At this point, this is the model that is used in subsequent sample selection models.

```

E54.3.2 Technical Details for the Selection Model

In the sample selection model, $[\varepsilon,u]$ are assumed to have a bivariate standard normal distribution with correlation ρ. Then, the probabilities in the log likelihood are:

For observations with $d_i = 0$, Prob = Prob[$d = 0$] = univariate normal CDF.

For observations with $d_i = 1$, Prob = Prob[y_i* in particular range and $d = 1 \mid \rho$]

= bivariate normal probability.

The log likelihood for the model with sample selection is

$$\log L = \Sigma_{d=0} \log \Phi(-\boldsymbol{\alpha}'\mathbf{x}_2) + \Sigma_{d=1} \log \{\Phi_2[a_j,\boldsymbol{\alpha}'\mathbf{z},\rho] - \Phi_2[a_{j-1},\boldsymbol{\alpha}'\mathbf{z},\rho]\}$$

where $\Phi(\bullet)$ = standard normal CDF,

$\Phi_2(\bullet,\bullet,\bullet)$ = bivariate standard normal CDF,

$a_j = \mu_j - \boldsymbol{\beta}'\mathbf{x}$,

$a_{j-1} = \mu_{j-1} - \boldsymbol{\beta}'\mathbf{x}$,

and j = the value taken by y_i for that observation.

The same convention used above is maintained for the μs. The first derivatives are tedious but straightforward. They can be derived by applying the formulas given in Chapter E33 for the bivariate probit model. The derivation is a bit simpler here because for the differentiation of the bivariate CDF, q_1 and q_2 are both +1.

E54.4 Poisson and Negative Binomial Regression Models with Selection

Extending the selectivity model to models for counts, such as the Poisson and negative binomial requires a change in approach from the models of the previous sections. Since there is no natural joint normality assumption that ties the count model to the selection model, a different approach is needed. We use the following structure. (See Terza (2010). The mathematical detail for this model is developed in full later in this section.) The Poisson and negative binomial specifications are modified as follows:

$$
\begin{aligned}
z_i^* &= \boldsymbol{\alpha}'\mathbf{w}_i + u_i \text{ in which } u_i \sim N[0,1] \\
z_i &= \mathbf{1}(z_i^* > 0) \qquad \text{(probit selection equation)} \\
\lambda_i | \varepsilon_i &= \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i) \\
y_i | \varepsilon_i &\sim \text{Poisson}(\lambda_i | \varepsilon_i) \qquad \text{(count model for outcome)} \\
[u_i,\varepsilon_i] &\sim N[(0,1),(1,\rho\sigma,\sigma^2)] \\
y_i,\mathbf{x}_i & \quad \text{are observed only when } z_i = 1.
\end{aligned}
$$

Thus, $y \mid \varepsilon$ is distributed as Poisson with mean (and variance) $E[y|\varepsilon] = \exp(\boldsymbol{\beta}'\mathbf{x} + \varepsilon)$. The distribution in the selected population is nonPoisson, but this does preserve its discreteness. The force of the sample selection is exerted on the mean of the discrete variable (and its variance). The estimator is full information maximum likelihood. (The negative binomial model is considered below.)

In the standard regression framework, the development proceeds by modeling the joint distribution of u_i and the disturbance in the regression model, which would correspond to

$$\varepsilon_i = y_i - E[y_i|\mathbf{x}_i].$$

The familiar Heckman model hinges on joint normality of $[u_i,\varepsilon_i]$, which is clearly untenable here – since y_i is discrete, its deviation from the conditional mean function could not be normally distributed. The approach taken is to introduce the unobservable factors in the mean of the count variable, then use a form of the selection approach to model it through the covariance of u and ε, as is done elsewhere. The change in this model is that the linear techniques used in Chapter E52 are inappropriate here.

E54.4.1 Full Information Maximum Likelihood Estimation

A full information maximum likelihood estimator for the sample selection model is requested with

PROBIT ; Lhs = ... ; Rhs = ... ; Hold $
POISSON ; Lhs = ... ; Rhs = ... ; Selection ; MLE $
or NEGBIN ; Lhs = ... ; Rhs = ... ; Selection ; MLE $

The computations are based on the heterogeneity model of Section E42.3. This must be preceded by the probit model in order to define the full set of variables in the model and to provide the starting values for the iterations.

All options that are useable for the Poisson model are supported here as well, including

Optimization:	**; Maxit = n**	to set maximum restrictions
	; Alg = name	to select algorithm (you generally should not change this)
	; Tlf [= value]	to set tolerance for convergence criteria
	; Output = value	to control intermediate output
	; Hpt = n	to specify number of nodes for Hermite quadrature
Constraints:	**; Rst = list**	to specify fixed value and equality restrictions
	; CML: spec	
	; Test: spec	to define Wald tests
Output:	**; Partial Effects**	
	; Covariance Matrix	to display the estimated asymptotic covariance matrix, same as **; Printvc**
	; List	to display predicted values
	; Keep = name	to retain fitted values
	; Res = name	to retain residuals
	; Parameters	to retain estimates of σ and ρ in *b* and *varb*

and so on for other program options are all supported. Output for this model will include the initial Poisson regression followed by the FIML results, then any optional output you have requested, such as a list of fitted values.

NOTE: This estimator reestimates the parameters of the probit model, and replaces the estimates that were initially retained with **; Hold** on the **PROBIT** command. See the example below.

WARNING: The negative binomial model with sample selection is quite volatile, and without prior scaling of the data (and a good fit of the model and the data), the numerical properties of the estimator appear to be somewhat unstable.

The results that are retained include

Matrices: *b* and *varb*, as usual
include Poisson slopes followed by probit parameters
σ then ρ with **; Parameters** option

Scalars:
logl = log likelihood
kreg = number of parameters in $[\boldsymbol{\beta}', \boldsymbol{\gamma}', \sigma, \rho]'$
nreg = number of observations, total, not just selected
s = estimate of σ
rho = estimate of ρ

E54.4.2 An Incidental Truncation Model

Winkelmann (2008, pp. 153-154) describes a model (attributed to Crepon and Duguet (1997)) which is labeled the 'incidental truncation' model. This is a case in which the binary variable is correlated with the Poisson outcome, and directly affects it, in a form similar to the ZIP models discussed below. In this model, the data are observed when $z_i = 0$, but $z_i = 0$ implies that $y_i = 0$. The difference between this and the ZIP model is only the correlation between the two latent disturbances. The structure is actually a small modification of the model we have considered above.

$$z_i^* = \boldsymbol{\gamma}'\mathbf{w}_i + u_i \text{ in which } u_i \sim N[0,1],$$

$$z_i = \mathbf{1}(z_i^* > 0).$$

Thus, a probit model applies to the indicator, z_i. The following applies to the observed y_i:

$$y_i^* \sim \text{Poisson }(\lambda_i|\varepsilon_i) \text{ is a latent variable distributed as Poisson,}$$

$$\lambda_i|\varepsilon_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i),$$

$$y_i = y_i^* \text{ and } \mathbf{x}_i \text{ are observed when } z_i = 1,$$

$$y_i = 0 \text{ when } z_i = 0, \mathbf{x}_i \text{ is still observed when } z_i = 0.$$

For the sample selection model, the joint density of the observed response variables y_i and z_i is of the form

$$\mathbf{1}(z_i = 1) \times \{\text{Prob}(z_i = 1) \times \text{Poisson probability}\} + \mathbf{1}(z_i = 0)\times\text{Prob}(z_i = 0)$$

while for the incidental truncation model, the joint density is of the form

$$\text{Prob}(z_i = 1) \times \text{Poisson probability} + \mathbf{1}(z_i = 0)\times\text{Prob}(z_i = 0).$$

This model is requested by adding

; All

to the **POISSON** command given earlier.

PROBIT ; Lhs = ... ; Rhs = ... ; Hold $
POISSON ; Lhs = ... ; Rhs = ... ; Selection ; MLE ; All $

All other aspects are the same as in the model described earlier.

E54.4.3 Imposing Restrictions and Fixing ρ

The parameter vector is [β′, γ′, σ, ρ]′. Use this if you wish to impose constraints. For example, to fix the value of ρ at -.5 (as we do below in an example), you could use the following:

```
NAMELIST    ; xp = Rhs variables in probit equation
            ; xr = Rhs variables in Poisson model $
CALC        ; kp = Col(xp) ; kr = Col(xr) $
PROBIT      ; Lhs = ... ; Rhs = xp ; Hold $
POISSON     ; Lhs = the dependent variable
            ; Rhs = xr
            ; Selection ; MLE
            ; Rst = kr_b, kp_c, sg, -.5 $
```

You can use this device to test for a selectivity effect as well. The simple t and likelihood ratio tests can be carried out based on the value of ρ that is estimated. But, the t test requires estimation of the full model while the LR test requires assembling estimates of the pair of models and collecting three terms:

```
PROBIT      ; ... ; Hold $
POISSON     ; ... estimate full model by FIML $
CALC        ; lfiml = logl $
CALC        ; lprobit = logl  $
REJECT      ; the Lhs variable for probit model = 0 $
POISSON     ; ... Poisson model without selection, on selected observations $
CALC        ; lpois = logl
            ; List
            ; lm = 2*(lfiml - lprobit - lpois)
            ; 1 - Chi(lm,1)  $
```

The LM test should be the simplest to carry out. In the earlier example, just change our -.5 to 0, and add **; Maxit = 0** to the command. An example appears below.

E54.4.4 Application

The variable *cardhldr* is a binary variable which indicates whether the individual holds the major credit card whose vendor produced the overall data set; *inc_per*, which is the ratio of household income to number of dependents. The probit equation is used to model *cardhldr* as a function of *age*, *income*, and *inc_per*. The count variable analyzed here is *majordrg*, the number of major derogatory credit reports (long defaults) reported in the first year of credit card usage. The selection corrected Poisson model is then fit using only those observations for which *cardhldr* equals 1. Since *majordrg* is by far the dominant determinant of whether an application for a credit card will be accepted, one would expect the effect of the selection to be substantive in these data. The other variables used in the count model are *age*, *income*, *ownrent* and *avgexp*. The first command fits an unrestricted model. In the second, the correlation coefficient is fixed at -.5.

The commands are:

NAMELIST ; xp = one,age,income,incper $
NAMELIST ; xr = one,age,income,ownrent,avgyrexp $
PROBIT ; Lhs = cardhldr ; Rhs = xp ; Hold $
POISSON ; Lhs = majordrg ; Rhs = xr
; MLE ; Selection ; Partial Effects $
PROBIT ; Quietly ; Lhs = cardhldr ; Rhs = xp ; Hold $
POISSON ; Lhs = majordrg ; Rhs = xr
; MLE ; Selection ; Rst = 5_b,4_c,sc,-.5 $

Technical Details on FIML Estimation

The log likelihood function for the full model is the joint density for the observed data. When z_i equals one, $(y_i,\mathbf{x}_i,z_i,\mathbf{w}_i)$ are all observed. We seek $P[y_i, z_i=1|\mathbf{x}_i,\mathbf{w}_i]$. To obtain it, proceed as follows:

$$P[y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i] = \int_{-\infty}^{\infty} P[y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i,\varepsilon_i]\, f(\varepsilon_i)d\varepsilon_i$$

$$= E_\varepsilon\{P[y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i,\boldsymbol{\varepsilon}_i]\}.$$

Conditioned on ε_i, z_i and y_i are independent. Therefore,

$$P[y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i,\varepsilon_i] = P[y_i|\mathbf{x}_i,\varepsilon_i]\text{Prob}[z_i=1|\mathbf{w}_i,\varepsilon_i].$$

The first part, $P[y_i\,|\mathbf{x}_i,\varepsilon_i]$ is the conditional Poisson distribution with heterogeneity defined earlier. By joint normality, $f(u_i|\varepsilon_i) = N[(\rho/\sigma)\varepsilon_i\,, (1-\rho^2)]$. Therefore, $\text{Prob}[z_i=1|\mathbf{w}_i,\varepsilon_i]$ is

$$\text{Prob}[z_i=1|\mathbf{w}_i,\varepsilon_i] = \Phi\left([\boldsymbol{\alpha}'\mathbf{w}_i + (\rho/\sigma)\varepsilon_i]/\sqrt{1-\rho^2}\right).$$

Combining terms and using the earlier approach, the unconditional probability is

$$P[y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i] =$$

$$\int_{-\infty}^{\infty} \frac{\exp[-\lambda_i(\varepsilon)]\lambda_i(\varepsilon)^{y_i}}{y_i\,!}\,\Phi\left([\boldsymbol{\alpha}'\mathbf{w}_i + (\rho/\sigma)\varepsilon_i]/\sqrt{1-\rho^2}\right)\frac{1}{\sigma\sqrt{2\pi}}\exp[-\varepsilon_i^2/(2\sigma^2)]d\varepsilon_i\,.$$

Let $v = \varepsilon/(\sigma\sqrt{2})$, $\theta = \sigma\sqrt{2}$, $\tau = \sqrt{2}\,[\rho/\sqrt{1-\rho^2}\,]$, and $\boldsymbol{\gamma} = [1/\sqrt{1-\rho^2}\,]\boldsymbol{\alpha}$.

(Thus, the reverse transformations are

$$\rho^2 = [\tau^2/(2+\tau^2)],\ \text{Sgn}(\rho) = \text{Sgn}(\tau),\ \text{and}\ \sigma = \theta/\sqrt{2}\,.)$$

After making the change of variable and reparameterizing the probability as before, we obtain

$$P[y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i] = \frac{1}{\sqrt{\pi}}\int_{-\infty}^{\infty} \exp(-v^2)\ \frac{\exp[-\lambda_i(v)]\lambda_i(v)^{y_i}}{y_i\,!}\Phi(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_i)\ dv_i$$

where $\lambda_i(v) = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \theta v)$. This is approximated with Hermite quadrature since no closed form exists. When z_i equals zero, only $(z_i,\mathbf{w}_i)$ are observed. The contribution to the likelihood function is

$$\text{Prob}[z_i = 0|\mathbf{w}_i\ ] = E_\varepsilon[1 - \text{Prob}[u_i > -\boldsymbol{\alpha}'\mathbf{w}_i|\mathbf{w}_i,\varepsilon_i]] = E_\varepsilon[\text{Prob}[u_i \leq -\boldsymbol{\alpha}'\mathbf{w}_i|\mathbf{w}_i,\varepsilon_i]].$$

This provides the probability needed to construct the likelihood function.

$$\text{Prob}[z_i = 0|\mathbf{w}_i,\varepsilon_i] = 1 - \Phi[\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_i/(\sqrt{2}\,\sigma)]$$

so

$$\text{Prob}[z_i = 0|\mathbf{w}_i] = \frac{1}{\sqrt{\pi}}\int_{-\infty}^{\infty} \exp(-v^2)\ \Phi[-(\boldsymbol{\gamma}'\mathbf{w} + \tau v)]dv.$$

Hermite quadrature is used to evaluate the integral.

Maximum likelihood estimates of $[\boldsymbol{\beta}, \boldsymbol{\gamma}, \theta, \tau]$ are obtained by maximizing

$$\log L = \Sigma_{z=0} \log\text{Prob}[z_i=0|\mathbf{w}] + \Sigma_{z=1} \log P[y_i,z_i=1|\mathbf{x},\mathbf{w}].$$

The approximate function is

$$\log L = \sum_{i=obs.\ with\ z_i=1} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h\frac{\exp(-\lambda_i(v_h))\lambda_i(v_h)^{y_i}}{y_i\,!}\Phi\left(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h\right)\right]$$

$$+ \sum_{i=obs.\ with\ z_i=0} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h\Phi\left(-\boldsymbol{\gamma}'\mathbf{w}_i - \tau v_h\right)\right]$$

where v_h and ω_h are the nodes and weights for the quadrature and

$$\lambda_i(v_h) = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \theta v_h).$$

The BHHH estimator of the asymptotic covariance matrix for the parameter estimates is a natural choice given the complexity of the function. The first derivatives must be approximated as well. For convenience, let

$$P_{ih} = P(y_i,\lambda_i(v_h)) = \frac{\exp(-\lambda_i(v_h))\lambda_i(v_h)^{y_i}}{y_i!}$$

$$\lambda_{ih} = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \theta v_h)$$

$$\Phi_{ih} = \Phi(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h\ )\ \text{(normal CDF)}$$

and

$$\phi_{ih} = \phi(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h\ )\ \text{(normal density).}$$

To save some notation, denote the individual terms summed in the log likelihood as log L_i. We also take advantage of the result that $\partial P(.,.)/\partial z = P\times\partial \log P(.,.)/\partial z$ for any argument z which appears in the function. Then,

$$
\begin{aligned}
\frac{\partial \log L}{\partial \boldsymbol{\beta}} &= \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h P_{ih}\Phi_{ih}(y_i-\lambda_{ih})\,\mathbf{x}_i \\
\frac{\partial \log L}{\partial \theta} &= \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h P_{ih}\Phi_{ih}(y_i-\lambda_{ih})\,v_h \\
\frac{\partial \log L}{\partial \boldsymbol{\gamma}} &= \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h P_{ih}\phi_{ih}\,\mathbf{w}_i - \sum_{z_i=0} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \phi_{ih}\,\mathbf{w}_i \\
\frac{\partial \log L}{\partial \tau} &= \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h P_{ih}\phi_{ih}\,v_h - \sum_{z_i=0} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \phi_{ih}\,v_h
\end{aligned}
$$

Estimates of the structural parameters, (α,ρ,σ) and their standard errors are computed using the delta method.

The incidental truncation model requires only minor modification of the preceding. The approximate log likelihood for that model is

$$
\begin{aligned}
\log L &= \sum_{all\ obs.} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \frac{\exp(-\lambda_i(v_h))\lambda_i(v_h)^{y_i}}{y_i!}\Phi\left(\boldsymbol{\gamma}'\mathbf{w}_i+\tau v_h\right)\right] \\
&\quad + \sum_{i=obs.\ with\ z_i=0} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \Phi\left(-\boldsymbol{\gamma}'\mathbf{w}_i-\tau v_h\right)\right].
\end{aligned}
$$

This merely changes the observations included in the first summation. Other changes in the subsequent results are likewise minor.

E54.5 Multinomial Logit Model

The multinomial logit model can be extended in the same fashion as the binomial logit model. As before, the first step is to incorporate the unobservable heterogeneity in the multinomial logit model in a consistent fashion, then extend the selection model. The basic probability model for choice among $J + 1$ alternatives is based on a random utility model,

$$U_{ij} = \boldsymbol{\beta}_j'\mathbf{x}_i + \varepsilon_{ij}$$

where ε_{ij}, $j = 0,...,J$ have independent type 1 extreme value distributions. This produces the familiar multinomial logit model

$$
\begin{aligned}
\text{Prob}(y_i = j|\mathbf{x}_i) &= \text{Prob}(U_{ij} > U_{ik})\ \forall\ k \neq j \\
&= \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_i)}{\Sigma_{m=0}^{J}\exp(\boldsymbol{\beta}_m'\mathbf{x}_i)},\ j = 0,1,...,J,\ \boldsymbol{\beta}_0 = \mathbf{0}.
\end{aligned}
$$

We introduce the individual heterogeneity into the model by augmenting the utility functions with the common individual term, v_i, so that

$$U_{ij} \mid v_i \;=\; \boldsymbol{\beta}_j'\mathbf{x}_i + \theta_j v_i + \varepsilon_{ij},\; v_i \sim \mathrm{N}[0,1].$$

Then, the conditional probabilities are

$$\begin{aligned}\mathrm{Prob}(y_i = j|\mathbf{x}_i,v_i) &= \mathrm{Prob}(U_{ij} > U_{ik}|v_i)\ \forall\ k \neq j \\ &= \frac{\exp(\boldsymbol{\beta}_j'\mathbf{x}_i + \theta_j v_i)}{\Sigma_{m=0}^{J}\exp(\boldsymbol{\beta}_m'\mathbf{x}_i + \theta_m v_i)},\ j = 0,1,...,J,\ \boldsymbol{\beta}_0 = \mathbf{0}, \theta_0 = 0.\end{aligned}$$

As before, the selection mechanism is

$$\begin{aligned} z_i^* &= \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\ u_i \sim N[0,1],\ z_i = 1(z_i^* > 0) \\ (y_i,\mathbf{x}_i) &\ \text{is observed only when } y_{i2} = 1 \\ (u_i,v_i) &\sim \mathrm{BVN}[(0,0),(1,\rho,1)] \end{aligned}$$

This model is estimated using maximum simulated likelihood.

An example appears below. Estimation proceeds in three steps. First, the starting values for the uncorrected multinomial logit model are obtained by simple linear regression of the choice binary variables, $A_{ij} = 1(y_i = j)$, $j = 1,...,J$ on $\mathbf{x}_i$. You can display these results by adding **; OLS** to your **MLOGIT** command, but we emphasize these OLS results are not useful for anything but computing starting values. Then, the multinomial logit model is computed ignoring the selection. (This step and the OLS results are based on the observations for which z_i equals one.) These results are not displayed. When these iterations are complete, the solver returns immediately to the iterations to compute the parameters of the full model. This intermediate step is used to improve the starting values. The final results are then displayed. You can also compute marginal effects, probabilities, etc. with the model in the same fashion as with the basic model without selectivity.

The commands for estimating this model are

```
PROBIT     ; Lhs = zi ; Rhs = variables in w ; Hold $
MLOGIT     ; Lhs = yi ; Rhs = variables in x  ; Selection $
```

All other parts of the command and optional features are the same as in the uncorrected case.

To illustrate this model, we have used the health care data employed in numerous earlier examples. Here, we have modeled the self reported health satisfaction variable (which is more naturally an ordered choice, but this is purely for a numerical example) as a multinomial logit outcome. The selection variable is whether or not the individual has visited the doctor. In order to simplify the application, we have reduced the sample size and truncated the distribution of outcomes by discarding observations with reported value greater than five. The commands and output are as follows:

```
REJECT     ; _groupti < 7 $
REJECT     ; hsat  > 5 $  (This leaves 1,939 observations in the sample.)
PROBIT     ; Lhs = doctor ; Rhs = one,age,married ; Hold $
MLOGIT     ; Lhs = hsat ; Rhs = one,hhninc,female
           ; Selection ; Partial Effects
           ; Pts = 25 ; Halton $
```

E54.6 Sample Selected Stochastic Frontier Model

This model does not yet appear in the literature, and is new with this release of *LIMDEP*. The model is a familiar sample selection form

$$z^* = \boldsymbol{\alpha}'\mathbf{w} + \omega, \qquad z = 1(z^* > 0)$$

$$y = \boldsymbol{\beta}'\mathbf{x} + v - u$$

$$u = |U| \text{ with } U \sim N[0,\sigma_u^2]$$

$$(v,\omega) \sim \text{Bivariate normal with } [(0,0),(\sigma_v^2, \rho\sigma_v, 1)]$$

and $(y,\mathbf{x})$ only observed when $z = 1$.

(It is necessary to deviate from the common notation of this chapter because the frontier function literature also has a common notation for the components of these models, that conflicts with our usage in this chapter. The difference will be immaterial.) The selection mechanism operates through the heterogeneity component of the production model, v, not the inefficiency, u. (Thus, 'observation' – being in the sample – is not viewed as a function of the level of inefficiency.)

The model is fit by maximum simulated likelihood. To request it, use

```
PROBIT     ; Lhs = d ; Rhs = variables in w ; Hold $
FRONTIER   ; Lhs = y ; Rhs = variables in x ; Selection $
```

The model must be the base case, half normal model, with no panel data application, no truncation, or heteroscedasticity, etc. Other aspects of the frontier model, in particular,

```
; Eff = JLMS estimates of u
```

operate in the usual way.

You may control the simulations with **; Halton** and **; Pts** for the simulation. The estimation method is developed in detail in Section E54.5 below.

In the example below, we use a contrived selection mechanism with the dairy farm data used to demonstrate the stochastic frontier models in Chapters E62-E64. The variables in the model are output, milk production, and four inputs, cows, land, feed and labor, in log form. We created *zi* as simply a dummy variable that splits the sample into large and small farms and used a logit model based simply on the number of cows. The second results do not correct for selection. The commands are

```
CREATE     ; group = yit > 11.1$
PROBIT     ; Lhs = group ; Rhs = one,cows ; Hold ; Quiet $
FRONTIER   ; Lhs = yit ; Rhs = one,x1,x2,x3,x4
           ; Selection
           ; Halton ; Pts = 15 ; tlg = 1.d-4 $
FRONTIER   ; Lhs = yit ; Rhs = one,x1,x2,x3,x4 $
```

```

E54.7 Tobit Model with Selectivity

The sample selection model detailed in Chapter E52 is extended to the tobit model. The model is

$$y^* \;=\; \boldsymbol{\beta}'\mathbf{x} + \varepsilon,$$

$$y \;=\; 0 \text{ if } y^* \leq 0,\ y = y^* \text{ otherwise, or } y = \max(0,y^*), \text{(tobit)}$$

$$z^* \;=\; \boldsymbol{\alpha}'\mathbf{w} + u,$$

$$z \;=\; 1 \text{ if } z^* > 0, \text{ or } 0 \text{ if } z^* \leq 0, \text{ or } z = 1[z^* > 0], \qquad \text{(probit)}$$

$$[y\ ,\mathbf{x}\ ] \quad \text{are observed only when } z = 1, \qquad \text{(sampling)}$$

This model is a mixture of censoring and a type of truncation. The procedure for estimating this model follows the standard set of steps for selectivity models given in Section E52.2.2. The standard procedure for estimating a sample selectivity model in *LIMDEP* is:

Step 1. Estimate the parameters of the probit model first and **; Hold** them aside for the next step in the procedure.

Step 2. Using the probit results from Step 1, fit the main equation of the model.

The tobit estimator to be described here is a full information maximum likelihood estimator. Nonetheless, at the beginning of Step 2, a second step least squares regression is computed in order to obtain the starting values for the MLE. These are corrected for selection, to a degree, *but they are still inconsistent*. The results given at this point are obtained by least squares, and, as such, are inconsistent in the same manner that the OLS coefficients are inconsistent in the basic tobit model. As noted, these are just starting values for the iterations. The MLE is consistent and efficient.

The commands are

PROBIT ; Lhs = z ; Rhs = list for w ; Hold $
SELECT ; Tobit ; MLE ; Lhs = y ; Rhs = list for x $

Note that the command for the tobit model in this case is **SELECT**, not **TOBIT**.

NOTE: As in the MLE for the selection model, there is no 'lambda' variable computed for this model. The estimator is not least squares. When a sample selection model is fit by maximum likelihood, there is no selection 'correction' variable added to the model.

The model parameters estimated by MLE are $\boldsymbol{\alpha}$, $\boldsymbol{\beta}$, σ, ρ. The probit coefficients precede the regression parameters in the parameter vector. You may provide your own starting values for the iterations with

; Start = ... list

Fixed value and equality restrictions may be imposed with

; Rst = ... list

The first set of output from the **SELECT** command is the standard output from the two step least squares estimation of this model. The final output includes the log likelihood and an indication of the parts of the parameter vector. The parameter vector shown is $[\boldsymbol{\alpha},\boldsymbol{\beta},\sigma_1,\rho]$. Remaining output is the same as for the selection model. The retrievable results from this estimator are as follows:

Matrices: *b* and *varb* as usual. These contain $[\boldsymbol{\alpha},\boldsymbol{\beta},\sigma,\rho]$. Do not use **; Par**.
*bsr*1 = all of *b* except α

Scalars: *logl, nreg, rho, varrho, s, ybar, sy, sigma*1

Last Model: *a_variables*, *b_variables*, *r*12, *sigma*

E54.7.1 Predictions from the Selection Model

The tobit model with sample selection uses the linear prediction of the underlying latent variable for the fitted values. This is

$$E[y^* \mid z = 1] = \boldsymbol{\beta}'\mathbf{x} + \rho\sigma\lambda$$

where $$\lambda = \phi(\boldsymbol{\alpha}'\mathbf{w}) / \Phi(\boldsymbol{\alpha}'\mathbf{w}).$$

This is the value that is displayed and kept with **; List** and **; Keep**. Other parts of the fitted values listing are the same as for the basic tobit model. These predictions are based on the linear, single equation specification, not the tobit specification, and they do not exploit the correlation between the primary equation and the selection model. As such, they can be improved with some further manipulation. For the observed variable in the tobit model, ignoring the selectivity,

$$\begin{aligned} E[y|\mathbf{x}] &= \text{Prob}(y > 0|\ \mathbf{x}) \times E[y|y > 0, \mathbf{x}] \\ &= \Phi[\boldsymbol{\beta}'\mathbf{x}/\sigma] \times [\boldsymbol{\beta}'\mathbf{x} + \sigma\lambda], \end{aligned}$$

where $$\lambda = \phi[\boldsymbol{\beta}'\mathbf{x}/\sigma] / \Phi[\boldsymbol{\beta}'\mathbf{x}/\sigma].$$

For the tobit model with selection, we need, instead,

$$E[y|\ \mathbf{x}, \text{selection}] = \text{Prob}(y > 0 \mid z = 1) \times E[y \mid \mathbf{x}, y > 0, z = 1].$$

The probability can be found from the bivariate normal distribution:

$$\text{Prob}(y > 0|z = 1) = \Phi_2[\boldsymbol{\beta}'\mathbf{x}/\sigma,\boldsymbol{\alpha}'\mathbf{w},\rho] / \Phi(\boldsymbol{\alpha}'\mathbf{w}).$$

The conditional mean function is more involved. We use a general result for truncation in a bivariate normal distribution. For present purposes, it would be as follows:

$$E[y|y > 0, z = 1] = \boldsymbol{\beta}'\mathbf{x} + E[\varepsilon|\varepsilon > -\boldsymbol{\beta}|\mathbf{x}, u > -\boldsymbol{\alpha}'\mathbf{w}].$$

To simplify the notation, write this as

$$E[\varepsilon|\varepsilon > -\boldsymbol{\beta}'\mathbf{x}, u > -\boldsymbol{\alpha}'\mathbf{w}] = \sigma E[q|q > h, u > k],$$

where $q = \varepsilon/\sigma$,

$h = -\boldsymbol{\beta}'\mathbf{x}/\sigma$,

and $k = -\boldsymbol{\alpha}'\mathbf{w}$.

Maddala (1983) gives an expression for this conditional mean of a bivariate standard normal distribution (0,0,1,1,ρ). Let Φ_2 denote the bivariate normal probability and

$$\delta = -1 / (1 - \rho^2)^{1/2}.$$

Then, $E[q \mid q > h, u > k] = \{\phi(h)\Phi[\delta(k - \rho h)] + \rho\phi(k)\Phi[\delta(h - \rho k)]\}/\Phi_2.$

Thus, $E[y \mid z = 1] = \Phi_2\boldsymbol{\beta}'\mathbf{x} + \sigma\{\phi(h)\Phi[\delta(k - \rho h)] + \rho\phi(k)\Phi[\delta(h - \rho k)]\}.$

The program below can be used for this computation: We first set up the data and fit the model.

```
NAMELIST    ; x = variables in tobit model ; w = variables in probit $
CREATE      ; y = dependent variable in regression
            ; z = dependent variable in probit equation $
PROBIT      ; Lhs = z ; Rhs = w ; Hold $
SELECT      ; Lhs = y ; Rhs = x  ; Tobit ; MLE $
```

Do the following only if data for the predictions are unavailable for the limit (*d*=0) observations.

```
REJECT      ; z = 0 $
```

Determine the size and location of parameter vectors in *b.*

```
CALC        ; ka = Col(w) ; kb = ka + Col(x) ; jb = ka+1 $
```

Extract subvectors of saved parameter vector. Scalars *s* and *rho* already contain σ and ρ needed below.

```
MATRIX      ; alpha = b(1 : ka) ; beta = b(jb : kb) $
```

This simplifies the bivariate normal calculation. Then, set up the variables for the bivariate normal.

```
CALC        ; delta = -1 / Sqr (1 - rho^2) $
CREATE      ; h = -beta'x/s ; mh = -h ; k = -alpha'w ; mk = -k $
NAMELIST    ; hk = mh, mk $
```

Compute the conditional mean function.

```
CREATE      ; phi2 = Bvn(hk,rho)
            ; ey = phi2 * beta'x
                 + s  * (N01(h) * Phi(delta*(k-rho*h))
                 + rho*N01(k) * Phi(delta*(h-rho*k))) $
```

The result can now be inspected or saved in a file.

```
LIST        ; ey $
```

E54.7.2 Application

To illustrate this model, we have fit an hours equation using the Mroz labor supply data analyzed in Section E52.2.2. Here, we use additional information about the determinants of labor force participation.

```
PROBIT      ; Lhs = lfp ; Rhs = one,kids,faminc,cit
            ; Hold $
SELECT      ; Lhs = whrs ; Rhs = one,kl6,k618,wa,we
            ; Tobit ; MLE $
```

This command sequence produces the following results:

E54.7.3 Technical Details on Estimation

The log likelihood function for the tobit model with sample selection is as follows:

$$\begin{aligned}\log L = & \Sigma_{z=0} \log\Phi(-\boldsymbol{\alpha}'\mathbf{w}) \\ & + \Sigma_{z=1,y=0} \log\Phi_2[-\boldsymbol{\beta}'\mathbf{x}/\sigma,\boldsymbol{\alpha}'\mathbf{w},-\rho] \\ & + \Sigma_{z=1,\,y>0} -\tfrac{1}{2}[\log 2\pi + \log\sigma + (\varepsilon_i/\sigma)^2] + \log\Phi[r_i/(1-\rho^2)^{1/2}],\end{aligned}$$

where $\varepsilon_i = y_i - \boldsymbol{\beta}'\mathbf{x}$,

$r_i = \boldsymbol{\alpha}'\mathbf{w} + \rho\varepsilon_i/\sigma$,

Let $\delta = 1/(1-\rho^2)^{1/2}$.

Derivatives in the three parts of the log likelihood are defined as:

$$\begin{aligned} g_\rho &= \partial\log L_i/\rho, \\ g_\sigma &= \partial\log L_i/\sigma, \\ \mathbf{d}_\alpha &= \partial\log L_i/\partial(\boldsymbol{\alpha}'\mathbf{w}), \\ \mathbf{d}_\beta &= \partial\log L_i/\partial(\boldsymbol{\beta}'\mathbf{x}). \end{aligned}$$

For the three parts of the log likelihood function, in the order above:

$$\begin{aligned} \mathrm{g}_\rho &= 0, \\ \mathrm{g}_\sigma &= 0, \\ \mathbf{d}_\alpha &= -\phi/\Phi \text{ from the first normal CDF term}, \\ \mathbf{d}_\beta &= 0. \end{aligned}$$

The second set of terms are from the bivariate probit model presented in Chapter E33.

$$\begin{aligned} g_\rho &= \phi_{00}/\Phi_{00} \text{ (bivariate normal density over CDF)}, \\ g_\rho &= (\phi/\Phi)[\delta\varepsilon_i/\sigma_1 + \rho u_i\delta^3], \\ g_\sigma &= -1/\sigma_1 + (\varepsilon_i/s_1)^2/\sigma_1 - (\phi/\Phi)\rho\delta\varepsilon_i/\sigma_1^2, \\ \mathbf{d}_\alpha &= (\phi/\Phi)\delta, \\ \mathbf{d}_\beta &= \varepsilon_i/\sigma_1^2 - (\phi/\Phi)\rho\delta/\sigma_1. \end{aligned}$$

Terms are then assembled for the gradient. The BHHH estimator is used for the asymptotic covariance matrix.

E54.8 Binomial Logit Model

The binomial probit model with sample selection converts naturally into a form of bivariate probit model. The simple result follows from the bivariate normality of the heterogeneity in the main equation and the unobservables in the selection equation. Likewise, the tobit model with the sample selection correction in Section E54.7 becomes convenient through the bivariate normality of the two random components. If the main equation is a logit model, rather than a probit or some other structure based on the normal distribution, then an alternative method is needed. We use the following: The departure point is a logit model of interest,

$$\text{Prob}(y_i = 1|\mathbf{x}_i) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i)},\ \text{Prob}(y_i = 0|\mathbf{x}_i) = 1 - \text{Prob}(y_i = 1|\mathbf{x}_i)$$

and the familiar selection mechanism,

$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\ u_i \sim N[0,1],\ z_i = 1(z_i^* > 0)$$

$$(y_i,\mathbf{x}_i) \text{ is observed only when } y_{i2} = 1.$$

There is no obvious connection between the logit model of interest and the selection mechanism. Since the force of sample selection is exerted through its influence on unobservables in the model, we modify the model as follows:

$$\text{Prob}(y_i = 1|\varepsilon_i, \mathbf{x}_i) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)}{1+\exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)},\ \varepsilon_i \sim N[0,1].$$

$$(u_i,\varepsilon_i) \sim \text{BVN}[(0,0),(1,\rho,1)]$$

The commands are

```
PROBIT    ; Lhs = zi ; Rhs = variables in w ; Hold $
LOGIT     ; Lhs = yi ; Rhs = variables in x  ; Selection $
```

Other features, such as marginal effects, predicted values, etc. are the same as with the binary logit model without selection. This model is estimated using maximum simulated likelihood. Full details are presented in Section E54.5. Note, marginal effects are computed using the final estimates of β, but without the indirect effects of the selection equation. Thus, as in the uncorrected case, the marginal effects are computed after estimation as

$$\boldsymbol{\delta} = \Lambda(\boldsymbol{\beta}'\mathbf{x})[1 - \Lambda(\boldsymbol{\beta}'\mathbf{x})]\,\boldsymbol{\beta}.$$

To illustrate, we have reestimated the bivariate probit model of the preceding section. The commands are

```
CREATE     ; avgyrexp = avgyrexp/10000 $
CREATE     ; income = income/10000 $
CREATE     ; incper = incper/10000 $
NAMELIST   ; card = one,age,income,ownrent,selfempl,curntadd $
NAMELIST   ; dflt  = one,income,avgyrexp,depdnt,incper,credmajr,tradacct $
PROBIT     ; Lhs = cardhldr ; Rhs = card ; Hold $
LOGIT      ; Lhs = default ; Rhs = dflt ; Selection ; Halton ; Pts = 25 $
```

The second set of estimates are the uncorrected logit estimates from the restricted sample of cardholders. As might be expected given the small estimate of ρ, the results are very similar.

E54.9 Grouped Data Model with Selection

The grouped data model is also extended to the sample selection treatment. (This model is developed in Bhat (1994).) (The model is described earlier in Section E47.3.) The structure is as follows:

$$
\begin{aligned}
y^* &= \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\ \varepsilon \sim N[0,\sigma^2],\\
y &= j \text{ if } A_{j-1} \leq y^* < A_j,\ j = 1,\ldots,J,\ A_0 = -\infty,\ A_J = +\infty,\\
d^* &= \boldsymbol{\alpha}'\mathbf{z} + u\\
d &= \text{if } d^* > 0 \text{ and } 0 \text{ otherwise,}\\
[\varepsilon,u] &\sim N[0,0,\sigma^2,1,\rho],\\
[y,\mathbf{x}] &\ \text{are observed only when } d = 1.
\end{aligned}
$$

The correlation between ε and u is ρ. The selection aspect of the model arises when ρ is not equal to zero. Note that this extension is the same as its counterpart discussed above for the tobit model. The command is

GROUPED DATA ; Lhs = y,d
; Rh1 = variables in x
; Rh2 = variables in z
; Limits = a1, a2,...,aJ-1 $

The **GROUPED DATA** command is exactly the same as in the nonselected case. As before, you give only the interior limit points. The difference is the specification of the probit equation by the second Lhs variable and the Rh2 list. (Since this model proceeds directly to the MLE, we do not begin with a separate **PROBIT** command, as we do with most other sample selection models.)

The usual options are available, including fitted values, residuals, optimization controls, etc., with two exceptions. First, the **; Partial Effects** option is not supported for this model. Second, the default algorithm is BFGS, and this cannot be changed. In addition, you may impose within equations restrictions with the **; Rst = list** option.

The retrievable results from this model are

Matrices: *b*, *varb*; use **; Par** to add (σ,ρ) to the parameter vector

Scalars: *s*, *rho*, *logl*, *kreg*, *nreg*, *ybar*, *sy*, *exitcode*

Last Model: *b_variables* = elements of $\boldsymbol{\beta}$
a_variables = elements of $\boldsymbol{\alpha}$, *sigma*, *r*12

Technical Details on the Grouped Data Regression Models

Optimization is the same as for **TOBIT**. All options, including **; Maxit**, **; Tlf**, **; Start**, **; Rst**, etc. operate the same. Olsen's transformation is used during the iterations. The log likelihood function for the grouped data model is

$$\log L = \Sigma_i\{\log[\Phi(\eta U - \boldsymbol{\gamma}'\mathbf{x}_i) - \Phi(\eta L - \boldsymbol{\gamma}'\mathbf{x}_i)]\}$$

where $\boldsymbol{\gamma} = \boldsymbol{\beta}/\sigma$ and $\eta = 1/\sigma$.

For this case, U is the upper limit of the range in which y_i falls, and L is the lower limit. Gradients and Hessians for these can be derived using the results shown earlier for the tobit model, as the terms are identical. The second derivatives are used in estimating the asymptotic covariance matrix for the estimates.

$$\partial \text{logL}/\partial(\boldsymbol{\gamma},\eta) = \sum\nolimits_{i=1}^{n} \frac{1}{\Phi_U - \Phi_L}\left[\phi_U\begin{pmatrix}-\mathbf{x}_i\\ U\end{pmatrix} - \phi_L\begin{pmatrix}-\mathbf{x}_i\\ L\end{pmatrix}\right].$$

Let $\lambda_m = \phi_{\text{m}} / [\Phi_{\text{U}} - \Phi_{\text{L}}],\ m = L,U.$

and $w_m = [-\mathbf{x}, m]',\ m = L,U$

Then, $$\frac{\partial^2 \log L}{\partial(\boldsymbol{\gamma},\eta)\partial(\boldsymbol{\gamma},\eta)'} = \sum\nolimits_{i=1}^{n} \{\lambda_U\mathbf{w}_U\,[(-\alpha_U - \lambda_U)\mathbf{w}_U' + \lambda_L\mathbf{w}_L']\} - \{\lambda_L\mathbf{w}_L\,[(-\alpha_L + \lambda_L)\mathbf{w}_L' - \lambda_U\mathbf{w}_U']\}.$$

For the sample selection version, estimates of $[\boldsymbol{\beta},\boldsymbol{\alpha},\sigma,\rho]$ are obtained by full information maximum likelihood. The log likelihood is constructed from the simple probabilities of the events:

$$\log L = \Sigma_{d=0} \log[1 - \Phi(\boldsymbol{\gamma}'\mathbf{z})]$$
$$+\Sigma_{d=1,y=j} \log[\Phi_2(\eta A_j - \boldsymbol{\beta}'\mathbf{x},\boldsymbol{\alpha}'\mathbf{z},-\rho) - \Phi_2(\eta A_{j\text{-}1} - \boldsymbol{\beta}'\mathbf{x},\boldsymbol{\alpha}'\mathbf{z},-\rho)],$$

where Φ_2 = bivariate normal CDF.

In the two polar cases, if $j = 1$, $\Phi_2(\eta A_{j\text{-}1} - \boldsymbol{\beta}'\mathbf{x}, \boldsymbol{\alpha}'\mathbf{z}, -\rho) = 0$

and if $j = J$, $\Phi_2(\eta A_j - \boldsymbol{\beta}'\mathbf{x}, \boldsymbol{\alpha}'\mathbf{z}, -\rho) = \Phi(\boldsymbol{\alpha}'\mathbf{z})$.

Derivatives of the log likelihood may be constructed using the results given in Chapter E33 for the bivariate probit model. The BHHH estimator is used for the asymptotic covariance matrix of the estimates.

The fitted values for this model are computed using Bhat's results: Let

$$\delta = 1/(1 - \rho^2)^{1/2},$$

$$\eta = 1/\sigma,$$

$$q = \boldsymbol{\alpha}'\mathbf{z},$$

$$W_m = \eta A_m - \boldsymbol{\gamma}'\mathbf{x}, \quad m = L,U \text{ (limits for the range in which } y \text{ falls)}$$

$$V_m = \delta(q + \rho W_m), \quad m = L,U$$

$$T_m = \delta(W_m + \rho q), \quad m = L,U.$$

Then,

$$E[y^*|\mathbf{x},d=1] = \boldsymbol{\beta}'\mathbf{x} + \sigma\frac{\phi(W_L)\Phi(V_L) - \phi(W_U)\Phi(V_U) + \rho\phi(q)[\Phi(T_U) - \Phi(T_L)]}{\Phi_2(W_U,q,-\rho) - \Phi_2(W_L,q,-\rho)}.$$

E54.10 Parametric Survival Models with Sample Selection

The random parameters model opens the possibility of a sample selection model for parametric survival models. The structure would be the base case parametric model, using the Weibull model as the standard case,

$$h(t_i) = \lambda_i P (\lambda_i t_i)^{P-1}$$

where

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i).$$

We accommodate this case by treating the random component as a random constant term in the parametric model. The observation mechanism is now

$$z_i^* = \boldsymbol{\alpha}'\mathbf{z}_\mathrm{i} + u_i, \; z_i = 1(z_i^* > 0)$$

where the correlation between u_i and ε_i is ρ. We assume that the data for the duration model are only observed when $z_i = 1$. The model is fit by full information maximum likelihood. (This means that there is no 'lambda' = the inverse Mills ratio added to the duration model. That treatment is only appropriate for the linear model fit by two step least squares.)

This model is requested by the following command set:

```
PROBIT      ; Lhs = z
            ; Rhs = variables in w
            ; Hold $
SURVIVAL    ; Lhs = logt [, and possibly a censoring indicator]
            ; Rhs = variables in x
            ; Model = one of Weibull, Normal, Loglogistic
            ; Selection
            ; RPM
            ; Fcn = one(n) $
```

(Other controls for the RP models, such as the number of replications, Halton draws, and so on, operate as usual.)

E54.11 A General Approach to Incorporating Selectivity in a Model

Based on the wisdom obtained from Heckman's modification of the linear model, there seems to be a widespread tendency (temptation) to extend that model to other frameworks by mimicking the two step approach used there. Thus, for example, one might fit a Poisson model with sample selection (developed Section E54.4 above), with the following two steps:

Step 1. Fit the probit model for the sample selection equation.

Step 2. Using the selected sample, fit the second step Poisson model merely by adding the inverse Mills ratio from the first step to the Poisson model as an additional independent variable.

This approach is inappropriate for several reasons

- The impact on the conditional mean of the Poisson does not take the form of an inverse Mills ratio. That is specific to the linear model. (See Terza (1995, 1998, 2010).)

- The bivariate normality assumption needed to justify the inclusion of the inverse Mills ratio in the Poisson mean does not appear anywhere in the model.

- The dependent variable, conditioned on the sample selection, is unlikely to have the Poisson distribution needed to use this technique.

Counterparts to these three problems will show up in any nonlinear model. Thus, note, in all of the preceding applications, we have built the selection into the model, rather than attempt to deal with it by dropping the inverse Mills ratio into the model at a convenient point.

The preceding development for the Poisson model suggests a method of incorporating sample selection in a model. The model is based on the premise that the force of 'sample selectivity' is exerted through the behavior of the unobservables in the model. As such, the key to modeling the effect is to introduce the unobservables that might be affected into the model in a reasonable way that maintains the internal consistency of the model itself. In the Poisson model, the standard approach to introducing unobserved heterogeneity is through the conditional mean, specifically,

$$\lambda_i(\varepsilon_i) = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i) \text{ where } \varepsilon \sim N[0,\sigma^2].$$

The negative binomial model arises, for example, if it is assumed that the unobserved heterogeneity, ε, has a log gamma distribution. 'Selectivity' would arise if the unobserved heterogeneity in this conditional mean is correlated with the unobservables in the selection mechanism, which is how it is modeled above. We propose a general approach to sample selection – one that we have used at several points above – by modifying the index function model along the lines of the Poisson model analyzed above. The following uses the Poisson model developed earlier as a template, and develops it more generally as an index function model that can be adapted to a specific model framework.

The generic model will take the form

$$
\begin{aligned}
z_i^* &= \boldsymbol{\alpha}'\mathbf{w}_i + u_i \text{ in which } u_i \sim N[0,1] \\
z_i &= \mathbf{1}(z_i^* > 0) && \text{(probit selection equation)} \\
\lambda_i |\, \varepsilon_i &= \boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i,\ \varepsilon_i \sim N[0,1] && \text{(index function with heterogeneity)} \\
y_i \,|\mathbf{x}_i, \varepsilon_i &\sim f(y_i \,|\, \mathbf{x}_i,\varepsilon_i) && \text{(index function model for outcome)} \\
[u_i,\varepsilon_i] &\sim N[(0,1),(1,\rho,1)] \\
y_i,\mathbf{x}_i & \quad \text{are observed only when } z_i = 1.
\end{aligned}
$$

The model given above is broad enough to include most of the models developed in the first 30 chapters of this manual, and most of them yet to follow. Again, the main equation of interest is taken to be an index function model, though, in fact, even that is merely a convenience, and the analysis will carry through if only we have $y_i \mid \varepsilon_i \sim f(\mathbf{x}_i,\sigma\varepsilon_i)$. But, this is more general than we will need.

The log likelihood function for the full model is the joint density for the observed data. When z_i equals one, $(y_i,\mathbf{x}_i,z_i,\mathbf{w}_i)$ are all observed. We seek $f(y_i, z_i=1|\mathbf{x}_i,\mathbf{w}_i)$. To obtain it, proceed as follows:

$$
\begin{aligned}
f(y_i, z_i=1|\mathbf{x}_i,\mathbf{w}_i) &= \int_{-\infty}^{\infty} f(y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i,\varepsilon_i)\, f(\varepsilon_i)d\varepsilon_i \\
&= E_\varepsilon[f(y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i,\boldsymbol{\varepsilon}_i)].
\end{aligned}
$$

Conditioned on ε_i, z_i and y_i are independent. Therefore,

$$f(y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i,\boldsymbol{\varepsilon}_i) = f(y_i|\mathbf{x}_i,\varepsilon_i)\text{Prob}(z_i=1|\mathbf{w}_i,\varepsilon_i).$$

The first part, $f(y_i\,|\mathbf{x}_i,\varepsilon_i)$ is the conditional index function model, however specified. By joint normality, $f(u_i|\varepsilon_i) = N[\rho\varepsilon_i\,, (1-\rho^2)]$. Therefore, $\text{Prob}(z_i=1|\mathbf{w}_i,\varepsilon_i)$ is

$$\text{Prob}(z_i=1|\mathbf{w}_i,\varepsilon_i) = \Phi\left([\boldsymbol{\alpha}'\mathbf{w}_i + \rho\varepsilon_i]/\sqrt{1-\rho^2}\right).$$

Combining terms and using the earlier approach, the unconditional joint density is

$$f[y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i] = \int_{-\infty}^{\infty} f(y_i|\mathbf{x}_i,\varepsilon_i)\ \Phi\left([\boldsymbol{\alpha}'\mathbf{w}_i + \rho\varepsilon_i]/\sqrt{1-\rho^2}\right) \frac{\exp(-\varepsilon_i^2/2)}{\sqrt{2\pi}}]d\varepsilon_i\,.$$

Let $\quad v = \varepsilon/\sqrt{2}$, $\theta = \sigma\sqrt{2}$, $\tau = \sqrt{2}\,[\rho/\sqrt{1-\rho^2}\,]$, and $\boldsymbol{\gamma} = [1/\sqrt{1-\rho^2}\,]\boldsymbol{\alpha}$.

(Thus, the reverse transformations are $\rho^2 = [\tau^2/(2 + \tau^2)]$, Sgn($\rho$) = Sgn($\tau$), and $\sigma = \theta/\sqrt{2}$.) After making the change of variable and reparameterizing the probability as before, we obtain

$$f(y_i,z_i=1|\mathbf{x}_i,\mathbf{w}_i) = \frac{1}{\sqrt{\pi}}\int_{-\infty}^{\infty} \exp(-v^2)\, f(y_i|\mathbf{x}_i,v_i)\Phi(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_i)\, dv_i$$

where the index function model now involves $\lambda_i|\, v_i = \boldsymbol{\beta}'\mathbf{x}_i + \theta v_i$.

E54.11.1 Using Quadrature to Maximize the Log Likelihood

The function in the form above can be approximated with Hermite quadrature since no closed form exists. When z_i equals zero, only $(z_i,\mathbf{w}_i)$ are observed. The contribution to the likelihood function is

$$\text{Prob}(z_i = 0|\mathbf{w}_i) = E_\varepsilon[1 - \text{Prob}(u_i > -\boldsymbol{\alpha}'\mathbf{w}_i|\mathbf{w}_i,\varepsilon_i)] = E_\varepsilon[\text{Prob}(u_i \le -\boldsymbol{\alpha}'\mathbf{w}_i|\mathbf{w}_i,\varepsilon_i)].$$

This provides the probability needed to construct the likelihood function.

$$\text{Prob}(z_i = 0|\mathbf{w}_i,\varepsilon_i) = 1 - \Phi(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_i/\sqrt{2})$$

so

$$\text{Prob}(z_i=0|\mathbf{w}_i) = \frac{1}{\sqrt{\pi}}\int_{-\infty}^{\infty} \exp(-v^2)\,\Phi[-(\boldsymbol{\gamma}'\mathbf{w} + \tau v)]dv.$$

Maximum likelihood estimates of $[\boldsymbol{\beta}, \boldsymbol{\gamma}, \theta, \tau]$ are obtained by maximizing

$$\log L = \Sigma_{z=0} \log\text{Prob}(z_i=0|\mathbf{w}) + \Sigma_{z=1} \log P(y_i,z_i=1|\mathbf{x},\mathbf{w}).$$

The approximating function is

$$\log L = \sum_{z_i=1} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h f(y_i\,|\,\mathbf{x}_i,v_h)\,\Phi\left(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h\right)\right]$$
$$+ \sum_{z_i=0} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h\Phi\left(-\boldsymbol{\gamma}'\text{w}_i - \tau v_h\right)\right]$$

where v_h and ω_h are the nodes and weights for the quadrature and

$$f(y_i|\,\mathbf{x}_i, v_h) = \text{the index function model, using } \boldsymbol{\beta}'\mathbf{x}_i + \theta v_h.$$

There are two useful further simplifications to employ. First, since z_i is binary,

$$(1\text{-}z_i) + z_i\, f(y_i|\,\mathbf{x}_i, v_h) = f(y_i|\,\mathbf{x}_i, v_h) \text{ when } z_i = 1 \text{ and } 1 \text{ when } z_i = 0.$$

Second, since the normal distribution is symmetric, the two appearances of the normal CDF above can be combined by using

$$\Phi[(2z_i - 1)(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h)] = \Phi[\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h] \text{ when } z_i = 1 \text{ and } \Phi[-(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h)] \text{ when } z_i = 0.$$

With these two devices, the approximating log likelihood function becomes

$$\log L = \sum_{i=1}^{N} \log\left[\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h\left[(1-z_i) + z_i\, f(y_i\,|\,\mathbf{x}_i,v_h)\right]\Phi\left[(2z_i-1)\left(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h\right)\right]\right].$$

The BHHH estimator of the asymptotic covariance matrix for the parameter estimates is a natural choice given the complexity of the function. The first derivatives must be approximated as well. For convenience, let

$$P_{ih} = f(y_i|\,\mathbf{x}_i, v_h)$$

$$\Phi_{ih} = \Phi(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h) \qquad \text{(normal CDF)}$$

and

$$\phi_{ih} = \phi(\boldsymbol{\gamma}'\mathbf{w}_i + \tau v_h) \qquad \text{(normal density)}$$

and to save some notation, denote the individual terms summed in the log likelihood as log L_i. We also take advantage of the result that $\partial P(.,.)/\partial z = P\times\partial \log P(.,.)/\partial z$ for any argument z which appears in the function. Then,

$$\frac{\partial \log L}{\partial \boldsymbol{\beta}} = \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \Phi_{ih} P_{ih} \frac{\partial \log f(y_i\,|\,\mathbf{x}_i, v_h)}{\partial \lambda_i}\mathbf{x}_i$$

$$\frac{\partial \log L}{\partial \theta} = \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \Phi_{ih} P_{ih} \frac{\partial \log f(y_i\,|\,\mathbf{x}_i, v_h)}{\partial \lambda_i} v_h$$

$$\frac{\partial \log L}{\partial \boldsymbol{\gamma}} = \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h P_{ih}\phi_{ih}\,\mathbf{w}_i - \sum_{z_i=0} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \phi_{ih}\,\mathbf{w}_i$$

$$\frac{\partial \log L}{\partial \tau} = \sum_{z_i=1} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h P_{ih}\phi_{ih}\,v_h - \sum_{z_i=0} \frac{1}{L_i}\frac{1}{\sqrt{\pi}}\sum_{h=1}^{H}\omega_h \phi_{ih}\,v_h$$

Estimates of the structural parameters, $(\boldsymbol{\alpha},\rho,\sigma)$ and their standard errors are computed using the delta method. The main parameter vector, $\boldsymbol{\beta}$, has been estimated explicitly.

E54.11.2 Using Simulation to Maximize the Log Likelihood

Simulation is another effective approach to maximizing the log likelihood function. To set this up, we return to the problem in its untransformed form. Using the simplifications suggested above, the log likelihood function to be maximized is

$$\log L = \sum_{i=1}^{N}\log \int_{-\infty}^{\infty} [(1\text{-}z_i) + z_i\, f(y_i|\mathbf{x}_i,\sigma\varepsilon_i)]\ \Phi[(2z_i-1)\left(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_i\right)]\ \ \phi(\varepsilon_i)d\varepsilon_i$$

where $\boldsymbol{\gamma} = [1/\sqrt{1-\rho^2}\,]\boldsymbol{\alpha}$, and $\tau = \rho/\sqrt{1-\rho^2}$. (The $\sqrt{2}$ has fallen out of the expression because we are not setting this up for Hermite quadrature.) The log likelihood in this form is an expectation that is amenable to estimation by simulation. The simulated log likelihood would be

$$\log L_S = \sum_{i=1}^{N}\log \frac{1}{R}\sum_{r=1}^{R} [(1\text{-}z_i) + z_i\, f(y_i|\mathbf{x}_i,\sigma\varepsilon_{ir})]\ \Phi[(2z_i-1)\left(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_{ir}\right)]$$

where ε_{ir} is a set of R random draws from the standard normal population. (We would propose to improve this part of the estimation by using Halton draws instead. See Section R24.7 for details.)

Derivatives of the simulated log likelihood are straightforward. For the *i*th observation,

$$\frac{\partial \log L_{S,i}}{\partial \boldsymbol{\beta}} = \frac{1}{\log L_{S,i}} \frac{1}{R} \sum_{r=1}^{R} z_i \left\{ f(y_i \mid \mathbf{x}_i, \sigma\varepsilon_{ir}) \left[\frac{\partial \log f(y_i \mid \mathbf{x}_i, \sigma\varepsilon_{ir})}{\partial \lambda_\iota} \right] \Phi[(2z_i - 1)(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_{ir})] \right\} \mathbf{x}_i$$

$$\frac{\partial \log L_{S,i}}{\partial \sigma} = \frac{1}{\log L_{S,i}} \frac{1}{R} \sum_{r=1}^{R} z_i \left\{ f(y_i \mid \mathbf{x}_i, \sigma\varepsilon_{ir}) \left[\frac{\partial \log f(y_i \mid \mathbf{x}_i, \sigma\varepsilon_{ir})}{\partial \lambda_i} \right] \Phi[(2z_i - 1)(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_{ir})] \right\} \varepsilon_{ir}$$

$$\frac{\partial \log L_{S,i}}{\partial \boldsymbol{\gamma}} = \frac{1}{\log L_{S,i}} \frac{1}{R} \sum_{r=1}^{R} [(1 - z_i) + z_i f(y_i \mid \mathbf{x}_i, \sigma\varepsilon_{ir})] \phi[(2z_i - 1)(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_{ir})] \mathbf{w}_i$$

$$\frac{\partial \log L_{S,i}}{\partial \tau} = \frac{1}{\log L_{S,i}} \frac{1}{R} \sum_{r=1}^{R} [(1 - z_i) + z_i f(y_i \mid \mathbf{x}_i, \sigma\varepsilon_{ir})] \phi[(2z_i - 1)(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_{ir})] \varepsilon_{ir}$$

To illustrate the technique, we consider constructing a binary logit model subject to sample selection. The immediate obstacle is the lack of a functional form for the joint distribution of a normally distributed ε and the logistically distributed variable that underlies the logit model. We use the template described here, instead.

z_i^* = $\boldsymbol{\alpha}'\mathbf{w}_i + u_i$ in which $u_i \sim N[0,1]$,

z_i = $\mathbf{1}(z_i^* > 0)$ (probit selection equation)

$$\text{Prob}(y_i = 1 \mid \mathbf{x}_i . \varepsilon_i) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)}{1 + \exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)}, \ \varepsilon_i \sim N[0,1]$$

$[u_i, \varepsilon_i] \sim N[(0,1),(1,\rho,1)]$

$y_i, \mathbf{x}_i$ are observed only when $z_i = 1$.

The simulated log likelihood function is

$$\log L_S = \sum_{i=1}^{N} \log \frac{1}{R} \sum_{r=1}^{R} \left[(1 - z_i) + z_i \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)}{1 + \exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i)} \right] \Phi[(2z_i - 1)\left(\boldsymbol{\gamma}'\mathbf{w}_i + \tau\varepsilon_{ir}\right)].$$

The Hermite quadrature method was used to obtain the estimates in the Poisson model applications in Section E54.4.4. The simulation technique was used for the binomial logit model in Section E54.8 and the stochastic frontier model in Section E54.6.

E55: Alternative Sample Selection Equations

E55.1 Introduction

Several of the forms of the selection model which can be estimated with *LIMDEP* depart from Heckman's now canonical form, a linear regression with a binary probit selection criterion model:

$$y = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,$$

$$z^* = \boldsymbol{\alpha}'\mathbf{w} + u,$$

$$\varepsilon,u \sim N[0,0,\sigma_\varepsilon^2,\sigma_u^2,\rho].$$

A bivariate classical normal (seemingly unrelated) regressions model applies to the structural equations. The standard deviations are σ_ε and σ_u, and the covariance is $\rho\sigma_\varepsilon\sigma_u$. If the data were randomly sampled from this bivariate population, the parameters could be estimated by least squares, or GLS combining the two equations. However, z^* is not observed. Its observed counterpart is z, which is determined by

$$z = 1 \text{ if } z^* > 0$$

and

$$z = 0 \text{ if } z^* \leq 0.$$

Moreover, values of y and $\mathbf{x}$ are only observed when z equals one. Thus, the model is two steps removed from the two equations seemingly unrelated regressions which would be simple to estimate. The essential feature of the model is that under the sampling rule, $E[y|\mathbf{x},z = 1]$ is not a linear regression.

This chapter will describe a set of alternative specifications for the selection mechanism. The regression part of the model is assumed to be linear, as in the first specification shown in Chapter E53. Some of the models are 'hardwired' as procedures in *LIMDEP*, for example the bivariate probit model. Others require fairly lengthy sets of commands in order to program the computations. We will include these in full in order to present the model and techniques and to demonstrate the range of calculations that can be added to the preprogrammed procedures.

WARNING: Users of these procedures should watch very closely for conflicts between their own variable, namelist, matrix, and scalar names and those which we are using in these programs. Sometimes these can cause subtle errors which will not be picked up by the program. For example, if you use one of our matrix or variable names for your own matrices, then use the program below as is, you may find the wrong calculations being done, for reasons that will not be obvious.

E55.2 The Univariate Probit Model

The standard selection rule in most of the existing programs is the single equation probit model, which you set up with

```
PROBIT      ; Lhs = dependent variable
            ; Rhs = independent variables
            ; Hold $
```

If you have already estimated the probit equation you want to use in a selection model, you can bypass the estimation stage with the following:

```
PROBIT      ; Lhs = z
            ; Rhs = v
            ; Hold
            ; Load ; Start = parameters $
```

Just set up the **PROBIT** command as if the model were to be estimated. When you provide a set of parameters with **; Load**, the estimation stage is skipped. The parameter vector you provide must correspond exactly to the list you provide in the **; Rhs** specification. This method would be useful primarily in a very large data set, in which multiple passes through the data could take a significant amount of time compared to the three needed for the selection model.

E55.3 Bivariate Probit Selection Rule

An extension of the sample selection model which allows a bivariate probit selection equation can be handled just by using **; Hold** with a bivariate probit model. Nothing else needs to be changed. The model is as follows:

$$
\begin{aligned}
y &= \boldsymbol{\beta}'\mathbf{x} + \varepsilon,\\
z_a^* &= \boldsymbol{\alpha}_a'\mathbf{w}_a + u_a,\\
z_b^* &= \boldsymbol{\alpha}_b'\mathbf{w}_b + u_b,\\
z_j &= 1 \text{ if } z > 0 \text{ and } 0 \text{ otherwise for } j = a,b.
\end{aligned}
$$

The random components, ε, u_a, and u_b have a trivariate normal distribution with variances σ^2, 1, and 1, respectively and correlations $\rho_{a\varepsilon}$, $\rho_{b\varepsilon}$ and ρ_{ab}. Estimates are obtained for all parameters of the model. We assume that y and $\mathbf{x}$ are observed only if $z_a = j_a$ and $z_b = j_b$ where j_a and j_b are either 0 or 1. I.e., you can select on any of the four possible combinations of z_a and z_b. The assumed combination is 1,1, but you can change this, as shown below.

If u_a and u_b are correlated, a bivariate probit model applies. The corresponding counterparts to the inverse Mills ratios, the λs, are complicated, but this is all taken care of internally. If u_a and u_b are not correlated, the model is one of two independent selection criteria, which is also easily handled. The estimates are obtained using a method analogous to the single equation selectivity model. In this case, the truncated bivariate normal distribution is needed to compute the estimates. As in the single equation case, negative estimated standard errors can arise in a finite sample. In this instance, OLS standard errors are used. The output contains the standard output for a least squares regression plus a listing of the corrected standard errors and the estimates of the two correlation coefficients.

All of the usual options for single equation models are available, including **; Test:** for restrictions, lists of predicted values, and so on. The **; Fill** option can be used to fill in missing data if the values of the regressors are provided. To estimate this model, you must provide the estimated probit equations through the **; Hold** option. We consider the bivariate probit case first. The set of instructions might look as follows: (You would, of course, substitute your own appropriate variables.)

```
BIVARIATE   ; Lhs = za,zb
            ; Rh1 = one,wa1,wa2
            ; Rh2 = one,wb1,wb2
            ; Hold for SELECT $
SELECT      ; Lhs = hours
            ; Rhs = one,x1,x2,x3,x29 $
```

The estimator assumes that you want to select those observations which have $za = zb = 1$. To use some other criterion, you add to the above

```
; Selection = ja,jb
```

where **ja** applies to the first probit equation in your model and **jb** the second. For example, to select observations with $za = 0$ and $zb = 1$, we would use **; Selection = 0,1**.

Once you estimate and **; Hold** a bivariate probit model, you can use it again without reestimating it. For example, in the preceding specification, we might reestimate the model for observations with $za = zb = 0$ by adding another line to the procedure:

```
SELECT      ; Lhs = hours
            ; Rhs = one,x1,x2,x3,x29
            ; Selection = 0,0 $
```

Remember that the bivariate probit criterion which you **; Hold** is replaced by another **; Hold** command. This means that if you estimate a single equation probit model and use **; Hold**, you will lose the bivariate probit you estimated earlier. Since the bivariate probit model can be time consuming to estimate, the option in the next section may be useful.

E55.3.1 Independent Probit Equations

The method of the previous section provides an easy way to estimate the selection model with two independent selection equations. Just estimate the two probit equations separately by maximum likelihood and pass a zero for the starting value for ρ_{ab}. I.e.,

```
PROBIT      ; ... first  equation $
MATRIX      ; ba = b $
PROBIT      ; ... second equation $
MATRIX      ; bb = b $
BIVARIATE   ; [specifications] ; Start = ba,bb,0 ; Load $
```

This sets up the regression (**SELECT**) command so it can be used as above.

E55.3.2 Loading a Probit Equation

If you have the parameter values from the bivariate probit model stored somewhere, you can use the **BIVARIATE PROBIT** (or just **BIVARIATE**) command just to load these known values, and bypass the estimation step. To do so, there are two ways to proceed. In each, you provide the entire command, exactly as if the model were to be estimated. If you just have the two slope vectors, you can use

```
BIVARIATE   ; Lhs = ... ; Rh1 = ... ; Rh2 = ... ; Start = ba,bb ; Load $
```

Given in this fashion, the command requests the procedure to compute an internal starting value for ρ. This will be attached to your slope vectors and passed on with the **; Load** specification which is now equivalent to **; Hold**. However, if you have your own estimate of the correlation coefficient, just add it to the list of starting values. That is,

```
BIVARIATE   ; Lhs = ... ; Rh1 = ... ; Rh2 = ... ; Start = ba,bb,rhoab ; Load $
```

Now, no computation is done at all. The equation is merely loaded and passed on to **SELECT**.

E55.3.3 Computing Lambda for the Sample Selection Model

The underlying regression model is

$$y = \boldsymbol{\beta}'\mathbf{x} + \varepsilon$$

Corr(u_a,ε) = $\rho_{a\varepsilon}$, Corr(u,ε) = $\rho_{b\varepsilon}$. But, (y,$\mathbf{x}$) are only observed when (z_1 = 1, z_2 = 1). Estimation of this model is done by a two step extension of Heckman's method for a single probit selection model. The linear regression is computed using the observed data, with regression of y on $\mathbf{x}$, λ_a and λ_b where the two 'lambda' variables are, in fact, g_a/Φ_2 and g_b/Φ_2 as defined in the next section.

These variables are computed internally during estimation, but not retained anywhere accessible. We are often asked how these can be computed and, moreover, can they be computed for the 'nonselected' observations. Using what is already done above, the computation is actually simple. The full set of computations would look as follows: (This is generic. Only the first two commands that set up the data would be specific to any application.)

```
NAMELIST    ; xa = equation a variables ; xb = equation b variables $
CREATE      ; ya = Lhs variable in equation a
            ; yb = Lhs variable in equation b $
BIVARIATE   ; Lhs = ya, yb ; Rh1 = xa ; Rh2 = xb $
CREATE      ; qa = 2*ya - 1 ; qb = 2*yb - 1 $
CALC        ; ka = Col(xa) ; kba = ka + 1 ; kvar = Row(b) $
MATRIX      ; ba = b(1:ka) ; bb = b(kba:kvar) $
CREATE      ; va = qa*xa'ba ; vb = qb * xb'bb ; rs = qa*qb*rho $
NAMELIST    ; v = va,vb $
CREATE      ; lambdaa = qa*Bv1(v,rs) / Bvn(v,rs)
            ; lambdab = qb*Bv2(v,rs) / Bvn(v,rs) $
```

E55.3.4 Technical Details

For the selectivity model with bivariate probit selection equation, the augmented regression is

$$y_i = \boldsymbol{\beta}'\mathbf{x}_i + \theta_a \lambda_{ai} + \theta_b \lambda_{bi} + \eta_i.$$

There are three correlation coefficients in the model,

$$\rho_{ab} = \text{corr}(u_a, u_b), \ \rho_{a\varepsilon} = \text{corr}(u_a, \varepsilon), \ \rho_{b\varepsilon} = \text{corr}(u_b, \varepsilon).$$

The bivariate probit model estimates ρ_{ab} in isolation. In the regression model, the parameters are

$$\theta_a = \rho_{a\varepsilon}\sigma_{a\varepsilon}, \ \theta_\text{b} = \rho_{b\varepsilon}\sigma_{b\varepsilon}.$$

The ‘λ‘ variables in the regression are

$$\lambda_a = \phi(w_a)\Phi[(w_b - \rho_{ab}z_a)/(1 - \rho_{ab}^2)^{1/2}] \ / \ \Phi_2$$

where $w_a = -\boldsymbol{\alpha}_a'\mathbf{w}_a$, and likewise for ‘$b$,’ and Φ_2 = bivariate normal CDF, $\Phi(w_a, w_b, \rho_{ab})$. The coefficients are computed by least squares regression of y on $\mathbf{x}$, λ_a, and λ_b. The estimator of the asymptotic covariance matrix is

$$\mathbf{V} = (\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1}[\mathbf{X}^{*\prime}(\sigma^2\mathbf{I} - \boldsymbol{\Pi})\mathbf{X}^* + \theta_a^2\mathbf{X}^{*\prime}\mathbf{G}_a\boldsymbol{\Sigma}\mathbf{G}_a'\mathbf{X}^* + \theta_b^2\mathbf{X}^{*\prime}\mathbf{G}_b\boldsymbol{\Sigma}\mathbf{G}_b'\mathbf{X}^*](\mathbf{X}^{*\prime}\mathbf{X}^*)^{-1},$$

where $\mathbf{X}^* = [\ \mathbf{X} : \boldsymbol{\lambda}_a : \boldsymbol{\lambda}_b\ ]$,

$\boldsymbol{\Pi} = \text{diag}(\pi_1, \ldots, \pi_N)$,

$\pi_i = \theta_a^2 w_a \lambda_a + \theta_b^2 w_b \lambda_b + (\theta_a \lambda_a + \theta_b \lambda_b)^2 - [2\theta_a \theta_b - \rho_{ab}(\theta_a^2 + \theta_b^2)]\phi_2/\Phi_2$,

$\boldsymbol{\Sigma}$ = asymptotic covariance matrix for estimates of $[\boldsymbol{\alpha}_a, \boldsymbol{\alpha}_b, \rho_{ab}]$,

and $\mathbf{G}_j = \partial\boldsymbol{\lambda}_j/\partial[\boldsymbol{\alpha}_a, \boldsymbol{\alpha}_b, \rho_{ab}]$, $j = a,b$.

The expressions for the derivatives are exceedingly cumbersome. The estimate of σ^2 is

$$\hat{\sigma}^2 = (1/N)\mathbf{e}'\mathbf{e} - (1/N)\Sigma_i \pi_i.$$

E55.4 A Binary Logit Selection Model

Lee (1983) describes a reformulation of the selection model which allows more general specifications of the criterion equations. The most common application of the techniques in this paper would be the use of a logit instead of a probit equation for the selection criterion equation. This results in a minor modification of the estimation procedure. In the probit case, λ is computed using $\boldsymbol{\alpha}'\mathbf{v}$. For the logit model, we use the transformed variable

$$q = \Phi^{-1}\left[\frac{\exp(\boldsymbol{\alpha}'\mathbf{v})}{1+\exp(\boldsymbol{\alpha}'\mathbf{v})}\right]$$

$$= \Phi^{-1}[\,P_{logit}\,].$$

Then, $\lambda = \phi(q) \,/\, \Phi(q)$ or $-\phi(-q)/\Phi(-q)$ if selection is on z = 0.

Other computations are now the same as before. To use this estimator in *LIMDEP*, simply use

```
LOGIT     ; Lhs = z ; Rhs = list of v ; Hold $
SELECT    ; ... exactly the same as before ... $
```

All necessary modifications – there are very few – are already set up internally. The model specification

; Hold (IMR = name)

is usually used for the probit model to set up a sample selection model. The same parameter may now be used with **LOGIT**, for the same purpose. This variable, λ can be computed as follows:

```
NAMELIST  ; v = ... $
LOGIT     ; Lhs = y ; Rhs = v $
CREATE    ; alphax = v'b           ? computes index α'v
          ; j1 = Inp(alphax)       ? computes Lee's j1
          ; lambda = Lmd(j1,z)     $ computes lambda
```

To illustrate the estimator, we analyze a data set on credit applications. The file (credit.lpj) contains 13,444 observations on applications for a major credit cards. Variables used in the model below include:

cardhldr = whether the application was accepted (0/1),
income = average monthly income,
depdnt = number of dependents in the household,
incper = income / (1 + depdnt),
credmajr = number of major credit cards held,
tradacct = number of merchant credit accounts,
age = age in months,
ownrent = dummy variable for home ownership,
selfempl = dummy variable for self employed,
curntadd = number of months living at current address,
spending = average monthly expenditure.

The regression model analyzes average yearly expenditure. The selection mechanism is, as before, cardholder status.

NAMELIST ; card = one,age,income,ownrent,selfempl,curntadd $
NAMELIST ; spending = one,income,depdnt,incper,credmajr,tradacct $
LOGIT ; Lhs = cardhldr ; Rhs = card ; Hold $
SELECT ; Lhs = avgyrexp ; Rhs = spending $

Results are shown below. Based on the estimate of ρ, cardholder status does not have much impact on average yearly spending.

E55.5 Multinomial Logit Selection Model

Lee (1983) also describes the computation of an estimator for the sample selection model when selection is based on the multinomial logit or discrete choice model of Chapter E37. The following will show how to compute the first model. (Another relevant study on this model is Hay (1980).) We first present some background, since Lee's paper stops at the point of presenting the estimating regression equation. Following Lee, we suppose, then, that z is the selection variable which takes values 0, 1, ..., J for J + 1 outcomes. The model for determination of z is

$$\text{Prob}[z_i=j] = \exp(\boldsymbol{\alpha}_j'\mathbf{w}_i) \,/\, \left[1 + \sum_{j=1}^{J} \exp(\boldsymbol{\alpha}_j'\mathbf{w}_i)\right],$$

where 'i' indexes the observation and 'j' indexes the choice or outcome. This embodies a number of assumptions about the joint and marginal distributions of disturbances in the model, for which reference can be made to Lee's paper. Selection is based on $z_i = j$. For convenience below, we drop the observation subscript. The implied regression equation for estimation derived by Lee is

$$\begin{aligned} y_j &= \boldsymbol{\beta}'\mathbf{x}_i + (\rho_j\sigma_j)\phi[H_j(\boldsymbol{\alpha}_j'\mathbf{w}_i)]/\Phi[H_j(\boldsymbol{\alpha}_j'\mathbf{w}_i)] + \eta_j \\ &= \boldsymbol{\beta}'\mathbf{x}_i + (\rho_j\sigma_j)\lambda_j + \eta_j \\ &= \boldsymbol{\beta}'\mathbf{x}_i + \theta_j\lambda_j + \eta_j. \end{aligned}$$

Our notation differs slightly from Lee's. We use 'H' for his 'J' function (the inverse of the standard normal CDF evaluated at Prob[$z = j$]) to avoid a conflict with our formulation of the logit model. We have also reversed the sign of the second term in the regression to be consistent with our notation elsewhere. This is merely a matter of interpreting ρ. As in Lee's paper, the functions $\phi(t)$ and $\Phi(t)$ are the PDF and CDF of the standard normal distribution. Finally, although the denominator in λ_j is just Prob[$z = j$], it is convenient to have it in the form above when we derive the appropriate standard errors. This full set of computations is fully automated. To fit this model, just use

MLOGIT ; Lhs = z ; Rhs = w; Hold $
SELECT ; Lhs = y ; Rhs = x ; Choice = j $

The **MLOGIT** command may fit a binomial or multinomial logit model. The **; Choice = j** may be omitted in the **SELECT** command if you are selecting observations with choice = 1. For any other choice, you must provide this specification. All of the other features of the selection model available in the standard case, including marginal effects, are supported for this selection mechanism as well.

E55.5.1 Application

To illustrate the estimator, we have contrived an application based on credit data used above. We suppose that cardholders (i.e., those with cardhldr = 1) are further divided into three card types, cardtype = 0,1,2. (The partition is artificial, for the purpose of our simulation.)

CREATE ; cardtype = cardhldr*(Rnd(3)-1) $
REJECT ; cardhldr = 0 $
MLOGIT ; Lhs = cardtype ; Rhs = card ; Hold $
SELECT ; Lhs = avgyrexp ; Rhs = spending ; Choice = 1 $
SELECT ; Lhs = avgyrexp ; Rhs = spending ; Choice = 2 $

Results are shown below for the first selection model. The second model result is similar, but is based on the different subset of the observations. Note that the method of moments based estimate of the correlation coefficient is larger than one, so one is used in the subsequent computations.

E55.5.2 Technical Details

The two step estimation technique is as follows: (The reader is referred to Lee's paper for some of the relevant background for this.) The first step is to estimate the multinomial logit model by maximum likelihood, retaining the coefficients, estimated asymptotic covariance matrix of these estimates, and the full set of predicted probabilities. Select those observations for which z takes the value in question. (This depends on the application.) For these observations, compute λ_j by obtaining, first, the predicted probability, P_i (Lee denotes this F_j), then

$$\mathrm{H}_j = \Phi^{-1}(P_j),\ \ \lambda_j = \phi(H_j) / \Phi(H_j).$$

In the following, 'i' is the observation, 'j' is the selection choice, $j = 0,...,J$, and K_2 is the number of variables in $\mathbf{w}$.

The second step is to obtain consistent estimates of $\boldsymbol{\beta}$ and θ_j by least squares regression of y_j on $\mathbf{x}$ and λ_j. Denote by $\mathbf{X}_j$ the $N_j{\times}(K_1{+}1)$ matrix of regressors used in this regression including λ_j. Then, the appropriate asymptotic covariance matrix is:

$$\mathbf{C} = (\mathbf{X}_j'\mathbf{X}_j)^{-1}[\sigma_j^2\mathbf{X}_j'(\mathbf{I}\text{-}\rho_j^2\boldsymbol{\Delta}_j)\mathbf{X}_j + \theta_j^2\ \mathbf{F}_j\boldsymbol{\Sigma}\mathbf{F}_j'](\mathbf{X}_j'\mathbf{X}_j)^{-1},$$

where $\delta_{ij} = \lambda_{ij}^2 + H_{ij}\lambda_{ij},\ \ \boldsymbol{\Delta}_j = \mathrm{diag}(\delta_{1j},\delta_{2j},...,\delta_{Nj,j}),$

$$\boldsymbol{\Sigma} = \text{asymptotic covariance matrix of estimated } \boldsymbol{\alpha} = [\boldsymbol{\alpha}_1,\boldsymbol{\alpha}_2,...\boldsymbol{\alpha}_J],$$

$$\mathbf{F}_j = \mathbf{X}_j'\mathbf{G}_\mathrm{j},$$

and $\mathbf{G}_j = N_j{\times}(JK_2) = \partial[N_j{\times}1 \text{ vector of } \lambda\text{s}]/\partial\boldsymbol{\alpha}'.$

This is a matrix of derivatives of the lambdas with respect to the logit parameters. We construct

$$\mathbf{G}_j = [\mathbf{G}_{1j}, \mathbf{G}_{2j}, ..., \mathbf{G}_{Jj}].$$

The ith row of the $N_j \times K_2$ matrix $\mathbf{G}_{sj}$ is

$$\mathbf{g}_{isj}' = (\delta_{ij} / F_{ij}) q_{isj} \mathbf{w}'.$$

The scalar q_{isj} depends on the choice. If selection is on $z = 0$,

$$q_{isj} = - P_{0i} P_{si},\ s=1,...,J.$$

If selection is on z = some other value, say, k, then, for the kth item,

$$q_{ikj} = P_{ik}(1 - P_{ik}),$$

while for all other items,

$$q_{isj} = -P_{ik} P_{sk},\ s = 1,...,J \text{ but not equal to } k.$$

E55.6 Tobit Selection Rule

It is possible to use a tobit or classical regression model as the selection criterion. (See Lee, Maddala, and Trost (1980).) Consider the tobit model first, where we take as the example the standard specification. One might select, for instance on 'hours worked' in a labor supply setting. This variable would be either zero for nonworkers, or positive for the remaining observations. One simple way to estimate this revised model is to reformulate the tobit model as a probit model. We would recode the dependent variable as zero as before and one for the existing nonzero observations. It is straightforward to show that doing so amounts to estimating by probit analysis the parameter vector $\boldsymbol{\alpha}/\sigma$, instead of obtaining the separate estimates of the two parameters with the tobit estimator. This is a practical solution which may sacrifice some efficiency by discarding information on the dependent variable. This would show up in the standard errors of the selection equation's parameter estimates, as the $\boldsymbol{\Sigma}$ in the second part of the bracketed term in the expressions given earlier is the asymptotic covariance matrix for the estimator of the parameters in the selection equation. It is not necessarily true though, that there would be any efficiency loss in a finite sample. The reason is that although the tobit estimator does, asymptotically, estimate $\boldsymbol{\alpha}/\sigma_u$ more efficiently than the probit model, in a finite sample, this nonlinear function of the parameters of the tobit model may be as variable as the estimates from the probit equation.

In a case in which the limit values in the tobit model are not zero and $+\infty$, the preceding is moot. When the censoring point in the tobit model is nonzero, the parameter σ (or its reciprocal) enters λ independently from $\boldsymbol{\beta}$. As such, in computing the asymptotic covariance matrix for the selectivity corrected parameter estimates, it is necessary to account for the variation in the estimate of σ.

We depart from the doubly censored regression model with lower censoring limit L and upper limit U. We use Olsen's reformulation of the tobit model,

$$\boldsymbol{\gamma} = \boldsymbol{\alpha}/\sigma_u,\ \eta = 1/\sigma_u.$$

Then, the auxiliary variable in the selectivity corrected regression will be

$$\lambda = \frac{\phi(\eta L - \boldsymbol{\gamma}'\mathbf{x}) - \phi(\eta U - \boldsymbol{\gamma}'\mathbf{x})}{\Phi(\eta U - \boldsymbol{\gamma}'\mathbf{x}) - \Phi(\eta L - \boldsymbol{\gamma}'\mathbf{x})}.$$

The asymptotic covariance matrix for the slopes in the regression of **y** on **X** and λ would take a familiar form,

$$\mathbf{C} = (\mathbf{X}^{*\prime}\mathbf{X}^{*})^{-1}[\sigma_\varepsilon^2(\mathbf{X}^{*\prime}(\mathbf{I} - \rho^2\boldsymbol{\Delta})\mathbf{X}^{*} + \mathbf{X}^{*\prime}\mathbf{G}\boldsymbol{\Sigma}\mathbf{G}'\mathbf{X}^{*}](\mathbf{X}^{*\prime}\mathbf{X}^{*})^{-1},$$

where

$$z_j = \eta j - \boldsymbol{\gamma}'\mathbf{x},\ j = L,U,$$

$$\phi_j = \phi(z_j),\ j = L,U,\ \ \Phi_j = \Phi(z_j),\ j = L,U,$$

$$\delta = \frac{\phi_L z_L - \phi_U z_U}{\boldsymbol{\Phi}_U - \boldsymbol{\Phi}_L},\ \ \boldsymbol{\Delta} = \text{diag}(\delta_1, \delta_2, \ldots),$$

$$\mathbf{X}^{*} = (\mathbf{X} : \boldsymbol{\lambda}),\ \ \mathbf{G} = \text{matrix of derivatives, rows} = \mathbf{g}_i,$$

$$\mathbf{g}_i = (\partial\lambda_i/\partial\boldsymbol{\gamma}' : \partial\lambda_i/\partial\eta),$$

$$\partial\lambda/\partial\boldsymbol{\gamma}' = \delta\mathbf{v}',\ \ \partial\lambda/\partial\eta = [U\phi_U(z_U - \lambda) - L\phi_L(z_L - \lambda)] / (\Phi_U - \Phi_L).$$

In the computation of **C**, $\boldsymbol{\Sigma}$ is the asymptotic covariance matrix for estimates of $[\boldsymbol{\gamma},\eta]$. The tobit program estimates

$$\mathbf{Q} = \text{asymptotic covariance matrix for estimates of } [\boldsymbol{\beta},\sigma],$$

not $\boldsymbol{\Sigma}$. To estimate $\boldsymbol{\Sigma}$ from **Q**, we reverse the usual application of the delta method. Let

$$\mathbf{K} = \begin{bmatrix} \partial\boldsymbol{\gamma}/\partial\boldsymbol{\beta}' & \partial\boldsymbol{\gamma}/\partial\sigma \\ \partial\eta/\partial\boldsymbol{\beta}' & \partial\eta/\partial\sigma \end{bmatrix} = \begin{bmatrix} (1/\sigma)\mathbf{I} & -\left(1/\sigma^2\right)\boldsymbol{\beta} \\ \mathbf{0} & -\left(1/\sigma^2\right) \end{bmatrix}.$$

Then,

$$\boldsymbol{\Sigma} = \mathbf{KQK}'.$$

The following is a program which will do all of the computations for the selectivity model for tobit equations with either lower, upper, or both tails censored. You control this aspect of the computation by specifying the limit values. E.g., for upper censoring at 6.25, you would use $-\infty$ (use -10000) as the lower limit and 6.25 as the upper, etc. The first few lines set up the data for the specific application.

```
CREATE     ; y  = dependent variable in regression
           ; z  = dependent variable in tobit model $
NAMELIST   ; x  = the Rhs in selectivity corrected regression
           ; w = the Rhs in tobit model $
```

Lower and *upper* must now be set to define the lower and upper limits of the selection region for *y*. Either or both may be infinite. For minus or plus infinity, use 10000 or -10000. These may be different from those used in the tobit model. For example, if the limit values used in estimation were zero and one and you want to select those at the upper limit value of one, you would set *lower* = 1 and *upper* = 10000 in the command below. Do note, in all cases, both values must be provided below, even if one of them is plus infinity or minus infinity. To allow these to vary by observations, we use variables, even if the limits do not vary by observation.

```
CREATE      ; Lower = the specification ; Upper = the specification $
```

None of the commands to follow require any modification. First, pick up tobit estimates of σ and β, and transform them to η and γ. Then, get the appropriate asymptotic covariance matrix for the transformed estimates.

```
TOBIT       ; Lhs = z ; Rhs = w ; Par ; Limits = lower,upper $
CALC        ; kw = Col(w) ; eta = 1/s ; etasq = -eta^2 $
MATRIX      ; beta = b(1 : kw)
            ; k11 = eta * Iden(kw) ; k12 = etasq * beta
            ; k21 = Init(1,kw,0) ; k22 = etasq
            ; k = [k11,k12 / k21,k22]
            ; sg = k * varb * k’ ; gamma = eta * beta $
```

Isolate the selected sample.

```
REJECT      ; y <= lower | y >= upper $
```

Create the variables needed to compute the estimates and asymptotic covariance matrix.

```
CREATE      ; wgamma = w’gamma
            ; zu = eta * upper - wgamma ; fu = N01(zu) ; pu = Phi(zu)
            ; zl  = eta * lower  - wgamma ; fl  = N01(zl) ; pl = Phi(lz)
            ; pul = pu - pl
            ; lambda = (fl - fu) / pul
            ; delta = (zl*fl - zu*fu) / pul - lambda ^ 2
            ; dldeta = (upper*fu*(zu - lambda) - lower*fl *(zl - lambda)) / pul $
```

Compute the slopes in the selectivity corrected regression. Pick up three parts: *c*1 = slope on *lambda*, *sigma*(1) = OLS disturbance standard deviation, *b*1 = full set of slopes including *c*1. Then, compute consistent estimates of σ^2 and ρ^2.

```
NAMELIST    ; xl = x,lambda $
REGRESS     ; Lhs = y ; Rhs = xl $
MATRIX      ; b1 = b $
CALC        ; l1 = b(kreg) ; csq = c1 ^ 2
            ; sigma1 = Sqr(s ^ 2 - csq * Xbr(delta))
            ; rho12 = c1 / sigma1 $
```

Compute the components of the variance matrix and $\theta = \sigma^2(1 - \rho^{2*})$.

```
CREATE        ; theta = sigma1 - rho12 ^ 2 * delta ; delta = Abs(delta) $
```

Compute the matrix components. We must deal with an extra column because of σ.

```
MATRIX        ; psi1 = xl' [theta]v
              ; f1 = xl' [delta]v ; f2   = xt'dldeta ; f = [f1,f2]
              ; c = xl'[theta]xl + csq * f * sg * f'
              ; f = <xt'xt> * c * <xt'xt>
              ; Stat(b1,f,xl)  $
```

E55.7 Ordered Probit Selection Rule

This program computes the regression coefficient estimates and the appropriate asymptotic covariance matrix for a sample selection model based on the ordered probit model. The ordered probit model is:

$$
\begin{aligned}
z^* &= \boldsymbol{\alpha}'\mathbf{w} + u,\\
z &= 0 \ \text{ if } -\infty \quad z^* \le 0,\\
& \quad 1 \ \text{ if } 0 < z^* \le \mu_1,\\
& \quad 2 \ \text{ if } \mu_1 < z^* \le \mu_2,\\
& \quad \text{and so on,}\\
& \quad J \ \text{ if } \mu_{J-1} < z^* \le +\infty.
\end{aligned}
$$

z^* is not observed; z is its observed counterpart. The disturbance, u is assumed to be distributed as standard normal. (See Greene and Hensher (2010) for details on the ordered probit model.) The equation of interest is

$$y = \boldsymbol{\beta}'\mathbf{x} + \varepsilon,$$

where ε is normally distributed with mean zero, standard deviation σ and correlation ρ with u. Data on y are only observed when z takes a particular value, so the selection mechanism is

y is only observed when $z = j$ for some j in $(0,1,...,J)$.

The estimation of this model by a two step procedure follows exactly the steps in Heckman (1979) and Greene (1981), which provide the standard results for the case in which $J = 1$ (simple probit model). The steps are

Step 1. Estimate the ordered probit by MLE using all observations.

Step 2. Select the observations for the regression.

Step 3. Estimate the primary equation by OLS including the correction term $E[\varepsilon \mid z = j]$.

Step 4. Correct the estimated asymptotic covariance matrix of the estimates.

The procedure follows, with annotation provided within the commands. The following must be set by the user prior to using this routine to set up the data:

```
NAMELIST  ; w = the Rhs variables in the ordered probit $
CREATE    ; z  = the Lhs variable in the ordered probit $
NAMELIST  ; x  = the Rhs variables in the regression model $
CREATE    ; y  = the Lhs variable in the regression model $
CALC      ; j  = the value on which sample selection is based $
```

Estimate the ordered probit model and collect results. The number of values taken by the dependent variable in the ordered probit model is $JP = J+1$. Retrieve the dimensions and estimates from ordered probit. KP is the number of variables in the ordered probit, $KP1 = KP+1$, M = number of threshold parameters, L = number of parameters estimated. Retrieve the slope vector as *alpha*.

```
ORDERED   ; Lhs = z ; Rhs = w ; Par $
CALC      ; Nolist ; jp = Max(z) + 1 ; jp1 = jp + 1
          ; kp = Col(w) ; kp1 = kp + 1 ; m = jp - 2 ; l = kp + m $
MATRIX    ; alpha = b(1 : kp) $
```

The full threshold vector is $-\infty,0,\mu_1,\mu_2,...,\mu_{J-1},+\infty$. The name *mu* is used by the ordered probit program, so we use *mua*.

```
MATRIX    ; u1 = [-10000 / 0 ] ; u2 = b(kp1:l ) ; u3 = [10000] ; mua = [u1/u2/u3] $
```

The covariance matrix for this full parameter vector, including thresholds with $(-\infty,0)$ embedded and ∞ at the end is as follows: (the four parts are KP, 2, M and 1 parameter, respectively)

$$Var\begin{pmatrix}\hat{\alpha}\\ -\infty,0\\ \hat{\mu}\\ \infty\end{pmatrix}=\begin{bmatrix}\Sigma_{\alpha\alpha} & \mathbf{0} & \Sigma_{\alpha\mu} & \mathbf{0}\\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0}\\ \Sigma_{\mu\alpha} & \mathbf{0} & \Sigma_{\mu\mu} & \mathbf{0}\\ \mathbf{0} & \mathbf{0} & \mathbf{0} & 0\end{bmatrix}$$

```
MATRIX    ; z11 = varb(1:kp, 1:kp)
          ; z21 = Init(2,kp,0) ; z22 = [0,0/0,0]
          ; z31 = varb(kp1:l, 1:kp) ; z32 = Init(m,2,0) ; z33 = varb(kp1:l, kp1,l)
          ; z41 = Init(1,kp,0) ; z42 = [0,0] ; z43 = Init(1,M,0) ; z44 = [0]
          ; v = [z11 / z21,z22 / z31,z32,z33 / z41,z42,z43,z44] $
```

Select the sample.

```
INCLUDE   ; New ; z  = j $
```

Construct some variables needed for the regression. For selection on z = j, $E[\varepsilon|z=j] = \rho\ \sigma\ \lambda$, $Var[\varepsilon|z=j] = \sigma^2(1 - \rho^2\ \delta)$.

```
CALC      ; j1 = j + 1 ; j2 = j + 2 $
CREATE    ; aj1 = mua(j1) - w'alpha ; aj = mua(j2) - w'alpha
          ; dj1 = N01(aj1) ; dj = N01(aj) ; fj1 = Phi(aj1) ; fj = Phi(aj)
          ; lambda = (dj1 - dj) / (fj - fj1)
          ; delta = (aj1*dj1 - aj*dj) / (fj - fj1) - lambda ^ 2 $
```

The regression is computed by regressing y on $\mathbf{x}$ and λ. Let c be the coefficient on λ. We estimate the residual variance with $s^2 = e'e/N(j) - c^2\ \bar{\delta}$ (the same as in the simpler case). Then the correlation between the regression disturbance and the structural disturbance in the ordered probit is estimated with $\rho^2 = c^2 / s^2$.

```
NAMELIST    ; xl = x,lambda $
REGRESS     ; Lhs  = y ; Rhs = xl $
CALC        ; p = Col(xl) ; c  = b(p)
            ; s2 = sumsqdev / nreg - c^2 * Xbr(delta)
            ; rhosqd = c^2 / s2 $
```

The asymptotic covariance matrix for the estimates is

$$\mathbf{C} \ = \ s^2\ (\mathbf{X'X})^{-1}[\mathbf{X'}(\mathrm{I}\text{-}\rho^2\Delta)\mathbf{X} + \rho^2(\mathbf{X'G})\boldsymbol{\Sigma}(\mathbf{G'X})]\ (\mathbf{X'X})^{-1}$$

where $\mathbf{X}$ includes lambda, $\boldsymbol{\Delta}$ is a diagonal matrix of δs, and $\mathbf{G}$ is a matrix whose columns are the derivatives of the lambda variable with respect to the parameters $[\boldsymbol{\alpha},\boldsymbol{\mu}]$. $\mathbf{G}$ is more complicated here than in the standard probit case. The first **KP** columns of $\mathbf{G}$ are $\mathbf{-\Delta W}$ where $\mathbf{W}$ is the $n\times KP$ matrix of regressors in the ordered probit model. We have augmented the slope parameter vector with M+3 values, three of which are zeros and $M = J$-1 are elements in the estimated threshold vector.

```
CREATE      ; pj1 = (j > 1) * dj1 / (fj - fj1) * (lambda - aj1)
            ; pj = (j > 0) * (j < (jp-1)) * ( - dj/(fj - fj1) * (lambda - aj)) $
CREATE      ; h = 1 - rhosqd * delta $
```

Note that if j = 0, both of these values are zero, while if j = 1, the first is zero, and if $j = J$, the second is zero. These are then inserted as the (KP+2)+(j-1) and (KP+2)+j columns of $\mathbf{G}$. The remaining columns of $\mathbf{G}$ are columns of zeros. To assemble this, we work with $\mathbf{X'G}$ rather than $\mathbf{G}$ itself and use some tricks from matrix algebra. Let $\mathbf{X'G}$ consist of two parts, $\mathbf{X'G1}$ and $\mathbf{X'G2}$. $\mathbf{X'G1}$ is just -$\mathbf{X'\Delta W}$, which is easy to get. $\mathbf{X'G2}$ is the $P\times(J+2)$ matrix of moments defined using the variables above. Suppose the two columns are $\mathbf{X'p1}$ and $\mathbf{X'p}$. We have to place these two columns into $\mathbf{G}$ in the right place. The following will do so without requiring the user to modify the program. Let $\mathbf{H}$ be a $P\times3$ column matrix consisting of $\mathbf{X'p1}$, $\mathbf{X'p}$, and a third column filled with zeros. Then, the full $\mathbf{X'G}$ matrix that we need is just $\mathbf{HR}$ where $\mathbf{R}$ is the matrix of zeros. The first row is JP+1 zeros save for a one in the column corresponding to where we want $\mathbf{X'p1}$ to be in $\mathbf{X'G}$. The second row is defined likewise for $\mathbf{X'p}$.

```
MATRIX      ; xp1 = xl'pj1 ; xp = xl'pj ; zero = Init(p,1,0)
            ; r = Init(3,jp1,0) ; r(1,j1) = 1 ; r(2,j2) = 1
            ; xpp = [xp1,xp,zero]
            ; xg1 = xl'[delta]w ; xg2 = xpp * r ; xg = [xg1,xg2] $
```

Obtain the corrected covariance matrix and display the results.

```
MATRIX      ; vc = xl'[h]xl + rhosqd * xg * v * xg'
            ; vc = s2 * <xl'xl> * vc * <xl'xl>
            ; Stat(b,varb,xl)      ? (uncorrected results)
            ; Stat(b,vc,xl)        $ (corrected results)
```

E56: Treatment Effects and Switching Regressions

E56.1 Introduction

The essential form of the treatment effects 'model' is a measure of an outcome, y, and an input, say z, which takes the form of some treatment – income equations with a college attendance dummy variable, or wage equations with training program participation dummy variables are common examples. Some of the more widely used methods are programmed in *LIMDEP*. This chapter will detail several models that are related to this type of analysis.

A variety of procedures are presented here. This chapter examines some formal regression approaches that specify the 'treatment effect' as an endogenous dummy variable in a model. The switching regressions and mover stayer models describe the effect of 'treatment' as a change in regime – that is, as a change in the applicable regression model. These are more general than the endogenous dummy variable models, but they are, as well, fully parameterized.

E56.2 The Mover Stayer Model

A fully parameterized model for treatment effects is the structural model

$$y_i = Y_1 = \boldsymbol{\beta}_1'\mathbf{x}_i + \varepsilon_{i1} \text{ when } z_i = 1$$

$$y_i = Y_0 = \boldsymbol{\beta}_0'\mathbf{x}_i + \varepsilon_{i0} \text{ when } z_i = 0$$

$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + \mathbf{u}_i, \; z_i = 1(z_i^* > 0).$$

In this model, z_i represents the presence ($z_i = 1$) or absence ($z_i = 0$) of the treatment. In this instance, a different model applies in the two 'states.' This has been labeled a 'mover stayer' model in studies of income of migrants (movers) and nonmigrants (stayers). The model can be estimated for the purpose of examining the various coefficients. However, in recent treatments (such as Heckman, Tobias and Vytlacil (2003)) the interesting feature of the model is what it can reveal about 'treatment effects,' such as $E[y|\mathbf{x},\mathbf{w},z=1]$ - $E[y|\mathbf{x},\mathbf{w},z=0]$.

This is an application of the mover stayer model. (See Willis and Rosen (1978), Lee (1978), Robinson and Tomes (1982), and Nakosteen and Zimmer (1980).) The structural equations of the model are:

$$y_1 = \boldsymbol{\beta}_1'\mathbf{x}_1 + \varepsilon_1 \text{ (may be a tobit model),}$$

$$y_0 = \boldsymbol{\beta}_0'\mathbf{x}_0 + \varepsilon_0 \text{ (may be a tobit model),}$$

$$c = \boldsymbol{\alpha}'\mathbf{w} + u_c,$$

$$z^* = y_1 - y_0,$$

$$z = 1 \text{ if } z^* > c \text{ and } z = 0 \text{ if } z^* \leq c,$$

$$y = y_1 \text{ if } I = 1 \text{ and } y = y_0 \text{ if } I = 0.$$

For an example (the setting of the Robinson and Tomes study), suppose y_j is the market wage obtainable at location '*j*' while '*c*' is the cost of moving from initial state 1 to alternative state 0. Observed wage is *y*, which will be in state 0 if the premium I^* exceeds the cost of the move, *c*. Otherwise, *y* is observed in state 1 and no transition of state takes place. Variants of this model can be applied in a variety of situations, as suggested by the sampling of the literature noted above.

Observed data consist of *y*, $\mathbf{x}_1$, $\mathbf{x}_0$, *z*, and **w**. The disturbances are assumed to be joint normally distributed. *I* is an indicator of whether the individual 'moves' ($I = 1$) or 'stays' ($I = 0$). The sample selectivity model described earlier applies here with only minor variation, and, as noted, could be applied separately to each structural equation. (The two step estimation techniques are presented in Lee (1976).) This section presents a FIML estimator for the full model. We will denote the model with endogenous switching, whether or not it fully conforms to the structural model shown above, as the mover stayer model.

NOTE: The two regression equations in the mover stayer model may be tobit models.

E56.2.1 Sample Selection Models

With an assumption of trivariate normality,

$$\begin{pmatrix}\varepsilon_{i1}\\ \varepsilon_{i0}\\ u_i\end{pmatrix} \sim N_3\left[\begin{pmatrix}0\\0\\0\end{pmatrix}, \begin{pmatrix}\sigma_1^2 & 0 & \rho_1\sigma_1\\ 0 & \sigma_0^2 & \rho_0\sigma_0\\ \rho_1\sigma_1 & \rho_0\sigma_0 & 1\end{pmatrix}\right].$$

This is actually precisely the sample selection model developed in Chapter E52 in each of the two regimes. (Note that in the trivariate normal distribution, it is assumed that ε_{i0} and ε_{i1} are uncorrelated. This is not a restriction. The sample will never contain individuals who exist in both states, so a nonzero correlation could never be estimated with any sample data. The zero 'assumption' is merely a convenient notation. This unidentified correlation will not play a role in any estimation.

Each regression equation can be treated separately, with the probit model, as a sample selection model. The conditional mean functions are

$$E[y_i \mid \mathbf{x}_i, z_i = 1] \;=\; \boldsymbol{\beta}_1'\mathbf{x}_1 \;+\; (\rho_1\sigma_1)\left(\frac{\phi(\boldsymbol{\alpha}'\mathbf{w}_1)}{\Phi(\boldsymbol{\alpha}'\mathbf{w}_1)}\right) \quad \text{if } z = 1$$

$$E[y_i \mid \mathbf{x}_i, z_i = 0] \;=\; \boldsymbol{\beta}_0'\mathbf{x}_0 \;+\; (\rho_0\sigma_0)\left(\frac{-\phi(\boldsymbol{\alpha}'\mathbf{w}_0)}{\Phi(-\boldsymbol{\alpha}'\mathbf{w}_0)}\right) \text{ if } z = 0,$$

so, the familiar two step estimator can be used for each equation. The commands would be

```
PROBIT      ; Lhs = z
            ; Rhs = variables in w
            ; Hold $
SELECT      ; Lhs = y
            ; Rhs = variables in x $ for the first equation
SELECT      ; Lhs = y
            ; Rhs = variables in x ? for the second equation
            ; Limits = 1 $
```

E56.2.2 Commands for the Mover Stayer Model

All relevant results for the estimated selection models above are those described in Section E52.2. However, one can fit the entire equation system at once, including the probit equation, by full information maximum likelihood. The commands will be as follows: The estimator requires several steps to set it up, but these are routine. The essential commands are as follows:

```
PROBIT     ; Lhs = z ; Rhs = w ; Hold $
SELECT     ; Lhs = y ; Rhs = x1 $
MATRIX     ; beta1 = bsr1 $
SELECT     ; Lhs = y ; Rhs = x0 ; Limits = 1 $
MATRIX     ; beta0 = bsr0 $
SELECT     ; Lhs = y ; Rh1 = x1 ; Rh2 = x0
           ; MLE ; All ; Start = beta1, beta0 $
```

The right hand sides of the two regressions can be different if desired. However, the formal model has the same regressors in both equations. The last select command may also include

; Tobit

if the model is a pair of tobit equations. The first two sample selection models are estimated just to get the complete set of starting values. Since this model requires several steps, there is no command builder for the mover stayer model.

NOTE: You may use **; Rst = list** to impose restrictions anywhere in the mover stayer model.

WARNING: *Do not fit the first two selection equations as tobit equations, even if the model actually is a tobit model (as specified by* ***; Tobit*** *in the final command).*

The two step linear regressions (**SELECT**) are needed to get the proper starting values put in the right place for *LIMDEP* to find them when the next command is carried out. Also, note that after each linear selection model is estimated, we pick up the matrix *bsrj* where *j* is 1 or 0, depending on what the selection rule was with respect to *z*. After estimating the selection model, *LIMDEP* automatically creates either *bsr*1 or *bsr*0 but the *bsr* matrix replaces the previous one. So, after the first **SELECT** command, *bsr*1 will be in your matrix work area, but *bsr*0 will not. After the **SELECT** command which selects on $z = 0$ (i.e., **; Limits = 1**), *bsr*0 will exist, but *bsr*1 will not. To make sure that the values are saved, we follow each **SELECT** command with a **MATRIX** command to make a copy of the coefficient vector in a place where it will not be overwritten. These matrices are constructed as follows:

$$bsrj = [\text{Estimate of } \boldsymbol{\beta} \text{ without the coefficient on } \lambda, \text{ or } \sigma_j, \rho_{uj}].$$

They are, thus, constructed precisely with the configuration needed for the mover stayer model. If you want to provide a different set of starting values, the full set you need is

$$\boldsymbol{\theta} = [\boldsymbol{\beta}_1, \sigma_1, \rho_{u1}, \boldsymbol{\beta}_0, \sigma_0, \rho_{u0}].$$

Note in the command template above how *beta*1, *beta*0 is used to supply exactly these values to the **SELECT** command.

For imposing restrictions with **; Rst = list**, it is necessary to rearrange the parameter vector. *(This is the only instance in LIMDEP's estimators that the parameter vector used to impose restrictions differs from the one that is set up with your starting values.)* For imposing restrictions, use the modified parameter vector, $\boldsymbol{\theta}^* = [\alpha, \boldsymbol{\beta}_1, \boldsymbol{\beta}_0, \sigma_0, \rho_{u0}, \sigma_1, \rho_{u1}]$. Other options for the mover stayer model are the same as in the list in Section E56.8 for the switching regressions model.

E56.2.3 Results for the Mover Stayer Model

Output from the mover stayer model is the same as the sample selection model estimated by maximum likelihood. Since the single equation, linear regressions have (presumably) preceded this command, the program proceeds directly to the maximum likelihood procedure, without a first round least squares estimation. Final output includes the log likelihood and a guide to the partitioning of the parameter vector.

Predictions for the mover stayer model are computed exactly the same as for the sample selection model In this case, we compute

$$\hat{y} = \boldsymbol{\beta}_1'\mathbf{x}_1 + (\rho_1\sigma_1)[\phi/\Phi] \qquad \text{if } z = 1$$

and

$$\hat{y} = \boldsymbol{\beta}_0'\mathbf{x}_0 + (\rho_0\sigma_0)[-\phi/(1-\Phi)] \quad \text{if } z = 0.$$

Recall that the coefficient on λ in the linear regression is an estimate of $\rho_j\sigma_j$, j = 0,1. In the mover stayer model, these are estimated separately, and both pairs of estimates will appear in the results. Note, however, since this is the maximum likelihood estimator, the parameters ρ_j and σ_j are estimated separately. There is no separate estimate of the product produced or displayed.

The following results are saved by this estimator:

Scalars: *ybar*, *sy*, *logl*, $s = \sigma_1$, $rho = \rho_{1u}$, *sigma*0, *rho*0*u*.

Matrices: *b* contains the entire vector of parameters estimated. In order, this is:

$\boldsymbol{\alpha}$ = parameters of the probit equation,
$\boldsymbol{\beta}_1$ = parameters in first regression,
$\boldsymbol{\beta}_2$ = parameters in second regression,
$[\sigma_0, \rho_{0u}, \sigma_1, \rho_{1u}]$ = ancillary parameters.

varb is the full asymptotic covariance matrix.

To obtain specific parts of the parameter vector, use the matrix **; Part** function to extract them.

E56.2.4 Application

The following will simulate the conditions of the switching regressions and mover stayer models in order to demonstrate the output that results. The commands were executed all at once from the editor.

```
SAMPLE    ; 1-500 $

E56.2.5 Technical Details

The log likelihood function for the mover stayer model is that of the sample selection model applied to each regime separately. Thus, we maximize

$$\log L \;=\; \sum\nolimits_{z=1} \log\left[\frac{\exp\left(-(1/2)\varepsilon_{i1}^2/\sigma_1^2\right)}{\sigma_1\sqrt{2\pi}}\Phi\left(\frac{\rho_1\varepsilon_{i1}/\sigma_1 \;+\; \boldsymbol{\alpha}'\mathbf{w}_i}{\sqrt{1-\rho_1^2}}\right)\right] \;+$$

$$\sum\nolimits_{z=0} \log\left[\frac{\exp\left(-(1/2)\varepsilon_{i0}^2/\sigma_0^2\right)}{\sigma_0\sqrt{2\pi}}\Phi\left(-\left(\frac{\rho_0\varepsilon_{i0}/\sigma_0 \;+\; \boldsymbol{\alpha}'\mathbf{w}_i}{\sqrt{1-\rho_0^2}}\right)\right)\right].$$

E56.2.6 Treatment Effects

There are several treatment effects that one can identify in the model. (See Heckman, Tobias and Vytlacil (2003) for example.) The obvious candidate is the 'treatment effect,'

$$TE = E[Y_1|z=1] - E[Y_0|z=0]$$

$$= \boldsymbol{\beta}_1'\mathbf{x}_1 + (\rho_1\sigma_1)\left(\frac{\phi(\boldsymbol{\alpha}'\mathbf{w}_1)}{\Phi(\boldsymbol{\alpha}'\mathbf{w}_1)}\right) - \boldsymbol{\beta}_0'\mathbf{x}_0 - (\rho_0\sigma_0)\left(\frac{-\phi(\boldsymbol{\alpha}'\mathbf{w}_0)}{\Phi(-\boldsymbol{\alpha}'\mathbf{w}_0)}\right).$$

The problem with this measure is that it refers to different people – no one can be in both states. Nonetheless, it could be averaged over all individuals under the assumption that the treatment assignment is random at least with respect to **x** (that is the point of the previous section). For an individual selected at random from the entire population, the 'average treatment effect' is

$$ATE = \boldsymbol{\beta}_1'\mathbf{x} - \boldsymbol{\beta}_0'\mathbf{x} = (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)'\mathbf{x}.$$

On the other hand, perhaps more interesting is the 'treatment effect on the treated,' which is

$$ATT = \mathrm{E}[\mathrm{Y}_1|z=1] - \mathrm{E}[\mathrm{Y}_0|z=1]$$

$$= \boldsymbol{\beta}_1'\mathbf{x} + (\rho_1\sigma_1)\left(\frac{\phi(\boldsymbol{\alpha}'\mathbf{w}_1)}{\Phi(\boldsymbol{\alpha}'\mathbf{w}_1)}\right) - \boldsymbol{\beta}_0'\mathbf{x} + (\rho_0\sigma_0)\left(\frac{\phi(\boldsymbol{\alpha}'\mathbf{w}_1)}{\Phi(\boldsymbol{\alpha}'\mathbf{w}_1)}\right)$$

$$= (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)'\mathbf{x} + [(\rho_1\sigma_1) - (\rho_0\sigma_0)]\left(\frac{\phi(\boldsymbol{\alpha}'\mathbf{w}_1)}{\Phi(\boldsymbol{\alpha}'\mathbf{w}_1)}\right).$$

Heckman et al. define as well, the 'local average treatment effect' which is the expected outcome gain for those induced to receive treatment through a change in the instrument from w_k to w_k^+. The variable w_k is assumed to change the treatment decision but not to directly affect the outcomes. Define, then, **w** to be the original vector and $\mathbf{w}^+$ to be the changed vector such that the one element has changed and moreover, $\boldsymbol{\alpha}'\mathbf{w}^+ > \boldsymbol{\alpha}'\mathbf{w}$, so that the margin increases the probability of choosing the treatment. Then, the local average treatment effect is

$$LATE = (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)'\mathbf{x} + [(\rho_1\sigma_1) - (\rho_0\sigma_0)]\left[\frac{\phi(\boldsymbol{\alpha}'\mathbf{w}^+) - \phi(\boldsymbol{\alpha}'\mathbf{w})}{\Phi(\boldsymbol{\alpha}'\mathbf{w}^+) - \Phi(\boldsymbol{\alpha}'\mathbf{w})}\right].$$

Unfortunately, both sign and magnitude of these quantities are completely ambiguous – only the actual computation with the data can reveal either. Signs of the coefficients are uninformative.

These results can be computed easily from the regression results. The following program does the computation. Its length is due to the need to collect quite a few specific inputs to the functions. We begin with the same data setup used previously. Your own application would replace the indicated parts.

Compute the raw data. Your own application would provide the variables for the namelists *wi* and *x* and the two dependent variables *yms* for the regression and *z* for the probit model.

```
SAMPLE     ; 1-500 $
CALC       ; Ran(12345) $
CREATE     ; x1 = Rnn(0,1)                ? regressor for equation 1

           ; (Else) ys = y0
           ; yms = z*y1+(1-z)*y0          $ Lhs for mover stayer model
CALC       ; n0 = n - Sum(z) ; n1 = Sum(z)$
NAMELIST   ; wi = one,w $
NAMELIST   ; x = one,x1,x0 $
```

The remainder of the program is generic and need not be changed for a particular application. This block computes the means for the whole sample and the two subsamples.

```
CALC       ; k = Col(x) ; m = Col(wi) $
PROBIT     ; Lhs = z ; Rhs = wi ; Hold $
MATRIX     ; alpha = b $
MATRIX     ; wb = Mean(wi)
           ; wb1 = 1/n1 *wi'z ; wb0 = 1/n0 * Mdif(wi'1,wi'z) $
MATRIX     ; xb = Mean(x)
           ; xb1 = 1/n1 *x'z ; xb0 = 1/n0 * Mdif(x'1,x'z) $
```

The two regressions produce coefficient vectors and estimates of ρ_j and σ_j.

```
SELECT     ; Lhs = yms ; Rhs = x $
MATRIX     ; beta1 = bsr1 ; b1  = bsr1(1:k) $
CALC       ; r1 = rho ; s1 = s $
SELECT     ; Lhs = yms ; Rhs = x ; Limits = 1 $
MATRIX     ; beta0 = bsr0 ; b0 = bsr0(1:k) $
CALC       ; r0 = rho ; s0 = s $
```

Compute the treatment effects.

```
CALC       ; List ; TE = b1'xb1 + r1*s1*  N01(alpha'wb1)/Phi(alpha'wb1)
                        -b0'xb0 - r0*s0*(-N01(alpha'wb0)/Phi(-alpha'wb0)) $
CALC       ; List ; ATE = b1'xb - b0'xb $
CALC       ; List ; ATT = ATE + (r1*s1 - r0*s0)*N01(alpha'wb)/Phi(alpha'wb) $
```

It would be useful to have standard errors for the computed average treatment effects. In principle, this can be done using the delta method. However, there are two obstacles in the preceding. The complexity of the computations does suggest it will be tedious. However, the single equation estimates do not provide the necessary asymptotic variances for the estimates of ρ_j and σ_j, so as it stands, the computation cannot be done (at least not without treating these as constants.) However, the MLE for the mover stayer model and the **WALD** command solve both problems easily.

```
SELECT    ; Lhs = yms
          ; Rh1 = x
          ; Rh2 = x
          ; Start = beta1, beta0 ; MLE ; All $
WALD      ; Start = b
          ; Var = varb
          ; Labels = m_alpha, k_bs1, k_bs0, ss0, rs0, ss1, rs1
          ; Fn1 = bs11'xb1 + rs1*ss1*N01(alpha1'wb1)/Phi(alpha'wb1)
                  -bs01'xb0 + rs0*ss0*N01(alpha1'wb0)/Phi(-alpha'wb0)
          ; Fn2 = bs11'xb - bs01'xb
          ; Fn3 = Fn2 + (rs1*ss1-rs0*ss0)*N01(alpha1'wb)/Phi(alpha1'wb) $
```

We applied these computations to the data in the preceding example. The estimates of the parameters are the same. The computations of the treatment effects are shown below. (The estimate of the variance of the first treatment effect was too close to zero; evidently with the rounding error of the computation, that diagonal element of the matrix became negative. The third estimate, the effect of treatment on the treated is the usual object of estimation.)

E56.3 Alternative Distribution for Selection and Treatment Effects

The treatment effects model developed above has structure

$$y_i = Y_1 = \boldsymbol{\beta}_1'\mathbf{x}_i + \varepsilon_{i1} \text{ when } z_i = 1$$
$$y_i = Y_0 = \boldsymbol{\beta}_0'\mathbf{x}_i + \varepsilon_{i0} \text{ when } z_i = 0$$
$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\ z_i = 1(z_i^* > 0).$$

$$\begin{pmatrix}\varepsilon_{i1}\\ \varepsilon_{i0}\\ u_i\end{pmatrix} \sim N_3\left[\begin{pmatrix}0\\0\\0\end{pmatrix}, \begin{pmatrix}\sigma_1^2 & 0 & \rho_1\sigma_1\\ 0 & \sigma_0^2 & \rho_0\sigma_0\\ \rho_1\sigma_1 & \rho_0\sigma_0 & 1\end{pmatrix}\right].$$

The trivariate normality of the random components is an important feature of the specification. Heckman, Tobias and Vytlacil (2001) (see also Heckman and Vytlacil (2000) and references cited) suggest that the model can be improved by allowing a different distribution with thicker tails to govern the selection mechanism. The logit model, instead of the probit is a natural candidate. In order to maintain the flexible structure of the model, they propose to link the selection model to the regressions through an inverse transformation that reproduces the joint normality of the system. Formally, using their notation, we maintain that

$u_i \sim F(u_i)$ with CDF $F(u_i)$ where $F(u_i)$ defines a symmetric distribution,

Let $J(t)$ be a strictly increasing function, such that

$$z_i = 1 \text{ when } u_i > -\boldsymbol{\alpha}'\mathbf{w}_i$$

or

$$z_i = 1 \text{ when } J(u_i) > J(-\boldsymbol{\alpha}'\mathbf{w}_i).$$

To map the model with nonnormal selection rule into the model where the normal distribution applies, they propose the mapping $\tilde{u}_i = J_\Phi(u_i) = \Phi^{-1}[F(u_i)]$. Then, $\tilde{u}_i$ has a standard normal distribution. The revised system is

$$y_i = Y_1 = \boldsymbol{\beta}_1'\mathbf{x}_i + \varepsilon_{i1} \text{ when } z_i = 1$$
$$y_i = Y_0 = \boldsymbol{\beta}_0'\mathbf{x}_i + \varepsilon_{i0} \text{ when } z_i = 0$$
$$z_i^{**} = J_\Phi(\boldsymbol{\alpha}'\mathbf{w}_i) + \tilde{u}_i,\ z_i = 1(z_i^* > 0).$$

$$\begin{pmatrix}\varepsilon_{i1}\\ \varepsilon_{i0}\\ \tilde{u}_i\end{pmatrix} \sim N_3\left[\begin{pmatrix}0\\0\\0\end{pmatrix}, \begin{pmatrix}\sigma_1^2 & 0 & \rho_1\sigma_1\\ 0 & \sigma_0^2 & \rho_0\sigma_0\\ \rho_1\sigma_1 & \rho_0\sigma_0 & 1\end{pmatrix}\right].$$

The implications for the conditional mean functions and treatment effects are simple;

$$E[y_i \mid \mathbf{x}_i, z_i = 1] \;=\; \boldsymbol{\beta}_1'\mathbf{x}_1 \;+\; (\rho_1\sigma_1)\left(\frac{\phi(J_\Phi(\boldsymbol{\alpha}'\mathbf{w}_1))}{F(\boldsymbol{\alpha}'\mathbf{w}_1)}\right) \text{ if } z = 1$$

$$E[y_i \mid \mathbf{x}_i, z_i = 0] \;=\; \boldsymbol{\beta}_0'\mathbf{x}_0 \;+\; (\rho_0\sigma_0)\left(\frac{-\phi(J_\Phi(\boldsymbol{\alpha}'\mathbf{w}_0))}{F(-\boldsymbol{\alpha}'\mathbf{w}_0)}\right) \text{ if } z = 0.$$

$$ATE \;=\; \boldsymbol{\beta}_1'\mathbf{x} - \boldsymbol{\beta}_0'\mathbf{x} \;=\; (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)'\mathbf{x}$$

$$ATT \;=\; \text{E}[\text{Y}_1|\text{z}=1] \;-\; \text{E}[\text{Y}_0|\text{z}=1]$$

$$= \boldsymbol{\beta}_1'\mathbf{x} \;+\; (\rho_1\sigma_1)\left(\frac{\phi(J_\Phi(\boldsymbol{\alpha}'\mathbf{w}_1))}{F(\boldsymbol{\alpha}'\mathbf{w}_1)}\right) - \boldsymbol{\beta}_0'\mathbf{x} \;+\; (\rho_0\sigma_0)\left(\frac{\phi(J_\Phi(\boldsymbol{\alpha}'\mathbf{w}_1))}{F(\boldsymbol{\alpha}'\mathbf{w}_1)}\right)$$

$$= (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)'\mathbf{x} + [(\rho_1\sigma_1) \;-\; (\rho_0\sigma_0)]\left(\frac{\phi(J_\Phi(\boldsymbol{\alpha}'\mathbf{w}_1))}{F(\boldsymbol{\alpha}'\mathbf{w}_1)}\right)$$

$$LATE \;=\; (\boldsymbol{\beta}_1 - \boldsymbol{\beta}_0)'\mathbf{x} + [(\rho_1\sigma_1) \;-\; (\rho_0\sigma_0)]\left[\frac{\phi(J_\Phi(\boldsymbol{\alpha}'\mathbf{w}^+)) - \phi(J_\Phi(\boldsymbol{\alpha}'\mathbf{w}))}{F(\boldsymbol{\alpha}'\mathbf{w}^+) - F(\boldsymbol{\alpha}'\mathbf{w})}\right]$$

The denominators of the results are all obtained from $\Phi\{\Phi^{-1}[F(u_i)]\} = F(u_i)$.

Though advocated as a ‘modern’ approach, this is precisely Lee’s (1982, 1983) model (the authors do note this) developed in Section E55.4. Thus, estimating the parameters and computing the treatment effects with this form is a small modification of what we have already done. The commands would be as follows. We have computed the treatment effects, but not the asymptotic standard errors. The Lee model is fit by two step least squares, so we do not have the asymptotic covariance matrix needed for the computation. One could possibly use bootstrapping to add this computation to the results.

The results below display only a trivial change due to the modification of the model. Of course, these are simulated data. The authors construct a Monte Carlo study which produces more pronounced differences. They also suggest that one might relax the joint normality assumption. Their proposal, a multivariate t distribution with small degrees is a bit ad hoc, but their results suggest that differences in the sizes of the tails of the distributions does induce changes in the results.

The commands are:

```
NAMELIST    ; wi = one,w $
NAMELIST    ; x = one,x1,x0 $
CALC        ; k = Col(x) ; m = Col(wi) $
LOGIT       ; Lhs = z ; Rhs = wi ; Hold $
MATRIX      ; alpha = b $
MATRIX      ; wb = Mean(wi)
            ; wb1 = 1/n1 *wi'z ; wb0 = 1/n0 * Mdif(wi'1,wi'z) $
MATRIX      ; xb = Mean(x)
            ; xb1 = 1/n1 *x'z ; xb0 = 1/n0 * Mdif(x'1,x'z) $
SELECT      ; Lhs = yms ; Rhs = x $
MATRIX      ; beta1 = bsr1 ; b1 = bsr1(1:k) $
CALC        ; r1 = rho ; s1 = s $
SELECT      ; Lhs = yms ; Rhs = x ; Limits = 1 $
MATRIX      ; beta0 = bsr0 ; b0 = bsr0(1:k) $
CALC        ; r0 = rho ; s0 = s $
CALC        ; jphi1 = Ntb(Lgp(alpha'wb1)); f1 = Lgp(alpha'wb1) $
CALC        ; jphi0 = Ntb(Lgp(alpha'wb0)); f0 = Lgp(-alpha'wb0) $
CALC        ; jphi = Ntb(Lgp(alpha'wb) ; f = Lgp(alpha'wb) $
CALC        ; List ; TE = b1'xb1 + r1*s1*N01(jphi1)/f1
                         -b0'xb0 - r0*s0*(-N01(jphi0)/f0) $
CALC        ; List ; ATE = b1'xb - b0'xb $
CALC        ; List ; ATT = ATE + (r1*s1 - r0*s0)*N01(jphi)/f $
```

These are the results from estimation with the logit selection rule. The results obtained earlier with the probit model follow.

```
+------------------------------------+
| Listed Calculator Results          |

```

E56.4 Treatment Effects Regression – Endogenous Dummy Variable Models

This section will narrow the analysis of the preceding estimator by formally embedding the treatment effect in a single regression model. The basic structure is

$$y_i = \gamma z_i + \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,$$

where z_i is a dummy variable that once again indicates the presence ($z_i = 1$) or absence ($z_i = 0$) of some treatment. For example, y_i might be lifetime income and z_i might record attendance at an elite college. As long as z_i is exogenous, this is merely a classical regression with a dummy variable in it. The problem is the likely endogeneity of the treatment. This is formalized in this model with the familiar auxiliary probit equation

$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\ z_i = 1(z_i^* > 0).$$

This is an ordinary probit equation. The problem for estimation of $(\gamma,\boldsymbol{\beta})$ is the possible endogeneity of the dummy variable. This is the 'treatment effects' sample selection model examined in Section E52.3. It is also a restricted version of the mover stayer model in the previous section, in which the two regimes, rather than having separate regressions, now have the same regression simply with different constant terms. (The models are nested, so this is a testable restriction.)

The modification of the earlier sample selection model is as follows:

$$E[y_i\,|\mathbf{x}_i, z_i = 1] = \boldsymbol{\beta}'\mathbf{x}_i + \gamma + (\rho\sigma)[\phi(\boldsymbol{\alpha}'\mathbf{w}_i)/\Phi(\boldsymbol{\alpha}'\mathbf{w}_i)]$$

while

$$E[y_i\,|\mathbf{x}_i, z_i = 0] = \boldsymbol{\beta}'\mathbf{x}_i + (\rho\sigma)[-\phi(\boldsymbol{\alpha}'\mathbf{w}_i)/\Phi(-\boldsymbol{\alpha}'\mathbf{w}_i)].$$

Once again, we are interested in estimation of the 'treatment effect' in the model. Contrary to intuition, this is not γ, which is what motivates the sample selection model approach to this model (and, more generally, much of the literature.)

E56.4.1 Estimation

There are three estimators available for this model, two step, maximum likelihood and two stage least squares. (There are others, including a nonlinear least squares approach, not considered here.)

Two Step Estimation

Heckman's two step, or 'Heckit' estimation method is consistent, but not efficient:

Step 1. Use a probit model for z_i to estimate $\boldsymbol{\alpha}$. For each observation, compute

$$\lambda_i = \phi(\boldsymbol{\alpha}'\mathbf{w}_i) / \Phi(\boldsymbol{\alpha}'\mathbf{w}_i) \quad \text{when } z_i = 1 \text{ and}$$

$$\lambda_i = -\phi(\boldsymbol{\alpha}'\mathbf{w}_i) / \Phi(-\boldsymbol{\alpha}'\mathbf{w}_i) \quad \text{when } z_i = 0$$

using the probit coefficients.

Step 2. Linearly regress y_i on $\mathbf{x}_i$, z_i and λ_i to estimate $\boldsymbol{\beta}$, δ and $\theta = \rho\sigma$.

After estimation, it is necessary to adjust the standard errors and the usual least squares estimate of σ^2, which is inconsistent. This uses the same prescription used in Chapter E52 for the simpler model. The corrected asymptotic covariance matrix for the two step estimator, (**b**,*c*), is

$$\text{Asy.Var}[\mathbf{b},c] = \sigma_\varepsilon^2(\mathbf{X^{*\prime}X^*})^{-1}[\mathbf{X^{*\prime}}(\mathbf{I} - \rho^2\boldsymbol{\Delta})\mathbf{X^*} + \rho^2(\mathbf{X^{*\prime}}\boldsymbol{\Delta}\mathbf{W})\boldsymbol{\Sigma}(\mathbf{W}'\boldsymbol{\Delta}\mathbf{X^*})](\mathbf{X^{*\prime}X^*})^{-1}$$

where $\mathbf{X}_* = [\mathbf{X},\mathbf{z} : \boldsymbol{\lambda}]$,

$\delta_i = -\lambda_i(\boldsymbol{\alpha}'\mathbf{w}_i + \lambda_i)$ $(-1 \le \delta_i \le 0)$,

$\boldsymbol{\Delta} = \text{diag}[\boldsymbol{\delta}]$,

and $\boldsymbol{\Sigma}$ = asymptotic covariance matrix for the estimator of $\boldsymbol{\alpha}$.

A consistent estimator of σ^2 is $\hat{\sigma}^2 = \mathbf{e}'\mathbf{e}/n - \hat{\theta}^2\overline{\hat{\delta}}$. The remaining parameters are estimated using the least squares coefficients. The computations used in the estimation procedure are those discussed in Heckman (1979) and in Greene (1981).

To estimate this model with *LIMDEP*, it is necessary first to estimate the probit model, then request the selection model. The pair of commands is

```
PROBIT      ; Lhs = name of z
            ; Rhs = list for w
            ; Hold results $
SELECT      ; Lhs = name of y
            ; Rhs = list for x,z
            ; All $
```

For this simplest case, **; Hold ...** may be abbreviated to **; Hold**. All of the earlier discussion for the probit model applies. (See Chapter E27.) This application differs only in the fact the **; Hold** specification requests that the model definition and results be saved to be used later. Otherwise, they disappear with the next model command. The **PROBIT** command is exactly as described in Chapter E18. The selection model is completely self contained. You do not need to compute or save λ_i. Here, we must use entire sample, that is, not select out any observations. Use the specification **; All** in the **SELECTION** command, and otherwise, set it up in the usual manner. In this instance, all computations are exactly as described earlier, save those in the calculations. This is precisely the same as the application in Chapter E52 for the basic selection model, save for the addition of the dummy variable to the right hand side of the regression, and **; All** to the command.

Maximum Likelihood Estimation

The log likelihood function for this treatment effects model is the same as that for the mover stayer model, with the various equality restrictions imposed. It is also a minor modification of the log likelihood for the basic sample selection model. Thus, we maximize

$$\log L = \sum\nolimits_{z=1}\log\left[\frac{\exp\left(-(1/2)(y_i - \delta - \boldsymbol{\beta}'\mathbf{x}_i)^2/\sigma^2\right)}{\sigma\sqrt{2\pi}}\Phi\left(\frac{\rho(y_i - \delta - \boldsymbol{\beta}'\mathbf{x}_i)/\sigma + \boldsymbol{\alpha}'\mathbf{w}_i}{\sqrt{1-\rho^2}}\right)\right] +$$

$$\sum\nolimits_{z=0}\log\left[\frac{\exp\left(-(1/2)(y_i - \boldsymbol{\beta}'\mathbf{x}_i)^2/\sigma^2\right)}{\sigma\sqrt{2\pi}}\Phi\left(-\left(\frac{\rho(y_i - \boldsymbol{\beta}'\mathbf{x}_i)^2/\sigma + \boldsymbol{\alpha}'\mathbf{w}_i}{\sqrt{1-\rho^2}}\right)\right)\right].$$

To fit the treatment effects model, just add **; MLE** to the two step estimator. The commands are

```
PROBIT    ; Lhs = variable z
          ; Lhs = variables in w
          ; Hold $
SELECT    ; Lhs = variable y
          ; Rhs = variables in x, variable z
          ; All
          ; MLE $
```

Two Stage Least Squares – Instrumental Variable Estimation

A second means of estimating the model is with two stage least squares. The problem with ordinary least squares estimates of the model based on the observed data is the correlation between z and ε. A solution to the inconsistency of OLS is to use 2SLS, using as the instrumental variable for z the predicted probabilities from the probit equation. It is not necessary to **; Hold** the results of the probit model in this case. The set of commands would be

```
NAMELIST  ; w = ... ; x = ... $
PROBIT    ; Lhs = z ; Rhs = w ; Prob = zfit $
2SLS      ; Lhs = y ; Rhs = x, z ; Inst = x,  zfit $
```

We note, there is a tendency in the literature to equate the simple replacement of z_i in the regression with the fitted probability as an 'instrumental variable' estimator. Ordinary least squares is then used to estimate the parameters. We emphasize, this is not 2SLS for this model and the replacement variable is not an instrument, it is a proxy. Whether the estimator so constructed is even consistent is debatable.

E56.4.2 Treatment Effects

Under the assumptions of the model, the 'treatment effect' would be

$$E[y \mid z = 1,x,w] - E[y \mid z=0,x,w] = \gamma + (\rho\sigma)\left[\frac{\phi(\boldsymbol{\alpha}'\mathbf{w})}{\Phi(\boldsymbol{\alpha}'\mathbf{w})} + \frac{\phi(\boldsymbol{\alpha}'\mathbf{w})}{\Phi(-\boldsymbol{\alpha}'\mathbf{w})}\right]$$

$$= \gamma + (\rho\sigma)\left[\frac{\phi(\boldsymbol{\alpha}'\mathbf{w})}{\Phi(\boldsymbol{\alpha}'\mathbf{w})[1-\Phi(\boldsymbol{\alpha}'\mathbf{w})]}\right].$$

As suggested earlier, the notable aspect is that this is not equal to γ unless ρ equals zero. The result is straightforward to compute using **CALC**, and the results of any of the estimators suggested below. If a standard error is desired, then the FIML estimator, and **WALD** would be the preferred approach. For the application that is developed below, the following commands would compute the effect and estimate its standard error.

The following does this computation for the model estimated below. The calculation is based on the maximum likelihood estimator. This is the third set of estimates given below. In the estimated model, the coefficient on *lfp*, the endogenous variable, is -153.226961. But, when the full model is accounted for in the **WALD** command below, the impact of the 'treatment' goes up substantially, to -250.110003.

```
NAMELIST   ; x = one,ha,he,hw,faminc $
CREATE     ; age = wa ; agesq = age*age $
NAMELIST   ; w = one,we,age,agesq,kl6,k618 $
PROBIT     ; Lhs = lfp ; Rhs = w ; Hold ; Prob = pfit $
SELECT     ; Lhs = hhrs ; Rhs = x,lfp ; All ; MLE $
CALC       ; kw = Col(w) ; kx = Col(x) $
MATRIX     ; wbar = Mean(w) $
WALD       ; Start = b ; Var = varb
           ; Labels = kw_alpha,kx_beta,gamma,sgma,ro
           ; Fn1 = gamma + sgma*ro*N01(alpha1'wbar) /
                   (Phi(alpha1'wbar)*Phi(-alpha1'wbar)) $
```

```

--------+--------------------------------------------------------------------
```

E56.4.3 Application

In the following, we fit a 'treatment model' for the husband's hours, where the endogenous dummy variable is the wife's labor force participation. The following uses all three estimators. The probit estimates are the same as those obtained earlier.

```
NAMELIST   ; x = one,ha,he,hw,faminc $
NAMELIST   ; w = one,we,age,agesq,kl6,k618 $
PROBIT     ; Lhs = lfp   ; Rhs = w ; Hold ; Prob = pfit $
SELECT     ; Lhs = hhrs ; Rhs = x,lfp ; All $
2SLS       ; Lhs = hhrs ; Rhs = x,lfp ; Inst = x,pfit $
SELECT     ; Lhs = hhrs ; Rhs = x,lfp ; All ; MLE $
```

These are the two step estimators using Heckman's method.

E56.5 Sample Selection with Two Treatments

Consider evaluating the impact of two treatments (e.g., programs). The basic regression is

$$y_i \;=\; \boldsymbol{\beta}'\mathbf{x}_i + \alpha_1 D_{1i} + \alpha_2 D_{2i} + \varepsilon_i.$$

Binary variables D_{1i} and D_{2i} indicate presence (=1) or absence (=0) of the two treatments. To this point, save for D_1 and D_2 in the equation (which need not be the case), this is the selection model with bivariate probit sample selection equations. To the preceding, however, we add an 'eligibility requirement,'

$$E_{1i} \;=\; 1 \text{ if individual is eligible for program 1, 0 otherwise,}$$

$$E_{2i} \;=\; 1 \text{ if individual is eligible for program 2, 0 otherwise.}$$

Then, $D_{1i} = 0$ if $E_{1i} = 0$ by definition and likewise for D_{2i}. Thus, the sample contains data on $[y_i,\mathbf{x}_i,D_{1i},D_{2i},E_{1i},E_{2i}]$ for observations $i = 1,...,N$. We suppose that $m_1 \le N$ individuals are eligible for program 1 and $m_2 \le N$ are eligible for program 2.

The selection equations defined over those eligible for the programs are:

$$D_j \;=\; \mathbf{z}_{1j}'\boldsymbol{\delta}_1 + v_{1j},\; j = 1,...,m_1,$$

$$D_k \;=\; \mathbf{z}_{2k}'\boldsymbol{\delta}_2 + v_{2k},\; k = 1,...,m_2.$$

The Ds (for participation *given eligibility* are determined by probit models in the usual way, save for the complications introduced by the eligibility requirements. The final element of the specification is a trivariate normal distribution assumed for $[\varepsilon_i,v_{1i},v_{2i}]$. The marginal distributions of v_1 and v_2 are standard normal as usual for the probit model.

Estimation proceeds along lines similar to those for the basic model, with the following changes:

Step 1. The two step estimation procedure is based on all observations in the sample, not just those for which $D_{1i} = D_{2i} = 1$. The model is estimated by using least squares in an augmented regression containing two 'λ' variables. These are computed differently, however, depending on eligibility.

Step 2. For observations with $E_{1i} = E_{2i} = 1$, the usual bivariate probit model applies and the procedure shown in Section E55.3 applies. This group will still contain observations in all four D_1/D_2 cells.

Step 3. If $E_{1i} = 1$ but $E_{2i} = 0$, λ_1 is computed based on the univariate probit model for D_{1i}, but λ_2 is taken to be 0. This group may have observations with D_{1i} equal to 1 or 0, but D_{2i} must be 0.

Step 4. For $E_{2i} = 1$ and $E_{1i} = 0$, the reverse of the procedure in Step 3 applies.

Step 5. If $E_{1i} = E_{2i} = 0$, then both D_{1i} and D_{2i} must be 0, so both λs are taken to be 0.

The necessary adjustments to the way the asymptotic covariance matrix is computed are all made internally. Note that it is possible to miscode the data. For example, the pair of values $D_{1i} = 1$, $E_{1i} = 0$, is invalid. Individuals cannot participate in programs for which they are ineligible. *LIMDEP* checks for miscoded data.

The procedure for estimation of this model must be as follows: With the exception noted, you can use any names you like.

```
CREATE     ; d1 = dependent variable in first probit
           ; d2 = dependent variable in second probit
           ; y = dependent variable in main regression $
NAMELIST   ; x = Rhs in primary equation
           ; z1 = Rhs for probit for d1
           ; z2 = Rhs for probit for d2 $
INCLUDE    ; New ; e1 = 1 | e2 = 0 $
PROBIT     ; Lhs = d1
           ; Rhs = z1 $      (No need to ; Hold)
MATRIX     ; delta1 = b $    (You must use name delta1)
INCLUDE    ; New ; e1 = 0 & e2 = 1 $
PROBIT     ; Lhs = d2
           ; Rhs = z2 $
MATRIX     ; delta2 = b $
INCLUDE    ; New ; e1 = 1 & e2 = 1 $
BIVARIATE  ; Lhs = d1, d2
           ; Rh1 = z1; Rh2 = z2
           ; Hold
           ; Start = delta1, delta2, 0 $
MATRIX     ; vdelta = varb $
INCLUDE    ; New ; e1 = 1 | e1 = 0 | e2 = 1 | e2 = 0 $ (all properly coded data)
SELECT     ; Lhs = y
           ; Rhs = x ; Rh2 = e1,e2 $
```

Output from this procedure is essentially the same as that for the selection model with bivariate probit selection. However, a complete tabulation of the numbers of observations in the various cells is given at the beginning of the results for the **SELECT** command.

E56.6 ML Estimation of a Tobit Model with an Endogenous Dummy Variable

Our interest is in a model which includes censoring of the dependent variable in the second equation. A fully operational estimator for the simultaneous equations model

$$z_i^* = \gamma_1 y_{i2}^* + \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\ z_i = \mathbf{1}(z_{i1}^* > 0)$$

$$y_i^* = \gamma_2 z_i + \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ y_i = \text{Max}(L_i, y_i^*) \text{ (note, } z_i\text{, not } z_{i1}^*)$$

remains to be derived. Maddala (1983) shows that the model cannot be internally consistent if γ_1 is nonzero.) This restricts us to recursive models. Consider, then, the model with $\gamma_1 = 0$

$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\ z_i = \mathbf{1}(z_{i1}^* > 0)$$

$$y_i^* = \gamma_2 z_i + \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\ y_i = \text{Max}(L_i, y_i^*).$$

The two step estimator is problematic in this case. The partial reduced form for y_{i2}* is not available – the precise prediction that should be inserted for z_i is unclear. But, a full information maximum likelihood estimator is feasible.

We continue to assume that u and ε are bivariate normally distributed with zero means, variances one and σ^2, and correlation ρ. Consider, first, the cases in which y_i* is censored. The probabilities associated with these outcomes are the probabilities of the joint events,

$$\text{Prob}[y_i = L_i\,,\, z_i = 0] \text{ and } \text{Prob}[y_i = L_i\,,\, z_i = 1].$$

These are simply the bivariate standard normal integrals,

$$\begin{aligned}\text{Prob}[y_i = L_i, z_i = 0] &= \text{Prob}[(\varepsilon_i/\sigma) \le (L_i - \boldsymbol{\beta}'\mathbf{x}_i)/\sigma,\ u_i \le -\boldsymbol{\alpha}'\mathbf{w}_i, \mid \rho] \\ &= \Phi_2[(L_i - \boldsymbol{\beta}'\mathbf{x}_i)/\sigma,\ -\boldsymbol{\alpha}'\mathbf{w}_i, \rho]\end{aligned}$$

and

$$\begin{aligned}\text{Prob}[y_i = L_i, z_i = 1] &= \text{Prob}[(\varepsilon_i/\sigma) \le (L_i - \gamma - \boldsymbol{\beta}'\mathbf{x}_i)/\sigma,\ u_i > -\boldsymbol{\alpha}'\mathbf{w}_i \mid \rho] \\ &= \text{Prob}[(\varepsilon_i/\sigma) \le (L_i - \gamma - \boldsymbol{\beta}'\mathbf{x}_i)/\sigma,\ u_i < \boldsymbol{\alpha}'\mathbf{w}_i \mid -\rho] \\ &= \Phi_2[(L_i - \gamma - \boldsymbol{\beta}'\mathbf{x}_i)/\sigma,\ \boldsymbol{\alpha}'\mathbf{w}_i, -\rho]\end{aligned}$$

where Φ_2 denotes the bivariate standard normal CDF. These are the terms in the likelihood function for the fully censored data. It might seem odd that this has ignored the simultaneity. However, the result can be obtained trivially by writing

$$\text{Prob}[y_i = L_i, z_i = 1] = \text{Prob}[y_i = L_i \mid z_i = 1]\text{Prob}[z_i = 1].$$

The former probability is just the joint probability divided by the marginal, which then cancels out of the product, and, of course, conditioned on z_i, we are free to treat z_i as a constant. The 'simultaneity' only becomes an issue in regression because of the use of covariances and moments. In this instance, we are using the probabilities directly.

For the uncensored observations, we require the two mixed distributions, $f(y_i, z_i = 0)$ and $f(y_i, z_i = 1)$. The first of these, $f(y_i, z_i{=}0)$, is derived from

$$\begin{aligned}f(\varepsilon_i, u_i \le -\boldsymbol{\alpha}'\mathbf{w}_i) &= \int_{-\infty}^{-\boldsymbol{\alpha}'\mathbf{w}_i} f(\varepsilon_i, u_i)\,du_i \\ &= \int_{-\infty}^{-\boldsymbol{\alpha}'\mathbf{w}_i} f(\varepsilon_i) f(u_i \mid \varepsilon_i)\,du_i \\ &= f(\varepsilon_i)\int_{-\infty}^{-\boldsymbol{\alpha}'\mathbf{w}_i} f(u_i \mid \varepsilon_i)\,du_i \\ &= \frac{1}{\sigma}\phi\left(\frac{y_i - \boldsymbol{\beta}'\mathbf{x}}{\sigma}\right)\int_{-\infty}^{-\boldsymbol{\alpha}'\mathbf{w}_i} \frac{1}{\sqrt{1-\rho^2}}\phi\left(\frac{u_i - (\rho/\sigma)\varepsilon_i}{\sqrt{1-\rho^2}}\right)du_i \\ &= \frac{1}{\sigma}\phi\left(\frac{y_i - \boldsymbol{\beta}'\mathbf{x}}{\sigma}\right)\int_{-\infty}^{-\boldsymbol{\alpha}'\mathbf{w}_i} \frac{1}{\sqrt{1-\rho^2}}\phi\left(\frac{u_i - (\rho/\sigma)(y_i - \boldsymbol{\beta}'\mathbf{x}_i)}{\sqrt{1-\rho^2}}\right)du_i \\ &= \frac{1}{\sigma}\phi\left(\frac{y_i - \boldsymbol{\beta}'\mathbf{x}}{\sigma}\right)\Phi\left(\frac{-\boldsymbol{\alpha}'\mathbf{w}_i - (\rho/\sigma)(y_i - \boldsymbol{\beta}'\mathbf{x}_i)}{\sqrt{1-\rho^2}}\right).\end{aligned}$$

For $f(y_i, z_i = 1)$, the numerator inside the CDF is changed to $\boldsymbol{\alpha}'\mathbf{w}_i + (\rho/\sigma)(y_i - \gamma - \boldsymbol{\beta}'\mathbf{x}_i)$ and all other parts remain the same. These four results, then, give the parts of the likelihood function, which can then be maximized to estimate the parameters.

The following program will estimate the parameters of the model by maximum likelihood. This is not built into *LIMDEP*, so we use **MAXIMIZE** instead. The left and right hand sides of the two equations are defined for the specific problem. The censoring limit for the second equation will typically be zero, but can be nonzero. That is defined here as well. The rest of the command set is generic, and can be used without modification.

```
NAMELIST    ; w = the Rhs of the probit model $
NAMELIST    ; x  = exogenous variables in the censored regression $
CREATE      ; z  = binary dependent variable $
CREATE      ; y  = censored dependent variable $
CREATE      ; li  = censoring limit $
```

Obtain the dimensions of the problem and pointers to partition the parameter vector.

```
CALC        ; k = Col(x) ; k1 = k+1 ; m = Col(w) $
```

Get the starting values for the probit model. These are consistent, but LIML so inefficient.

```
PROBIT      ; Lhs = z ; Rhs = w $
MATRIX      ; alpha 0 = b $
```

Obtain the starting values for censored regression. These are inconsistent, but better than zero.

```
TOBIT       ; Lhs = y ; Rhs = z,x ; Limit = li $
CALC        ; gamma0 = b(1) $
MATRIX      ; beta0 = b(2:k1) $
```

Compute a starting value for σ in the tobit equation, then use the Olsen transformation. The starting value for ρ is zero.

```
CALC        ; s0 = s  ; r0 = 0 ; h0 = 1/s $
CREATE      ; d = y > li ; q = 2*z - 1 $
```

Finally, compute the FIML estimation of all model parameters using maximum likelihood.

```
MAXIMIZE    ; Labels = c,k_beta,m_alpha,h,r
            ; Start = gamma0,beta0,alpha0,h0,r0
            ; Fcn = alphaw = alpha1'w                  |
                    betax = beta1'x                    |
                    a0 = (li – c*z - betax)* h         |
                    a1 = (y  - c*z - betax)* h         |
                    dr = 1/Sqr(1 - r*r)                |
                    uz = q*alphaw                      |
                    ur = -q*r                          |
              Log((1-d) * BVN(a0,uz,ur) + d * h*N01(a1) * Phi(dr*(q*alphaw + r*a1))) $
```

The following application reestimates the husband's hours equation that was estimated earlier. To force the data into the present framework, we have censored the hours variable at 1,800 hours.

```
NAMELIST   ; x = one,ha,he,hw,faminc $
NAMELIST   ; w = one,we,age,agesq,kl6,k618 $
CREATE     ; hours = hhrs ; If(hours < 1800)hours = 1800 $
CREATE     ; z = lfp ; li = 1800 ; y = hours $
CALC       ; k = Col(x) ; k1 = k+1 ; m = Col(w) $
PROBIT     ; Quietly ; Lhs = z ; Rhs = w $
MATRIX     ; alpha 0 = b $
TOBIT      ; Quietly ; Lhs = y ; Rhs = z,x ; Limit = li $
CALC       ; gamma0 = b(1) $
MATRIX     ; beta0 = b(2:k1) $
CALC       ; s0 = s ; r0 = 0 ; h0 = 1/s $
CREATE     ; d = y > li ; q = 2*z - 1 $
MAXIMIZE   (exactly as shown above)
```

```

E56.7 Endogenous Dummy Variable in a Probit Model

A natural extension of the model examined in the previous section is one in which both variables are binary. This would be a probit model with an endogenous variable on the right hand side,

$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + u_i,\; z_i = \mathbf{1}(z_{i1}^* > 0)$$

$$y_i^* = \gamma z_i + \boldsymbol{\beta}'\mathbf{x}_i + \varepsilon_i,\; y_i = 1(y_i^* > 0).$$

Estimation of this model turns out to be considerably simpler than the models that we have considered thus far. Consider the model for the probabilities of the event $y = 0/1$ and $z = 0/1$. For the (1,1) case,

$$\text{Prob}[y = 1, z = 1 \mid \mathbf{x}, \mathbf{w}] \quad \text{Prob}[y = 1 \mid z = 1, \mathbf{x}, \mathbf{w}] \times \text{Prob}[z = 1 \mid \mathbf{w}]$$

$$\Phi\left[\frac{\boldsymbol{\beta}'\mathbf{x} + \gamma + \rho(\boldsymbol{\alpha}'\mathbf{w})}{\sqrt{1-\rho^2}}\right]\Phi\left[\boldsymbol{\alpha}'\mathbf{w}\right]$$

$$\Phi_2(\boldsymbol{\beta}'\mathbf{x} + \gamma, \boldsymbol{\alpha}'\mathbf{w}, \rho).$$

This is simply the joint probability from the bivariate probit model. The other three cells would be constructed likewise, giving

$$\text{Prob}[y_1 = 1, y_2 = 0 \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2(\boldsymbol{\beta}_1'\mathbf{x}_1, \quad -\boldsymbol{\beta}_2'\mathbf{x}_2, -\rho)$$

$$\text{Prob}[y_1 = 0, y_2 = 1 \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2(-\boldsymbol{\beta}_1'\mathbf{x}_1 + \gamma_1, \boldsymbol{\beta}_2'\mathbf{x}_2, -\rho)$$

$$\text{Prob}[y_1 = 0, y_2 = 0 \mid \mathbf{x}_1, \mathbf{x}_2] = \Phi_2(-\boldsymbol{\beta}_1'\mathbf{x}_1, \quad -\boldsymbol{\beta}_2'\mathbf{x}_2, \rho)$$

This is a recursive simultaneous equations model. Surprisingly enough, it can be estimated by full information maximum likelihood *ignoring the simultaneity* in the system;

```
BIVARIATE   ; Lhs  = y,z
            ; Rh1 = x,z ; Rh2 = w $
```

An application of the result to the gender economics study is given in Greene (1998), redone below. Some extensions are presented in Greene (2011).

This model presents the same ambiguity in the conditional mean function and marginal effects that were noted earlier in Chapter E33 in the bivariate probit model. The conditional mean for *y* is

$$E[y \mid z = 1, \mathbf{x}, \mathbf{w}] = \Phi_2(\boldsymbol{\beta}'\mathbf{x} + \gamma_1, \boldsymbol{\alpha}'\mathbf{w}, \rho) / \Phi(\boldsymbol{\alpha}'\mathbf{w})$$

for which derivatives were given earlier. Given the form of this result, we can identify direct and indirect effects in the conditional mean:

$$\frac{\partial E[y \mid z = 1, \mathbf{x}, \mathbf{w}]}{\partial \mathbf{x}} = \frac{g_1}{\Phi(\boldsymbol{\alpha}'\mathbf{w})}\boldsymbol{\beta} \;=\text{ direct effects}$$

$$\frac{\partial E[y \mid z = 1, \mathbf{x}, \mathbf{w}]}{\partial \mathbf{w}} = \left[\frac{g_2}{\Phi(\boldsymbol{\alpha}'\mathbf{w})} - \frac{\Phi_2(\boldsymbol{\beta}'\mathbf{x}, \boldsymbol{\alpha}'\mathbf{w}, \rho)\phi(z_2)}{\left[\Phi(\boldsymbol{\alpha}'\mathbf{w})\right]^2}\right]\boldsymbol{\alpha} \;=\text{ indirect effects}$$

The total effect for any variable which appears in both **x** and **w** would be the sum of the two effects above. The unconditional mean function is

$$
\begin{aligned}
E[y \mid \mathbf{x}, \mathbf{w}] &= \Phi(\boldsymbol{\alpha}'\mathbf{w})\, E[y \mid z = 1, \mathbf{x}, \mathbf{w}] + [1-\Phi(\boldsymbol{\alpha}'\mathbf{w})]\, E[y \mid z = 0, \mathbf{x}, \mathbf{w}] \\
&= \Phi_2\, (\boldsymbol{\beta}'\mathbf{x} + \gamma_1, \boldsymbol{\alpha}'\mathbf{w}, \rho) + \Phi_2\, (\boldsymbol{\beta}'\mathbf{x}, -\boldsymbol{\alpha}'\mathbf{w}, -\rho).
\end{aligned}
$$

Derivatives for partial effects can be derived using the results given earlier. Analysis appears in Greene (1998).

To illustrate the estimator, we examine the model estimated in Burnett (1997) and revisited in Greene (1998). The study examines the likelihood that an economics department at a liberal arts college will offer a gender economics course ($y = 1$). The endogenous dummy variable is whether there is a women's studies program offered on the campus ($z = 1$). There are 132 observations in the data set. The variables in the data set are

gndrecon	=	$y = 1$ if a gender economics course is offered, 0 if not
womstud	=	$z = 1$ if there is a women's studies program, 0 if not
acrep	=	a measure of the academic reputation of the school, a ranking
econfac	=	size of the economics faculty
pctwecn	=	percentage of the economics faculty that are women
pctwfac	=	percentage of the faculty that are women
relig	=	1 if the school has a religious affiliation, 0 if not
sou	=	1 if the school is located in the south, 0 if not
nor	=	1 if the school is located in the north, 0 if not
mid	=	1 if the school is located in the middle of the country, 0 if not
west	=	1 if the school is located in the west.

The bivariate probit model described above is estimated in Greene (1998) and examined further in Greene (2011). The lists of variables are

x	=	*constant*, *acrep*, *econfac*, *pctwecn*, *relig*
w	=	*acrep*, *pctwfac*, *relig*, *sou*, *west*, *nor*, *mid*.

The commands are as follows. The second estimator constrains ρ to equal zero.

```
NAMELIST    ; gendrecn = one,acrep,womstud,econfac,pctwecn,relig $
NAMELIST    ; womnstud = acrep,pctwfac,relig,sou,west,nor,mid $
BIVARIATE   ; Lhs = gndrecon,womstud
            ; Rh1 = gendrecn ; Rh2 = womnstud ; Partial Effects $
CALC        ; kg = Col(gendrecn) ; kw = Col(womnstud) $
BIVARIATE   ; Lhs = gndrecon,womstud ; Rh1 = gendrecn ; Rh2 = womnstud
            ; Rst  = kg_bg, kw_bw, 0 $
```

E56.8 Switching Regressions

We consider variants of the following model:

Latent structure, two regimes: $y_{1i} = \boldsymbol{\beta}_1'\mathbf{x}_{1i} + \varepsilon_{1i}, \varepsilon_{1i} \sim N[0,\sigma_{11}]$,

$y_{0i} = \boldsymbol{\beta}_0'\mathbf{x}_{0i} + \varepsilon_{0i}, \varepsilon_{0i} \sim N[0,\sigma_{00}]$,

$\text{Corr}[\varepsilon_{1i}, \varepsilon_{0i}] = \rho_{10}$ (may be assumed to equal zero).

Observation mechanism: $y_i = \min(y_{0i}, y_{1i})$ or $y_i = \max(y_{0i}, y_{1i})$.

Observed data: y_i, $\mathbf{x}_{1i}$, and $\mathbf{x}_{0i}$, $i = 1,...,N$.

The observed quantity traded in a disequilibrium model of supply and demand is an example. Maddala (1983) contains extensive discussion. The model with 'exogenous switching' (Maddala's terminology) holds that the separation into one regime or the other is determined outside the structure of the model. Two cases are possible:

Observed separation indicator: There exists an observed indicator variable, z_i, which equals 1 if regime 1 applies and 0 if regime 0 applies. Continuing the earlier example, one suggestion for an indicator has been Sgn(P_t - $P_{t\text{-}1}$). I.e., whether price is rising or falling indicates whether the market is in shortage (Q on supply equation) or surplus (Q on demand equation).

No separation indicator: It is not known which regime applies for a given observation. This case produces a variant of the latent class model.

All combinations of the preceding are available for the basic model, i.e.:

- Minimum or maximum observation mechanism,
- Correlated or uncorrelated disturbances,
- Observed sample separation or none observed.

A model with ‘endogenous switching’ would have an auxiliary equation for the separation indicator,

$$z_i^* = \boldsymbol{\alpha}'\mathbf{w}_i + u_i,$$

$$z_i = 1 \text{ if } z_i^* > 0, \text{ and } 0 \text{ otherwise},$$

$$\text{Corr}[u_i, \varepsilon_{1i}] = \rho_{u1},$$

$$\text{Corr}[u_i, \varepsilon_{0i}] = \rho_{u0}.$$

This is the mover stayer model presented above in Section E56.2. This section is concerned with the model with exogenous, observed switching, or with an unobserved switching indicator.

E56.8.1 Model Commands

Commands for the switching regressions models are as follows:

```
SWITCH    ; Lhs  = y
          ; Rh1 = x1
          ; Rh2 = x2 $
```

This requests the basic model with

- no sample separation indicator,
- uncorrelated disturbances, and
- $y = \text{Min}(y_1, y_0)$.

To request the alternative specifications, use

; Sep = name of z,	sample separation binary variable
; Cor	to request the model with ρ_{10} not fixed at 0
; Max	to use the alternative observation mechanism
; Wts = weighting variable	

The parameter vector for **SWITCH** is

$$\boldsymbol{\theta} = [\boldsymbol{\beta}_1, \boldsymbol{\beta}_0, \sigma_1, \sigma_0].$$

The restrictions in **; Rst = list** may be used for within and across equations. If the model is estimated with correlation, ρ_{10} will precede σ_1 in the parameter vector.

Standard Model Specifications for the Switching Regressions Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps ancillary parameters such as a correlation in main results vector *b*.
; Partial Effects	displays marginal effects, same as **; Marginal Effects**.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix	displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Cluster = spec	requests computation of the cluster form of corrected covariance estimator.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm. The only fitting algorithm available is Newton’s method.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level ‘**n**’ is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E56.8.2 Results for Switching Regressions Models

Initial output consists of least squares regressions for both equations. If there is no sample separation indicator, the full sample is used in both regressions. If a sample separation indicator is available, the relevant subsample is used in each regression. Either way, the OLS estimates are inconsistent, and are used only as starting values. The starting value for ρ, when the model with correlation is requested, is 0.0.

The iterations are followed by the maximum likelihood estimates. Output includes the log likelihood, an indication of whether the observation mechanism is '**; Minimum**' or '**; Maximum**,' and, if one is present, the identification of the sample separation indicator. The final estimates include, in order, $\boldsymbol{\beta}_1$, $\boldsymbol{\beta}_0$, σ_1, and σ_0.

Results saved by this procedure are

Matrices: $b = [\boldsymbol{\beta}_1, \boldsymbol{\beta}_0]$ and *varb*. **; Par** adds (σ_1, σ_0) to the parameter vector.

Scalars: *sy*, *ybar*, *kreg* = $k_1 + k_0$, *nreg* = N, *logl*, *sigma*1, *sigma*0.
If the correlation model is specified, *rho* contains the estimate of D.

Last Model: *b*1_*variables*, *b*0_*variables*, *r*10, *sigma*1, *sigma*0.

Last Function: None

Predicted values are computed as follows: If there is a separation indicator, z, available, then

$$\hat{y} = \boldsymbol{\beta}_1'\mathbf{x}_1 \text{ if } z = 1, \text{ and } \hat{y} = \boldsymbol{\beta}_0'\mathbf{x}_0 \text{ if } z = 0.$$

If there is no separation indicator, the prediction is

$$\hat{y} = \text{Prob}[y = y_1^*]\boldsymbol{\beta}_1'\mathbf{x}_1 + \text{Prob}[y = y_0^*]\boldsymbol{\beta}_0'\mathbf{x}_0.$$

The probability is computed using

$$\text{Prob}[y = y_1^*] = \text{Prob}[\boldsymbol{\beta}_1'\mathbf{x}_1 + \varepsilon_1 < \boldsymbol{\beta}_0'\mathbf{x}_0 + \varepsilon_0]$$

$$= \text{Prob}[\varepsilon_1 - \varepsilon_0 < \boldsymbol{\beta}_0'\mathbf{x}_0 - \boldsymbol{\beta}_1'\mathbf{x}_1].$$

Let $$\sigma = [\sigma_1^2 + \sigma_2^2 - 2\rho_{10}\sigma_1\sigma_0]^{1/2}$$

Then, $$\text{Prob}[y = y_1^*] = \Phi[(\boldsymbol{\beta}_0'\mathbf{x}_0 - \boldsymbol{\beta}_1'\mathbf{x}_1)/\sigma].$$

If the observation is the maximum instead of the minimum, the sign of the argument in the normal CDF is reversed. The other two variables shown when **; List** is requested are $\boldsymbol{\beta}_1'\mathbf{x}_1$ and $\boldsymbol{\beta}_0'\mathbf{x}_0$.

E56.8.3 Application

The following will simulate the conditions of the switching regressions model in order to demonstrate the output that results. The commands were executed all at once from the editor.

```
SAMPLE    ; 1-500 $
CALC      ; Ran(12345) $
CREATE    ; x1 = Rnn(0,1)                 ? regressor for equation 1
          ; x0 = Rnn(0,1)                 ? regressor for equation 0
          ; e1 = Rnn(0,1)                 ? disturbance for equation 1
          ; e0 = .5*e1+.5*Rnn(0,1)        ? u for equation 0, correlated
          ; u = Rnn(0,1)+.5*(e1+e0)       ? u for endogenous selection
          ; w = Rnn(0,1)                  ? regressor for selection equation
          ; z = w+u                       ? underlying regression for probit
          ; z = z > 0                     ? binary variable for probit
          ; y1 = x1+e1                    ? structural variable, y1*
          ; y0 = x0+e0                    ? structural variable, y0*
          ; If(y1<y0) ys = y1             ? choose minimum of y1*, y0*
          ; (Else) ys = y0 $
```

We fit four variants of switching regressions model:

1. Uncorrelated disturbances, no separation indicator. Least squares are displayed.

   SWITCH ; Lhs = ys ; Rh1 = one,x1 ; Rh2 = one,x0 ; OLS $

2. Correlated equation, no separation indicator.

   SWITCH ; Lhs = ys ; Rh1 = one,x1 ; Rh2 = one,x0 ; Cor $

3. Uncorrelated disturbances, observed separation indicator.

   SWITCH ; Lhs = ys ; Rh1 = one,x1 ; Rh2 = one,x0 ; Sep = z $

4. Correlated disturbances, observed separation indicator.

   SWITCH ; Lhs = ys ; Rh1 = one,x1 ; Rh2 = one,x0 ; Sep = z ; Cor $

Results are shown for the fourth model.

E56.8.4 Technical Details

Technical results for the switching regressions model with exogenous switching appear in Maddala (1983), though most of his results pertain to the uncorrelated case. For the general case here, we have:

$$\text{parameters} = \sigma_1, \sigma_0, \rho,$$

$$\delta = 1 / (1 - \rho^2)^{1/2},$$

$$v_1 = \varepsilon_1 / \sigma_1, \qquad v_0 = \varepsilon_0 / \sigma_0,$$

$$f_j = (1/\sigma_j)\phi(v_j), \quad j = 0,1,$$

$$u_1 = \rho v_1 - v_0, \qquad u_0 = \rho v_0 - v_1,$$

$$P_1 = \Phi[\delta v_0], \qquad P_0 = \Phi[\delta v_1],$$

$$P_{01} = P_0 f_1, \qquad P_{10} = P_1 f_0.$$

With no sample separation,

$$\log L = \Sigma_i \log(P_{10} + P_{01}).$$

With sample separation,

$$\log L = \Sigma_i z_i \log P_{10} + (1 - z_i)\log P_{01}.$$

In both cases, the BHHH estimator is used to estimate the asymptotic covariance matrix of the parameter estimates. The BFGS algorithm is used by default.

NOTE: The nonconvergence problems and possible unboundedness of the log likelihood function in the case in which the sample separation is unknown have been widely documented.

E56.8.5 MLE for the Endogenous Switching Model

As noted earlier, this is the mover stayer model in Section E56.2. We provide some further details and a command language estimator for this model. The log likelihood can be reparameterized to equal

$$L_i = \theta_0\phi(\varepsilon_i)\Phi\left[\frac{-\mathbf{z}_i'\boldsymbol{\alpha} - \rho_0\varepsilon_{0i}}{\sqrt{1-\rho_0^2}}\right] + \theta_1\phi(\varepsilon_{1i})\Phi\left[\frac{\mathbf{z}_i'\boldsymbol{\alpha} + \rho_1\varepsilon_{1i}}{\sqrt{1-\rho_1^2}}\right]$$

where

$$\begin{aligned}
&\theta_0 = 1/\sigma_0,\ \rho_0 = \sigma_{u0}/\sigma_0,\\
&\theta_1 = 1/\sigma_1,\ \rho_1 = \sigma_{u1}/\sigma_1,\\
&\varepsilon_{0i} = \theta_0 y_i - \mathbf{x}_{i0}'\boldsymbol{\lambda}_0,\ \ \boldsymbol{\lambda}_0 = (1/\sigma_0)\boldsymbol{\beta}_0\\
&\varepsilon_{1i} = \theta_1 y_i - \mathbf{x}_{i1}'\boldsymbol{\lambda}_1,\ \ \boldsymbol{\lambda}_1 = (1/\sigma_1)\boldsymbol{\beta}_1
\end{aligned}$$

The log likelihood function is Σ_i log(L_i). The formulation suggested here uses the Olsen transformation of the model parameters. A command file that estimates the model parameters is

```

```

E57: Propensity Score Matching

E57.1 Introduction

Propensity score matching is the least parametric approach provided for examining treatment effects. This procedure is targeted essentially at measuring the change in the average value of y pre- and post- treatment. This program is used for estimating average treatment effects by matching observations based on propensity scores. Let O denote the outcome variable and T denote the treatment dummy variable, such that for an observation which has experienced the 'treatment,' $T = 1$, and $T = 0$ if not. We are interested in the effect of treatment *on the treated*. In principle, this means observing the treated individual before and after treatment. The problem, of course, is that ex post, we don't observe the counterfactual outcome variable, O, for the treated, in the absence of the treatment. If assignment to the treatment is nonrandom, estimation of treatment effects is biased by the effect of the variables that effect the treatment assignment. The strategy is to locate an untreated individual who looks like the treated one in every respect except the treatment, then compare the outcomes. We then average this across individual pairs to estimate the 'average treatment effect on the treated.'

E57.2 Methodology

Let $\mathbf{x}$ denote the vector of characteristics of the individual, before the treatment. Let the probability of treatment be denoted $P(T{=}1|\mathbf{x}) = \mathrm{P}(\mathbf{x})$. Since T is binary, $P(\mathbf{x}) = E[T|\mathbf{x}]$. If treatment is random *given* $\mathbf{x}$, then treatment is random given $P(\mathbf{x})$, which in this context is called the *propensity score*. It will generally not be possible to match individuals based on all the characteristics individually – with continuously measured characteristics, such as income, there are too many cells. The matching is done via the propensity score. Individuals with similar propensity scores are expected (on average) to be individuals with similar characteristics. Overall, the strategy is, for a 'treated' individual with propensity $P(\mathbf{x}_i)$ and outcome O_i, we locate a control observation with similar propensity $P(\mathbf{x}_c)$ and with outcome O_c. The effect of treatment on the treated for this individual is estimated by O_i - O_c. This is averaged across individuals to estimate the average treatment effect on the treated. The underlying theory asserts that the estimates of treatment effects across treated and controls are unbiased if the treatment assignment is random among individuals with the same propensity score – the propensity score, itself, captures the drivers of the treatment assignment. (Relevant papers that establish this methodology are too numerous to list here. Useful references are three canonical papers, Heckman et al. (1997, 1998a, 1998b) and a study by Becker and Ichino (2002).)

The steps in the propensity matching analysis consist of the following: (Steps 2 and 3 are tests of the 'balancing hypothesis.')

Step 1. Estimate the propensity score function, $P(\mathbf{x})$, for each individual by fitting a probit or logit model, and using the fitted probabilities.

Step 2. Establish that the average propensity scores of treatment and controls are the same within particular ranges of the propensity scores.

Step 3. Establish that the averages of the characteristics for treatment and controls are the same for observations in specific ranges of the propensity score.

Step 4. For each treated observation in the sample, locate similar control observation(s) based on the propensity scores. Compute the treatment effect, O_i - O_c. Average this across observations to get the average treatment effect.

Step 5. In order to estimate a standard error for this estimate, Step 4 is repeated with a set of bootstrapped samples.

E57.3 Commands for Matching

The commands used for propensity score matching are similar to those for the sample selection estimator. First, you must set the sample to include observations to be used to estimate the propensity score function. These use any set of observations you wish – they need not be the same ones subject to the propensity score analysis.

The commands to request the propensity score matching program are

PROBIT ; Lhs = treatment dummy variable
or LOGIT ; Rhs = covariates ; Hold $
MATCH ; Lhs = outcome variable $

The sample may be changed in any way desired after the **PROBIT/LOGIT** command. The sample is set to be those observations containing the treated individuals and control individuals to be used in the analysis. No other specifications are mandatory in the **MATCH** command. The current sample and the previously fit propensity score function are used. Some optional specifications are:

; Nbt = number of bootstraps (default = 25)

NOTE: To replicate an earlier set of bootstrap results, use **CALC ; Ran(seed) $** to set the seed for the random number generator to a specific value immediately before the **MATCH** command.

; List to request detailed output during analysis

; Common Support to use observations in common support of propensity scores for treated and controls. (See Section E57.6.)

Matching on the single nearest neighbor is the default. The other methods are specified with either a kernel weighting function or a ‘caliper’ to define a range of neighbors. Use

; Kernel to use kernel weights to create the neighbor. Epanechnikov is the default, with bandwidth of 0.06

or **; Range = value** to use a caliper approach. Values .001 to .50 are allowed. If the value given is positive, then the range is +/- value. If the value given is negative, then the range is +/- a proportion of the propensity scores. For example, -5.0 means +/- 5% of P_{max} - $P_{min.}$

Options for the kernel estimator are

; Normal (with **; Kernel**) to specify the standard normal kernel function
; Logit (with **; Kernel**) to specify the logistic kernel function
; Smooth = bandwidth (default = .06, .001 to .25 allowed)

E57.4 Retained Results

In addition to the numerical displays shown in the examples below, this routine keeps the following results in your project. (All are defaults; there are no options.)

Scalars: *nused* = number of observations analyzed.

Beginning from the original current sample, *nused* is the number of observations that remain after observations with missing values for any *x* variables, *O*, or *T* are eliminated and, if the common support option is requested, after observations which fall outside the common support are eliminated from the sample.

ntreated = number of observations among *nused* with $T = 1$.
ncontrol = number of controls = *nused* – *ntreated.*
trt_efct = estimated average treatment effect.
sd_trtmt = estimated standard error for estimated effect.

The standard deviation is the square root of the mean squared deviation of the bootstrap estimates around the estimated treatment effect (not around the mean of the bootstrap estimates).

Variable: *ps_range* = number of the interval in the partitioned range of propensity scores that each observation falls in.

This is the identity of the interval in the mesh [P*] determined in Section E57.6 in the mathematical details below. For example, if the mesh is [.1, .2, .3, .4, .5, .6] and a score is 0.34, this variable would take value 3 for this observation.

Matrix: *psranges* = partitioning of the range of propensity scores used to analyze the balancing hypothesis.

In the example immediately above, this matrix would be the column vector,

psranges = [.1, .2, .3, .4, .5, .6]′

E57.5 Applications

In the following, we redo the example reported in Becker and Ichino (2002) (BI). This application and data are derived from Dehejia and Wahba (1999) (DW), whose study, in turn was based on LaLonde (1986). The data set consists of observed samples of treatments and controls from the *National Supported Work* demonstration. Some of the institutional features of the data set are given by Becker and Ichino. The data were downloaded from Rajeev Dehejia's data page http://www.nber.org/~rdehejia/nswdata.html. Becker and Ichino report that they were unable to replicate DW's results, though they did obtain similar results. (They indicate that they did not have the original authors' specifications of the number of blocks used in the partitioning of the range of propensity scores, significance levels, or exact procedures for testing the balancing property.) In turn, we could not replicate BI's results – we can identify the reason, as discussed below. Likewise, however, we obtain qualitatively similar results.

There are 2,675 observations in the data set. The variables in the data set are

t	=	treatment dummy variable
age	=	age in years
educ	=	education in years
marr	=	dummy variable for married
black	=	dummy variable for black
hisp	=	dummy variable for Hispanic
nodegree	=	dummy for no degree (not used)
*re*74	=	real earnings in 1974
*re*75	=	real earnings in 1975
*re*78	=	real earnings in 1978

Transformed variables added to the equation are

*age*2	=	*age* squared
*educ*2	=	*educ* squared
*re*742	=	*re*74 squared
*re*752	=	*re*75 squared
*blacku*74	=	*black* times 1(*re*74 = 0)

In order to improve the readability of some of the reported results, we have divided the income variables by 10,000. The outcome variable is *re*78. The sample contains, in total, 2490 controls and 185 treated observations.

The data set is setup and described first.

--------+-----------------------------------------------------------------
```

We next fit the logit model for the propensity scores. An immediate problem arises with the data set as used by Becker and Ichino. The income data are in raw dollar terms – the mean of *re*74, for example is $13,714.86. The square of it, which is on the order of 200,000,000, as well as the square of *re*75 which is similar, is included in the logit equation with a dummy variable for Hispanic which is zero for 96.5% of the observations and the *blacku*74 dummy variable which is similar. This data set is numerically unstable, and estimation of the logit model in this form is next to impossible. It was not possible to replicate the (*Stata* generated) coefficients without scaling the data. Thus, we have divided the income variables by 10,000 before beginning the analysis. From this point forward, none of their reported results can be reproduced. However, as noted at various points below, our results are quite similar to theirs in spite of this. (Comparable values appear in parentheses at some points below.)

| Note:Estimation sample may not be the sample analyzed here. |
| Observations analyzed are restricted to the common support =|
| only controls with propensity in the range of the treated.  |
+---------------------------------------------------------------+
```

The note in the reported logit results reports how the common support is defined, that is, as the range of variation of the scores for the treated observations.

The next set of results reports the iterations which partition the range of probabilities. The report includes the results of the F tests within the partitions as well as the details of the full partition itself. Becker and Ichino do not report the results of this search for their data, but do report that they ultimately found seven blocks whereas we find eight. They do not report the means by which the test of equality is carried out within the blocks or the critical value used. The method used here is reported in the mathematical details in Section E57.6.

Partitioning the range of propensity scores

Iteration 1. Partitioning range of propensity scores into 5 intervals.

Range		Controls			Treatment					
		# Obs.	Mean PS	S.D. PS	# obs.	Mean PS	S.D. PS	F	Prob	
.00059	.19544	1086	.02108	.03352	18	.08025	.06307	15.77	.0010	*
.19544	.39029	41	.28559	.05967	24	.30771	.05508	2.29	.1361	
.39029	.58514	15	.49623	.05068	21	.48810	.06451	.18	.6748	
.58514	.77999	13	.68860	.04677	19	.64604	.04682	6.39	.0179	
.77999	.97484	7	.96228	.00706	103	.92986	.05425	29.44	.0000	*

Iteration 1 Mean scores are not equal in at least one cell

Iteration 2. Partitioning range of propensity scores into 6 intervals.

Range		Controls			Treatment					
		# Obs.	Mean PS	S.D. PS	# obs.	Mean PS	S.D. PS	F	Prob	
.00059	.09802	1030	.01509	.02117	11	.03650	.03263	4.72	.0550

Mean PSCORES are tested equal within the blocks listed below.

After partitioning the range of the propensity scores, we report the empirical distribution of the propensity scores and the boundaries of the blocks estimated above. The values below show the percentiles that are also reported by Becker and Ichino. Finally, the reported search algorithm notwithstanding, the block boundaries shown are rough.

```
+------------------------------------------------------------+

```

Becker and Ichino report the following blocks and sample sizes:

	Lower	Upper	Observations
1	0.0006	0.05	931
2	0.05	0.10	106
3	0.10	0.20	63
4	0.20	0.40	69
5	0.40	0.60	35
6	0.60	0.80	33
7	0.80	1.00	105

The next set of results reports the analysis of the balancing property for the independent variables. Note that a test is reported for each variable in each block as listed in the table above. The lines marked (by the program) with ‘*’ show cells in which one or the other group had no observations, so the F test could not be carried out. This was treated as a ‘success’ in each analysis. Lines marked with an ‘o’ note where the balancing property failed. There are relatively few of these, but those we do find are not borderline. Becker and Ichino report their finding that the balancing property is satisfied. Note that this finding does not prevent the further analysis. It merely suggests to analysts that they might want to consider a richer specification of the propensity function model.

```
Examining exogenous variables for balancing hypothesis
* Indicates no observations, treatment and/or controls, for test.
o Indicates means of treated and controls differ significantly.

This part of the analysis ends with a recommendation that the analyst reexamine the specification of the propensity score model. Since this is not a numerical problem, the analysis continues with estimation of the average treatment effect on the treated.

The first example below shows estimation using the kernel estimator to define the counterpart observation from the controls. This stage consists of *nbot* + 1 iterations. The first is the actual estimation, which is reported in the intermediate results. Then the *nboot* repetitions are reported. (These will be omitted if **; List** is not included in the command.)

Recall, we divided the income values by 10,000. The value of .157435 reported below thus corresponds to $1,574.35. Becker and Ichino report a value (see their Section 6.4) of $1537.94 based on the 185 treateds and 1,157 controls. The result below is based on the same 185 treateds and 1,162 controls. Note that the kernel estimator is the most time consuming of the three approaches. For this sample of over 2,600 observations, the entire procedure required less than one second.

```
+--------------------------------------------------------------------+
| Estimated Average Treatment Effect (T       )  Outcome is RE78       |
| Kernel            Using Epanechnikov kernel with bandwidth =  .0600  |
| Note, controls may be reused in defining matches.                   |
| Number of bootstrap replications used to obtain variance    =    25 |
+--------------------------------------------------------------------+

  End bootstrap iterations   *******************************************
```

(Note, the values reported in parentheses below for the average treatment effect and the estimated asymptotic standard error are Becker and Ichino's estimates, not part of the output of the program. Their counterpart to the confidence interval shown below is (-.0479755 to 3.555643).

```
+--------------------------------------------------------------------+
| Number of Treated observations =    185  Number of controls =   1162 |
| Estimated Average Treatment Effect   =       .157435  (.1537943)    |
| Estimated Asymptotic Standard Error  =       .096927  (.1016874)    |
| t statistic (ATT/Est.S.E.)           =      1.624276                |
| 95% Confidence Interval for ATT      = -.032541 to .347411) 95%     |
| Average Bootstrap estimate of ATT    =       .119419                |
| ATT - Average bootstrap estimate     =       .038017                |
+--------------------------------------------------------------------+
Elapsed time:     0 hours,  0 minutes,  0.75 seconds.
```

The next set of estimates is based on all of the program defaults. The single nearest neighbor is used for the counterpart observation; 25 bootstrap replications are used to compute the standard deviation, and the full range of propensity scores (rather than the common support) is used. Intermediate output is also suppressed.

```

The reported estimated propensity score function is the same as before, as it is simply an echo of the earlier function. All of the subsequent results will be different because the previous example restricted the sample in use to those in the common support while the results to follow use all observations in the sample. Becker and Ichino do not report a like set of results, so we can only compare the final results here. The partitioning of the range of propensity scores once again produces eight blocks.

```
Partitioning the range of propensity scores
Iteration  1  Mean scores are not equal in at least one cell
Iteration  2  Mean scores are not equal in at least one cell
Iteration  3  Mean scores are not equal in at least one cell
Mean PSCORES are tested equal within the blocks listed below.
```

+----------------------------------------------------------------------+
```

Using the full sample in this fashion produces an estimate of $1,418.70 for the treatment effect with an estimated standard error of $1,189.04. Note that from the results above, we find that only 55 of the 2490 control observations were used as nearest neighbors for the 185 treated observations. In comparison, using the 1,342 observations in their estimated common support, and the same 185 treateds, Becker and Ichino report estimates of $1,667.64 and $2,113.59 for the effect and the standard error, respectively and use 57 of the 1,342 controls as nearest neighbors. Finally, this is the fastest of the three procedures. Computation based on the same sample now requires about a third of a second.

The next set of results uses the caliper form of matching and again restricts attention to the estimates in the common support.

Examining exogenous variables for balancing hypothesis
Variable BLACKU74 is unbalanced in block  1
Other variables may also be unbalanced
You might want to respecify the index function for the P-scores
```

Results to this point will be identical to the first set as the same sample and the same procedures are used to partition the range of propensity scores and test the balancing property. The estimated treatment effects are very different. We see that only 28 of the 185 controls had a neighbor within a range (radius in the terminology of Becker and Ichino) of 0.0001. The treatment effect is estimated to be only $167.16 with a standard error of $294.66. In contrast, using this procedure, and this radius, Becker and Ichino report a nonsense result of -$5,546.10 with a standard error of $2,388.72. They note that this illustrates the sensitivity of the estimator to the choice of radius, which is certainly the case. To examine this aspect, we recomputed the estimator using a range of 0.01 instead of 0.0001. This produces the expected effect, as seen in the second set of results below. The estimated treatment effect rises to $1,552.11 which is comparable to the other results already obtained.

```
+----------------------------------------------------------------------+
| Estimated Average Treatment Effect (T       )  Outcome is RE78       |
| Caliper           Using distance of  .00010 to locate matches        |

| ATT - Average bootstrap estimate     =        .031850                |
+----------------------------------------------------------------------+
```

Finally, we examine the effect of using a probit model instead of a logit for the propensity scores. The first set of results below repeats the first set computed above. The second set is otherwise the same, save for the change to a probit model. The effect on the estimated treatment is very small, only $70 or about 4%. The standard error falls noticeably, but this is probably not a general result. The logit results are

```
+----------------------------------------------------------------------+
| Number of Treated observations =    185  Number of controls =   1162 |
| Estimated Average Treatment Effect   =        .157435                |
| Estimated Asymptotic Standard Error  =        .096927                |
| t statistic (ATT/Est.S.E.)           =       1.624276                |
| Confidence Interval for ATT = (     -.032541  to        .347411) 95% |
| Average Bootstrap estimate of ATT    =        .119419                |
| ATT - Average bootstrap estimate     =        .038017                |
+----------------------------------------------------------------------+
```

The same set of computations based on a probit model for the propensity scores produces the following:

```
+----------------------------------------------------------------------+
| Number of Treated observations =    185  Number of controls =   1042 |
| Estimated Average Treatment Effect   =        .150392                |
| Estimated Asymptotic Standard Error  =        .077791                |
| t statistic (ATT/Est.S.E.)           =       1.933289                |
| Confidence Interval for ATT = (     -.002078  to        .302862) 95% |
| Average Bootstrap estimate of ATT    =        .160183                |
| ATT - Average bootstrap estimate     =       -.009791                |
+----------------------------------------------------------------------+
```

E57.6 Mathematical Details of the Procedure

The following are the computations used to estimate the average treatment effect.

Propensity Score Model

The propensity scores are calculated using an estimated probit or logit binary choice model. The model estimates

$$
\begin{aligned}
P(T{=}1|\mathbf{x}) &= P(\mathbf{x}) \\
&= \Phi(\boldsymbol{\beta}'\mathbf{x}) \text{ for a probit model} \\
\text{and} \qquad &= \Lambda(\boldsymbol{\beta}'\mathbf{x}) \text{ for a logit model.}
\end{aligned}
$$

The model need not be estimated with the sample analyzed to compute the treatment effects. Any subsample, or a different sample entirely may be used. The specification of the treatment model should contain sufficient richness, perhaps with quadratic or interaction terms, to capture, as fully as possible, the underlying drivers of assignment to treatment. The next series of steps are applied to the sample to be used to estimate the average treatment effect.

Balancing Hypothesis

The data are examined to see if they satisfactorily meet the balancing hypothesis of equal means of treatment and controls – that is, to see if the treatment assignment between treated and controls is random given the characteristics.

Let the sample of propensity scores for the full sample be denoted P_i, those for the treated as P_t and for the controls P_c. It is decided at the outset whether to examine all individuals in the sample, or those whose propensities lie in the 'common support.' The common support consists of the range of propensities defined by

$$P_{min} = \text{Min}_t\, P_t \text{ to } P_{max} = \text{Max}_t\, P_t.$$

Thus, the sample consists of all the treated observations and the subset of controls whose propensity scores lie in this range.

The range of propensity scores is divided into a set of K intervals and the average propensity scores of treated and controls are tested for equality using the observations whose propensities lie within these ranges. *LIMDEP* uses the standard F test of equality of means,

$$\text{F}_k[1,d] = (\overline{P}_C^k - \overline{P}_T^k)^2 / (s_{C,k}^2 / N_C^k + s_{T,k}^2 / N_T^k),\ k = 1,...,K.$$

For the degrees of freedom for the denominator, we use the Satterthwaite approximation,

$$d = \frac{(s_{C,k}^2 / N_C^k + s_{T,k}^2 / N_T^k)^2}{[(s_{C,k}^2 / N_C^k)^2 / (N_C^k - 1)] + [(s_{T,k}^2 / N_T^k)^2 / (N_T^k - 1)]}\,.$$

We use a critical p value of 0.01 for the test. The default number of ranges is five. If the test fails in any cell, we use a finer partition of the range of scores. Two strategies are used.

1. Becker and Ichino recommend halving the range of the cell in which the test fails and repeating the test in the halves. Thus, if the initial ranges are .1-.2, .2-.3, .3-.4, .4-.5, .5-.6, and the test fails in the third cell, they convert the .3-.4 cell to two cells, .3-.35 and .35-.4 and repeating. By this calculation, a single cell can be partitioned into many small parts. In our first pass, we use this strategy, up to a maximum of 15 cells in total.

2. If the maximum of 15 cells is reached in pass one, we then start again with five equal length intervals, and if a cell fails the equal means test, we increase the number of cells to six and repeat the testing. In the case examined above, the second iteration would start again with cells .1000-.1833, .1833-.2666, .2666-.3500, .3500-.4333, .4333-.5167, .5167-.6000, and so on. By this strategy, the range of propensity scores is divided into finer, still equal length intervals. Once again, the iterations continue up to a maximum.

If a cell has insufficient observations to carry out the test, treat the F statistic as zero – that is, the means test passes for such a cell.

The outcome of this search will either be an indication that the overall test appears to pass, or if it persistently fails, a recommendation that the propensity score function is insufficiently specified. Either way, this failure does not prevent further processing. The result of this step is a mesh of points,

$$[P^*] = [P_1, P_2, ..., P_{K+1}]$$

that is then used in the next step. This mesh is the set of ranges shown at the right of the sample output below (which was reported earlier with our first set of results).

```

+---------------------------------------------------------------+
```

Once the mesh [P*] is obtained, we then carry out a test of the balancing hypothesis for each variable in **x**, using the sets of observations that are contained in the ranges. A test of equality of means is carried for each variable in **x**, in each range defined by [P*]. The test statistic is computed in the same manner as above for the propensity scores, and, again, the 0.01 critical value is used. The outcome of this step is either a notification that the data are consistent with the balancing hypothesis (equal means), or they are not. Either way, this does not prevent further computation. The test of the variable age in our first analysis was reported as

```
Examining exogenous variables for balancing hypothesis
* Indicates no observations, treatment and/or controls, for test.
o Indicates means of treated and controls differ significantly.
=================================================================

```

Note that there are no control observations in the sixth and seventh blocks. These are taken to represent successes of the hypothesis.

Average Treatment Effect

The average treatment effect on the treated is now estimated. For each treated observation/outcome, O_t, we locate the counterpart control observations, O_c* that are similar in the characteristics, by using closeness of the propensity scores. The treatment effect for this observation is then estimated with O_t - O_c*. The average over the treated observations is then our estimate of the effect of treatment on the treated.

Note that this computation proceeds regardless of the outcome of the data examination in the previous step. However, a negative outcome in that step might call the results of this computation into question.

We offer three methods of locating the counterpart observation, O_c*:

Single Nearest Neighbor

The counterpart observation is the one that has the nearest propensity score. O_c* is the outcome for the person for whom $|P_t - P_c|$ is minimized. Note that a particular control observation may be the nearest neighbor to more than one treated observation. And, some controls may not be the closest neighbors to any treated observations.

Caliper

The counterpart observation is constructed by averaging all control observations whose propensity scores fall in a given range. Thus, we first locate the set $[C_t^*]$ = the set of control observations for which $|P_t - P_c| \leq r$, where the user specifies the value of r in the command. (The distance may be specified to be a specific value, such as .01, or a percentage of the range of propensity scores, such as P_t +/- 2% of $(P_{max} - P_{min})$. By this construction, the neighbor may be an average of several control observations. It may also not exist, if no observations are close enough. As in the single nearest neighbor computation, control observations may be used more than once, or they might not be used at all. (E.g., if the caliper is .01, a control observation has propensity .5 and the nearest treated observations have propensities of .45 and .55, then this control will never be used.)

Kernel

The counterpart observation is obtained by constructing a kernel estimator,

$$O_c^* = \frac{\sum_{c=1}^{N_c} O_c K\left[(P_t - P_c)/h\right]}{\sum_{c=1}^{N_c} K\left[(P_t - P_c)/h\right]} = \sum_{c=1}^{N_c} w_c O_c$$

where $K[.]$ is a kernel weighting function and h is the bandwidth. Three kernel functions are supported

Epanechnikov[z]	=	$.75\,(1 - z^2/5) / 5^{1/2}$ for $\lvert z\rvert \leq 5$
Normal	=	$\phi(z)$ = standard normal density
Logistic	=	$\Lambda(z)[1-\Lambda(z)]$ = logistic density
		$\Lambda(z) = \exp(z)/[1+\exp(z)]$.

The bandwidth may be specified by the user. The default value is 0.6; any positive value less than .25 may be specified. (The kernel function becomes unstable if the bandwidth is too large.) Note that this is a weighted average of the outcomes for all control observations, where the weights sum to one and are

$$w_c = \frac{K\left[(P_t - P_c)/h\right]}{\sum_{c=1}^{N_c} K\left[(P_t - P_c)/h\right]},\ 0 < w_c < 1,\quad \Sigma_c\, w_c = 1$$

In this instance, the neighbor is an average of all control observations.

Estimated Standard Error for the Average Treatment Effect

The variance of the estimator is estimated by using bootstrapping. The entire process is repeated *nboot* times, specified by the user. The default number is 25; up to 1,000 may be requested. The mean squared deviation around the actual estimator is used as the variance estimator. The square root is reported as the estimated asymptotic standard error.

Computation Time

Searching for the neighbors could be time consuming in a very large sample. The procedure is limited to samples of 200,000 observations or less. *LIMDEP's* algorithms are quite fast. The search is optimized by sorting the observations on propensity scores before any searching is done. Thus, for example, the search for the single nearest neighbor, which might involve searching the entire data set if the data are unsorted, is a trivial inspection of the few adjacent observations with the sorted data. Doing this entire analysis with a sample of 2,500 observations, and using the kernel estimator and 25 bootstrap iterations takes about 0.5 seconds, including estimating the probit equation, on a recent vintage desktop computer. Computation time will generally not be a substantive constraint.

E58: Nonparametric Analysis of Duration Data

E58.1 Introduction

This and the next two chapters will document *LIMDEP*'s programs for analyzing duration or lifetime (sometimes called 'survival' or 'failure time') data. This chapter presents the nonparametric (life table) methods. Chapter E59 narrows the analysis to 'semiparametric' models, which make minimal, but nonetheless substantive assumptions about the underlying distribution. Finally, Chapter E60 presents models which make explicit distributional assumptions for the duration data. Principal references for the developments in these chapters are: Kalbfleisch and Prentice (1980), Cox and Oakes (1984), Gross and Clark (1975), and Kiefer (1988).

The techniques and *LIMDEP* routines described here are used for analyzing duration data such as survival times, length of time until failure, lengths of spells of unemployment, strike duration, and so on. The data consist of measurements on the length of survival and, possibly, a set of regressors (covariates). In addition, the data may be 'right censored.' That is, the time measured may represent only the last observation of an individual who had not yet 'exited' the process being studied. For example, in studying spells of unemployment, the observed duration time may represent the full length of the spell, i.e., the length of time it took for the individual to find a job. Alternatively, at the time of measurement, the individual might have still been seeking a job. The duration datum in this case is censored; we know only (assume) that the individual left unemployment at some time after the measurement. The methods described here assume that observations are homogeneous in the probability distribution over duration times, with the exception of the measured covariates, if any. This is relaxed in Chapter E60. In addition, it is assumed that any censoring in the data is unrelated to the duration values themselves.

This chapter will show how to compute, store, and plot simple life tables for duration data. Treatment for a single sample is shown first. A method of stratifying the sample is shown at the end of the chapter.

E58.2 Life Tables

If only the duration times are available (i.e., no covariates), then life tables and survival curves can be derived by actuarial methods. In addition, if any observations are censored, the data must contain an indicator (binary) variable indicating which observations 'exited' (indicator = 1) and which observations are censored (indicator = 0).

NOTE: The maximum number of observations which can be analyzed is 75,000.

Suppose, then that observations consist of survival times, t_1, t_2, ..., t_N. Survival times are ordered low to high by the program. Your data need not be ordered; they are sorted internally. Also, let c_1, c_2, ..., c_N be the censoring indicator equal to zero for censored, or one for exited observations.

The following are computed:

Table 1. Life table based on the method of Cutler and Ederer (1958): The range of t is divided into K equal intervals. For each interval, $j = 1,\ldots,K$, we compute:

a. the number of observations, n_j,
b. size of the risk set, $r_j = n_j - C_j/2$, where C_j is the number of censored observations,
c. the number of observations which 'exit,' m_j ,
d. the proportion of observations in the risk set which exited, $q_j = m_j/r_j$,
e. the proportion surviving (the survival function) = the cumulative proportion of individuals surviving to the beginning of the interval,

$$p_j \quad = (1-q_{j-1})P_{j-1}, \text{ where } P_1=1,$$

f. standard error for estimated survival rate,

$$\text{se}(P_j) = P_j[\textstyle\sum_{j=1}^{k-1} q_k/(r_k(1-q_k))]^{1/2},$$

g. hazard rate,

$$\lambda_j \quad = 2q_j/(h(2-q_j)), \text{ where } h \text{ is the interval width,}$$

h. standard error for the hazard function,

$$\text{se}(\lambda_j) = \lambda_j[(1-(h\lambda_j/2)^2)/(r_j q_j)]^{1/2}.$$

The survival function and hazard function are then plotted. The median survival time is reported with the plotted survival function.

Table 2. If requested, the survival rates may be computed for the individual observations. The observations are sorted from low to high and the following are reported in a table:

a. observation,
b. survival time,
c. status – either exited or censored,
d. the cumulative survival rate to the time at which this individual was measured,
e. estimated standard error of the survival rate,
f. total number of observations which have exited up to that duration,
g. total number of observations censored at or less than that duration,
h. size of the risk set at the beginning of the period. (This is the number of observations whose duration is at least as large as that of this observation.)

Table 3. If the results in Table 2 are requested, the same information is reported for each distinct exit time in the sample. This will differ from the preceding if there are ties in the data. In the first table, when the data are sorted, the survival rate is computed based simply on observation number, so that only the last observation in a set of ties is meaningful.

E58.3 Commands for Life Tables

The basic command to request the nonparametric survival analysis is

SURVIVAL ; Lhs = time variable $

If the data are censored, the censoring indicator is given as a second Lhs variable. For example,

SURVIVAL ; Lhs = time,status $

The censoring indicator must be coded 1 for actual exit times and 0 for censored observations. The number of intervals in the life table is set at 10. This may be changed by using

; Int = number desired

The number given may be any value from 10 to 120.

The estimated hazard function and survival function can be plotted after the life table is displayed by adding

; Plot

to the command.

E58.3.1 Tables for Individuals and Specific Exit Times

The default output for the program is Table 1. Tables 2 and 3 are requested by adding

; List

to the command. The results in Table 3 may be kept permanently as data with the following: (Note, these are for the distinct exit times, not the observations.)

; Res = name saves the integrated hazard

The integrated hazard is a form of 'generalized residual,' which can be used to analyze model specification. (See Lancaster (1985).) (At this point, there is no model as such.) When the density, $f(t)$ and survival rate, $S(t)$ are defined, the integrated hazard is computed as

$$\int \lambda_i(t)dt = \int [f(t)/S(t)]d\mathrm{t} = -\log S(t).$$

We approximate this function with our estimated survival rates.

; Keep = name saves the hazard rate
; Fill keeps the distinct duration times

Since these variables are not specific to the observation, they are placed in the first K rows of the data area, where K is the number of distinct exit times. A scalar called '*numexit*' contains the number of exit times observed in the data set.

HINT: The **; Fill** option replaces the duration variable with its results. So, if you intend to use this option, use **CREATE** to make a copy of the original duration variable and use the copy as your duration variable in the command.

Separate plots will show the hazard and survival rates. An example is given below.

E58.3.2 Stratification

The survival tables and other analysis may be based on stratified data. The stratification must be provided by a variable which takes values 1, 2, ... As many as nine strata may be analyzed. A full set of results is provided for each stratum identified. At the end, two statistics, the log-rank and generalized Wilcoxon, are computed for testing homogeneity of the survival distributions across the strata. The command is:

```
SURVIVAL    ; Lhs = time [,status]
            ; Str = stratification indicator variable
            ; other options $
```

The strata must be identified explicitly. If you have a variable whose values you wish to use to define the strata, it is only necessary to use **RECODE** to create the stratification variable. For example, suppose *age* in the ranges 18-24, 25-45, and 46-99 is used to define three strata. You could use

```
CREATE      ; strat = age $
RECODE      ; strat ; 18 / 24 = 1 ; 25 / 45 = 2 ; 46 / 99 = 3 $
SURVIVAL    ; Lhs = time ; Str = strat $
```

E58.4 Applications

The estimators are illustrated with two data sets, one on strike duration from Kennan (1985) and the other a simulated data set with covariates.

E58.4.1 Strike Duration Data

The data listed below are the durations of 62 strikes reported by Kennan (1985). The last 12 are censored at 80 weeks.

```
READ        ; Nobs = 62 ; Nvar = 1 ; By Variables ; Names = time $
  1   2   2   2   2   3   3   3   9   12   21   27   43   49
 52   3   4   5   7   8   9  10  11   12   13   14   15   17
 19  21  22  23  25  26  27  28  29   32   33   35   37   38
 41  42  43  44  49  52  61  72  80   80   80   80   80   80
 80  80  80  80  80  80
CREATE      ; status = time < 80 $
SURVIVAL    ; Lhs = time,status ; Int = 20 ; List ; Plot $
```

```
Estimated Survival Function
Duration variable is        TIME
Status is given by variable STATUS
Number of observations in stratum =    62
Number of observations exiting    =    50
Number of observations censored   =    12
```

```

E58.5 Technical Details for the Homogeneity Tests

The log-rank and generalized Wilcoxon tests are both used for testing the hypothesis of homogeneity of the strata. They are computed as follows: Let

K = the number of strata, strata denoted $k = 1,...,K$,
N = the number of distinct exit times,
T_i = the exit time at time 'i,'
n_{ik} = the number of individuals in stratum k with exit time $t_{ik} \geq T_i$,
$n_{i.}$ = $\Sigma_k n_{ik}$ = number of individuals in the sample with $t_{ik} \geq T_i$,
x_{ik} = number of individuals who exit stratum k at time T_i,
$x_{i.}$ = $\Sigma_k x_{ik}$ = number of individuals in the sample who exit at time T_i,
$\mathbf{x}_i$ = $[x_{i1}, x_{i2}, ..., x_{iK}]'$.

Under the assumption of homogeneity, conditioned on the sums n_{ik} and $x_{i.}$, the vector $\mathbf{x}_i$ has a (K-1) dimensional hypergeometric distribution with mean vector

$$E[x_{ik}] = n_{ik} x_{i.} / n_{i.}, \; k = 1,...,K,$$

and covariances

$$\mathrm{Cov}[x_{ik}, x_{il}] = n_{ij} (\delta_{kl} - n_{il} / n_{i.}) x_{i.} (n_{i.} - x_{i.}) / [n_{i.} (n_{i.} - 1)], \; \delta_{kl} = \mathbf{1}(k = l).$$

Let $\mathbf{x} = \Sigma_i \mathbf{x}_i$, $\mathbf{E} = \Sigma_i E[\mathbf{x}_i]$, and $\mathbf{V} = \Sigma_i \mathrm{Var}[\mathbf{x}_i]$.

The log-rank statistic is

$$\mathrm{LR} = (\mathbf{x} - \mathbf{E})'\mathbf{V}^{-1}(\mathbf{x} - \mathbf{E}).$$

This has a limiting chi squared distribution with K-1 degrees of freedom. Since $\mathbf{V}$ is short ranked, its ordinary inverse does not exist. We use a G2 inverse to compute the statistic.

The generalized Wilcoxon statistic is a slight modification. Let

$$w_{ik} = n_{i.} (x_{ik} - x_{i.} n_{ik} / n_{i.}),$$

$$w_k = \Sigma_i w_{ik},$$

and

$$\mathbf{w} = [w_1, w_2, ..., w_K]'.$$

This vector has mean $\mathbf{0}$ and covariance matrix

$$\mathbf{Q} = \Sigma_i n_{i.}^2 \mathrm{Var}[\mathbf{x}_i].$$

The statistic is

$$\mathrm{GW} = \mathbf{w}'\mathbf{Q}^{-1}\mathbf{w}.$$

Once again, a generalized inverse is needed to compute the statistic.

E59: Proportional Hazard Models

E59.1 Introduction

Two models for duration data are presented in this chapter. Cox's proportional hazards model has proven useful for modeling duration data with only minimal assumptions about the underlying distribution. The shortcoming, however, is that this approach can be rather inflexible. The second model considered here, Han and Hausman's ordered logit model is, like the Cox model, semiparametric in that it only assumes a basic form for the hazard function.

E59.2 The Proportional Hazards Model

If one or more covariates are observed with the duration data, a regression-like model derived by Cox (1972) may be estimated. The formal model is based on the hazard rate at time t,

$$h(t,\mathbf{x}) = h(t,\mathbf{0})e^{\boldsymbol{\beta}'\mathbf{x}},$$

where $h(t,\mathbf{0})$ is the baseline hazard rate at time t for covariate vector $\mathbf{0}$. Assumptions for the model are presented in Cox (1972, 1975) and the related references cited there. The parameters are estimated as follows: We allow for ties and censored data in the measured durations. Let $T_1,...,T_K$ be the set of K distinct times in the N observations. Let R_j be the index set of the individuals at risk just prior to time T_j (i.e., the set of individuals with duration greater than or equal to t_j). For every individual i in R_j, $t_i \geq T_j$. The probability that an individual 'exits' (dies, leaves, etc.) at time T_j, given that exactly this one individual exits at time T_j, is

$$\text{Prob(exit at time } T_j) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_j)}{\sum_{i\in R_j}\exp(\boldsymbol{\beta}'\mathbf{x}_i)}.$$

The conditioning eliminates the baseline hazard. If exactly one individual exits at each time and no observations are censored, the partial log likelihood (see Cox (1975)) is

$$\log L = \sum_{j=1}^{K} \boldsymbol{\beta}'\mathbf{x}_j - \log\left[\sum_{i\in R_j}\exp(\boldsymbol{\beta}'\mathbf{x}_i)\right].$$

If $m_j \geq 1$ individuals exit at the same t_j, the partial log likelihood is the sum of the individual likelihoods,

$$\log L = \sum_{j=1}^{K} \boldsymbol{\beta}'\sum_{r\in T_j}\mathbf{x}_r - m_j\log\left[\sum_{i\in R_j}\exp(\boldsymbol{\beta}'\mathbf{x}_i)\right].$$

Censored observations enter the risk set at each observation but do not contribute to the numerator of the partial likelihood.

The partial log likelihood is maximized using Newton's method. Options available for this model include stratification, time dependent covariates, and fixed values of the parameters.

E59.2.1 Commands for the Proportional Hazards Model

The minimal command for this model is

SURVIVAL ; Lhs = time [,status] ; Rhs = list of covariates $

This differs from the model of the previous chapter only in the list of Rhs variables.

NOTE: This model is homogeneous of degree zero in **x**. Any variable which does not vary over individuals will simply multiply both numerator and denominator of the partial likelihood, and hence drop out of it. If it is found, the variable *one* is automatically removed from your Rhs list. But, if there are other covariates which are constant over individuals, the Hessian will become singular and the estimation process will break down.

A censoring indicator variable is provided exactly as before, as a second Lhs variable. This is indicated as the optional **[,status]** variable above. If you provide a status variable, code it as one for complete observations and zero for censored observations.

Standard Model Specifications for the Cox Proportional Hazards Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps survival rates as a new (or replacement) variable in data set.
; Res = name	keeps integrated hazards as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.
; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

The algorithm is preset to Newton's method. This form of the partial likelihood is quite well behaved, and convergence is normally routine after only a few iterations. If you do not find this to be the case, the problem is probably multicollinearity among the covariates. Time dependent covariates can also be problematic. However, there may be cases in which BFGS is a preferable algorithm. In general, Newton's method should be best.

There are no predictions or residuals produced for this model, since the baseline hazard is not estimated. A number of related variables are computed. These are described below.

E59.2.2 Plotting the Survival and Integrated Hazard Functions

As part of the results for this model, *LIMDEP* will display plots of the survival function and the integrated hazard rate, computed at the means of the covariates. Use

; Plot

to request the figures. You may also request additional plots at specified values of the Rhs variables. To use other values which you provide:

Step 1. Load these values as the rows of a matrix using the **MATRIX** command. Load one row for each set of values you wish to use for a plot.

Step 2. Add **; Plot = name of the matrix** to the **SURVIVAL** command.

This will produce an additional pair of plots for each row of the matrix, i.e., for each set of values.

E59.2.3 Keeping the Survival and Integrated Hazard Functions

You can also keep an estimate of the survival and/or integrated hazard function in your data area. Use

; Keep = name of variable for survival function
and **; Res = name of variable for integrated hazard**

(The integrated hazard function is a 'generalized residual.') These are computed for each observation in the sample. The formulas used for these computations are as follows: (Note, no correction is made for censoring. This can be problematic if the data are heavily censored.)

1. Obtain N distinct exit times, $t_1, t_2, ..., t_N$; $t_0 = 0$.

2. Obtain N counts of exit times; m_i = number of exits at time t_i.

3. The baseline hazard at t_i is

$$h(t_i,0) \quad = \quad h(t_i,0) = \frac{m_i}{(t_i - t_{i-1})\sum_{j\in \mathrm{R_i}\ \text{such that}\ T_j \geq t_i} \exp(\boldsymbol{\beta}'\mathbf{x}_j)}.$$

4. The baseline integrated hazard is

$$H(t_i,0) \quad = \quad \sum_{j=1}^{i}(t_j - t_{j-1})h(t_j,0)$$

5. For each individual,

$$H(t_i,\mathbf{x}_i) \; = \; \exp(\boldsymbol{\beta}'\mathbf{x}_i)H(t_i,\mathbf{0}).$$

   (This is the generalized residual for individual i. It is kept by **; Res**.)

6. The survival probability is

$$S(t_i,\mathbf{x}_i) \quad = \exp[-H(t_i,\mathbf{x}_i)].$$

   This estimated survival rate is not necessarily monotonic in t_i in the sample because $\mathbf{x}_i$ differs across observations.

E59.2.4 Time Dependent Covariates

It may be useful to include in the model covariates which change over time or are functions of time and other variables. *LIMDEP* allows a large amount of flexibility in specifying these. The feature described here is for covariates which are explicit functions of time, i.e., time *dependent* covariates. Time *varying* covariates, such as marital status, cannot be handled in the proportional hazards model. They are, however, permissible in the parametric models discussed in the next chapter. To include time *dependent* covariates (TVCs), add the following specification, once for each one you want to specify:

; TVC = specification
; TVC = specification ...

The covariates in the model will now be the Rhs variables plus the TVCs. Thus, each one adds a new coefficient to the model. The Rhs variables must exist in the data set. The TVCs are computed during the iterations. (An example is given below.)

The specifications which may be used are as follows:

TVC = *expression*,
TVC = Log(*expression*) - natural log,
TVC = Exp(*expression*) - e raised to the power,
TVC = Abs(*expression*) - absolute value.

Expressions are any algebraic function of the data and 'time' (see below) with the following restrictions:

- Expressions may not contain parentheses except for the special notation described below.
- Expressions are evaluated strictly from left to right, with multiplication, division, and the other operators described below taking precedence over addition and subtraction.

The basic operators which may be used in the expression are +, -, *, /, and ^. (The last means raise to the following power). Operands in the expressions may be any variable in the data set, whether in the model elsewhere or not, or any scalar, either given explicitly, i.e., 3.14159265, or in a scalar referred to by name, such as *pi* (also 3.14159265) or *myown* (which you would have calculated earlier). Before describing the entry of time into the expression, we note an important aspect of the computational rule. The left to right rule will only depart from the obvious when the '^' operator is used. When calculated in this fashion,

$$x \wedge 2 * y = x^2 y,$$

but

$$y * x \wedge 2 = (xy)^2 = x^2 y^2$$

because in the second case, $y * x$ is calculated first. For other operations, the rules of arithmetic apply. Thus,

$$TVC = x * y + z * w * r / c + 1.1 / var$$

is evaluated exactly as it appears. You may not have analytic functions (such as log(.) or cos(.)) of the variables directly in the expression. If you need them, just use **CREATE** to produce them beforehand, then use the created variables in the expression.

Time is entered into the expression by using the name, enclosed in parentheses. As described below, you can use any calculable function of time in the expression. For the simplest case, note that '*time*,' itself is the Lhs variable in the model. A model with a TVC defined as $z(time) = z_1 * time$ might appear as follows:

```
SURVIVAL   ; Lhs = time ; Rhs = x1,x2
           ; TVC = z1 * (time) $
```

Be sure to remember the parentheses! The variable *time*, which is fixed for each observation (at its respective value) is a valid variable in this expression. It is only by including the parentheses in the expression that you insure that $z_i(t)$ is computed as a function of time as it varies and not time for the ith individual. That is, as the partial likelihood is evaluated, at each observation, '(time)' is the value of '*time*' that applies for the specific value for which the risk set is being defined. Recall the partial likelihood is computed over the K distinct exit times in the N observations, t_i , $i = 1,...,K$. With a TVC, $z_i(t)$, the partial likelihood becomes

$$\log L = \sum_{j=1}^{K} \boldsymbol{\beta}'\mathbf{x}_j + \gamma z_j(t) - \log\left[\sum_{i \in R_j} \exp(\boldsymbol{\beta}'\mathbf{x}_i + \gamma z_i(t))\right].$$

You can also enter any function of time by computing the variable using the **CREATE** command to obtain the function of time you want. (*LIMDEP* will keep track and use the correct values in computing $z_i(t)$.) For example, suppose instead of time itself, you wish to use

$$z_i(t) \;=\; z_{1i} \times \exp(-0.01\times time)$$

for the effect of a covariate whose influence fades over time. The commands could be

```
CREATE      ; time1 = Exp(-.01 * time) $
SURVIVAL    ; Lhs = time ; Rhs = x1,x2
            ; TVC = x1 * (time1) $
```

There are several other operations which can be used. These are all of the form

$$result \;=\; x \text{ operator } y,$$

where x, because of the left to right rule, may already be a function of one or more other variables. The operations are:

$x\ @\ y = e^{xy}$,

$x\ !\ y \;= \max(x,y)$ [note, $x!y!w... = \max(x,y,w...)$],

$x\ \#\ y \;= \min(x,y)$,

$x\ \&\ y \;= 1$ if $x > y$ and 0 else,

$x\ \%\ y = \max(x\text{-}y,0)$ (useful for splines),

$x\ \_\ y \;= \min(x\text{-}y,0)$.

The first of these would allow you to specify the TVC shown in the earlier example without having to create it. We could have used

$$z(i,t) \;=\; z_1 * \exp(-.01\times time) = -.01\ @\ (time) * z_1.$$

(Because of the left to right rule, z_1 must appear last, not first.)

With the dummy variable operator, '&,' you have some limited capability for 'time *varying* covariates,' that is covariates that vary, perhaps discretely, over time. For example, consider creating the variable

$$z(i,t) \;=\; age \text{ if } t > T \text{ and 0 otherwise},$$

where T is some threshold. You could obtain this with

; TVC = (time) & t * age

The other logical operators, '%' and '_' give some additional possibilities, but they are fairly limited. In particular, although this allows discrete jumps at points in time, it cannot be computed for the specific individual; it is computed as the same function of time for all individuals. Once again, direct handling of true time varying covariates is accomplished with the parametric models described in the next chapter.

You may also add an 'IF' sort of construction to the TVC specification. The syntax of the conditional TVC specification is

; TVC = alternative value: [condition] expression

where:

'*expression*' is exactly as shown above.

'*alternate value*:' (with its trailing colon) is the value to give the TVC if the condition is false. This is optional. If you do not provide this, the TVC equals zero if the condition is false.

'[*condition*]' (enclosed in brackets) is a logical condition which is evaluated to determine whether or not to set the TVC equal to the value of the expression.

The alternate value may be any of:

- a number, e.g., 1.234,
- a calculator scalar, e.g., *rho*,
- any variable existing in the data set, in which case the value for that individual is used,
- functions of (*time*) enclosed in parentheses to indicate that this is the value obtained as we move through the risk set for this observation.

The [condition] is a logical expression of the form

entity relation entity +/& entity relation entity ...

Entities may be any of those listed above. Relations are >, >=, <, <=, =, and #. Use '+' for 'OR' and '&' for 'AND.' This may be as involved as you like, but the compiler will run out of space if the number of operations (relation or +/&) exceeds 10 in any TVC. For examples:

Set TVC = 1 if (*time*) is greater than or equal *warranty* and 0 otherwise.

; TVC = [(time) >= warranty] 1

Set TVC = (*time*) if (*time*) is less than *warranty*, and exp(-.01(*time*)) otherwise.

; TVC = (time) : [(time) >= warranty] -.01@ (time)

Set TVC = 1 if (*time*) >= 12 and (*time*) < *age* or if (*time*) < *retire*, and 0 otherwise.

; TVC = [(time) >= 12 & (time) < age + (time) < retire] 1

An error occurs and estimation is halted if a TVC cannot be calculated for any observation. For example, '(*time*)@1' = exp(time) will cause an overflow error if (*time*) exceeds 308. The observation and sequence number of the TVC are given at the point at which the error occurs. It is not possible to anticipate such conditions; they will only be found during estimation.

E59.2.5 Stratification

The sample may be stratified with separate baseline hazard functions for each stratum by specifying a stratification variable. This is done as follows:

; Str = stratification variable

It is assumed that this variable is coded 1,2,3,... The expanded specification given below can be used if some other scheme is desired. But, it is important to be sure that this variable does not contain zeros. Instead of stratifying on the values of a variable, you might wish to stratify based on limit values. Specify the variable as above and add the **; Limits** specification as shown below. For example, suppose the stratification is based on weight, with separate strata for the following classes:

1 = weight # 150 pounds,
2 = 150 < weight # 200,
3 = weight > 200.

We use

```
SURVIVAL    ; Lhs = time ; Rhs = ...
            ; Str = weight
            ; Limits = 150,200 $
```

Note that only two limits need to be specified. The number of strata will be one more than the number of limits you give since you need not give the extreme end values. The strata in this formulation are always defined as 'greater than lower limit and less than or equal to upper limit.' The low end of the first class is always negative infinity, and the highest limit is plus infinity.

E59.2.6 Cox Model with Fixed Effects

Suppose the data can be divided into G groups, possibly strata, for example. The model for stratification assumes that the model is the same in all strata, but the risk set and partial likelihood are recomputed for each stratum. A type of fixed effects model would allow variation of the model itself across the groups. A fixed effects approach, for example would be

$$\text{Prob(exit at time } T_j) = \frac{\exp(\boldsymbol{\beta}'\mathbf{x}_j + \alpha_g d_{j,g})}{\sum_{i \in R_j} \exp(\boldsymbol{\beta}'\mathbf{x}_i + \alpha_g d_{i,g})}$$

Thus, the probabilities shift based on which group the individual is in. But, the risk set is computed as usual as if there were no stratification. This model assumes that the baseline hazard is

$$h_g(t_i,0) = \gamma_g h(t_i,0)$$

where $\gamma_i = \exp(\alpha_i)$. Since the baseline hazards are not estimated, their scale is unknown. As such, the individual group effects must be normalized, which we do by setting $\alpha_G = 0$. After estimation,

$$\gamma_g = \exp(\alpha_g) \;/\; \Sigma_g \exp(\alpha_g).$$

The model with stratification and the one with fixed effects differ in the treatment of the grouping in the data. The log likelihood, neglecting ties, for the stratification case is

$$\log L = \sum_{s=strata} \left\{ \sum_{j=1}^{K_s} \boldsymbol{\beta}'\mathbf{x}_{j,s} - \log\left[\sum_{i \in R_{j,s}} \exp(\boldsymbol{\beta}'\mathbf{x}_{i,s})\right]\right\}.$$

For the fixed effects case, it is

$$\log L = \sum_{s=strata} \sum_{j=1}^{K_s} \boldsymbol{\beta}'\mathbf{x}_{js} + \gamma_s d_{js} - \log\left[\sum_{i \in R_j} \exp(\boldsymbol{\beta}'\mathbf{x}_{i,s} + \gamma_s d_{is})\right].$$

The risk set in the stratification case is composed only of the individuals in the stratum. In the fixed effects case, the risk set is composed of the entire sample.

To request this estimator, it is necessary to have a group variable, which will appear exactly the same as a stratification variable. Then,

```
SURVIVAL    ; Lhs = duration ; Rhs = the desired variables
            ; Str = the group variable ; Fixed Effects $
```

This estimator is limited to 150 - K groups. The parameters are estimated by creating the dummy variables and augmenting the model. An example appears below.

E59.2.7 Output from the Proportional Hazards Model

Initial output from this estimator contains a tally of the number of observations, number of distinct exit times, number of censored observations, and number of observations which exited (were not censored). If any TVCs have been specified, the specification is echoed in the initial output.

After the iterations end, the report includes the partial log likelihood and the value of the partial log likelihood evaluated at the starting values. If you do not provide starting values, these are zero. A chi squared test of the hypothesis that the coefficients equal the starting values is given next. The log-rank test is a Lagrange multiplier test of the same hypothesis. Tabulated output includes estimates, standard errors and descriptive statistics for the regressors.

A listing of the estimates of 10 points from the survival distribution and integrated hazard function is given. Finally, the estimated survival function and integrated hazard (negative log-survival) function are plotted at the means of the regressors and at any additional points that you have specified.

Results saved automatically by this procedure are only scalar *logl*, matrices *b* and *varb*, and *Last Model* labels *b_variables*. If your model included TVCs, the additional labels would be *tvc*1, *tvc*2, ...

E59.2.8 Applications of the Proportional Hazards Model

To illustrate the technique, we apply Cox's proportional hazard model to the data used in the previous chapter.

```
READ        ; Nobs = 22 ; Nvar = 4
            ; Names = time,status,sex,married ; By Variables $

  11  3 19 32 2 14 8 21 16 5 2 8 14 18 18 21 10 1 9 23 19 7
   1  1  0  1 1  1 1  1  0 1 1 1  1  1  1  1  0 1 0  1  1 1
   0  0  1  0 1  0 1  1  1 0 0 1  1  0  1  1  0 0 1  1  0 1
   1  1  2  2 1  1 1  1  2 2 2 1  1  1  2  1  2 2 1  1  2 1
```

This sets up a matrix for plotting the survival function. The matrix command loads two rows in the matrix, so there will be two additional plots of the survival function. The models have censoring, stratification, a fixed coefficient, and a time varying covariate, respectively.

```
MATRIX      ; mf = [0 / 1] $
SURVIVAL    ; Lhs = time,status ; Rhs = sex ; Plot = MF $
SURVIVAL    ; Lhs = time,status ; Rhs = sex ; Str = married $
SURVIVAL    ; Lhs = time,status ; Rhs = sex,married ; Rst = b1 , 0.01 $
SURVIVAL    ; Lhs = time,status ; Rhs = married ; TVC = -.1*(time)*sex $
```

E59.2.9 Cox Model with Time Varying Covariates

The Cox proportional hazard (semiparametric) model may be modified to allow time varying covariates. In order to construct this form, the estimator requires one record of data for each interval within which the covariates are constant, and T records in total for each person, if covariates change T - 1 times (altogether – more than one covariate may be changing). The command changes as follows:

SURVIVAL ; Lhs = time
; Rhs = the list of covariates
; Entry = a variable which gives t0, the time of the beginning of the interval
; Pds = the number of records $

The interval described by a particular data record are interval (*t*0 to *t*1) measured by *T* to *time*, i.e., 'entry' to 'Lhs.' Note that in records after the first, *t*0 will be *time* on the previous record. All records but the last are treated as censored. The last may be also, in which you would also include a censoring indicator as a second Lhs variable, as usual. Note, also, that this is the same setup that is currently used in the TVC versions of the parametric survival models. Other options available with this estimator include all previous features, as well as

; Robust to request the sandwich estimator
; Cluster = ... specification
; Wts = a weighting variable

The Cox model also now creates a matrix named *cox_bsln* with five columns containing

1. exit times,
2. baseline survival rates,
3. hazard functions,
4. cumulative hazard functions,
5. integrated hazard function = -log(survival function).

The Cox model may be fit with group 'fixed effects' by specifying

; Str = the group identifier
; Fixed Effects

(In other treatments, this is labeled a 'frailty' model. That is probably not appropriate here, as the usual random effects 'frailty model' is not identified in this context.) With this option in use, the estimated effects are renormalized to have mean 1.0 while the variance is left unrestricted.

The output results reported for this model may be modified to include 'hazard ratios,' which are, for a specific coefficient b_k, equal to exp(b_k). Add

; Hazard Ratios

to the command to request this treatment.

E59.3 The Ordered Extreme Value Model

Han and Hausman (1988) have devised a semiparametric estimator for the proportional hazards model. They cite three virtues:

1. It is suited to discrete data.
2. It is unhindered by large numbers of ties.
3. It circumvents problems associated with heterogeneity.

In addition, they argue that an advantage of the technique is that the parameters of the covariates are invariant to the length of time intervals chosen. As such, the grid of intervals, which need not be of equal length, can be made finer as the sample size increases.

The hazard rate is

$$\lambda_i(\tau) = \lim_{\Delta \to 0} \frac{\text{Prob}[\tau < t_i < \tau + \Delta]}{\Delta} = \lambda_0 \exp(\boldsymbol{\beta}'\mathbf{x}_i)\ .$$

They specify this as

$$\log \int_0^{t_i} \lambda_0(\tau)d\tau = \boldsymbol{\beta}'\mathbf{x}_\text{i} + \varepsilon_\text{i},$$

where $F(\varepsilon_i) = \exp(-\exp(-\varepsilon_i))$ (extreme value, or Gompertz).

Let $\log \int_0^{t} \lambda_0(\tau)d\tau = R_t,\ t = 1,...,T.$

The probability of failure in period t by individual i is

$$\text{Prob}[T_{t\text{-}1} < t_i < T_t] = \int_{l_{t-1}-\boldsymbol{\beta}'\mathbf{x}_i}^{l_t-\boldsymbol{\beta}'\mathbf{x}_i} f(\varepsilon)d\varepsilon\ .$$

The logs of the integrated baseline hazards, R_t are treated as unknown parameters. (The authors observe that Cox's proportional hazard model treats them as nuisance parameters and conditions them out of the likelihood function.) Let $y_i = t - 1$ if t_i falls in interval t. Then, the probability defined above, with the extreme value distribution for ε, defines exactly the ordered probability model described in Chapter E58 with an extreme value (Gompertz) probability model. The ls in the present context would be the μs in the ordered probability model discussed previously.

To estimate this model, therefore, it is necessary only to code the dependent variable appropriately and submit it with the **ORDERED PROBABILITY** (or just **ORDERED**) command. The data are assumed to be generated as observations on duration in intervals

$$t = \begin{matrix} 0 & T_1 & T_2 & T_3 & \cdots & T_J \\ 0 & 1 & 2 & 3 & \cdots & J \end{matrix}$$

The lower row shows the values taken by what will be the Lhs variable in the model. The *time* variable in the data must be recoded to conform to the preceding layout. **RECODE** may be used if necessary. The threshold values μ_0, μ_1, ... are then interpreted as the logs of the integrated baseline hazard functions. This may be estimated as an ordinary ordered Gompertz model, with up to 50 values (J = 49) taken by the Lhs variable. At the end of the estimation, *LIMDEP* computes estimates of the hazard rate at the means of the regressors by the computation

$$h(t) = \text{Prob}[t_j < t < t_j{+}1] \,/\, \text{Prob}(t \geq t_j).$$

This is computed by using the predicted cell probabilities for the ordered logit model at the means of the covariates. These probabilities are divided by the interval width if values are provided that allow these to be calculated.

The model command is simply

```
ORDERED     ; Lhs = ...
            ; Rhs = ...
            ; Hazard
            ; Model = Gompertz $
```

By this formulation, the intervals are assumed to be one period in length. The specification

; Endpoints = $\mathbf{T_1,T_2,...,T_J}$

can be used to provide the interior endpoints of the intervals. The authors discuss using the ordered probit model instead of the Gompertz model. This is a bit ambiguous, however. Nonetheless, the hazard rates are computed using whichever distribution has been used to fit the model.

If desired, the Rhs may contain only a constant term, *one*. That is, it is not necessary to have covariates in the model. This produces a semiparametric alternative to the Kaplan-Meier estimator of the previous chapter. The program first estimates the ordered probability model. All results saved are the same as the ordered probability model discussed earlier, except that the matrix *mu* which is normally saved for the ordered Gompertz model is now replaced with a matrix named *hazard* which contains the estimated hazard rates. There is one hazard rate computed for each interval. The last one is assumed to be the same as the second to last one. Suppose your dependent variable takes values 0,1,...,7. This is eight values, and eight hazard rates will be computed. You can then plot the hazard rates against the left endpoints of the intervals, which can be defined separately. An example is given below.

Application

We apply Han and Hausman's technique to the Kennan strike data used earlier. Since there are no covariates, the estimated hazard function compares directly to the one computed earlier.

```

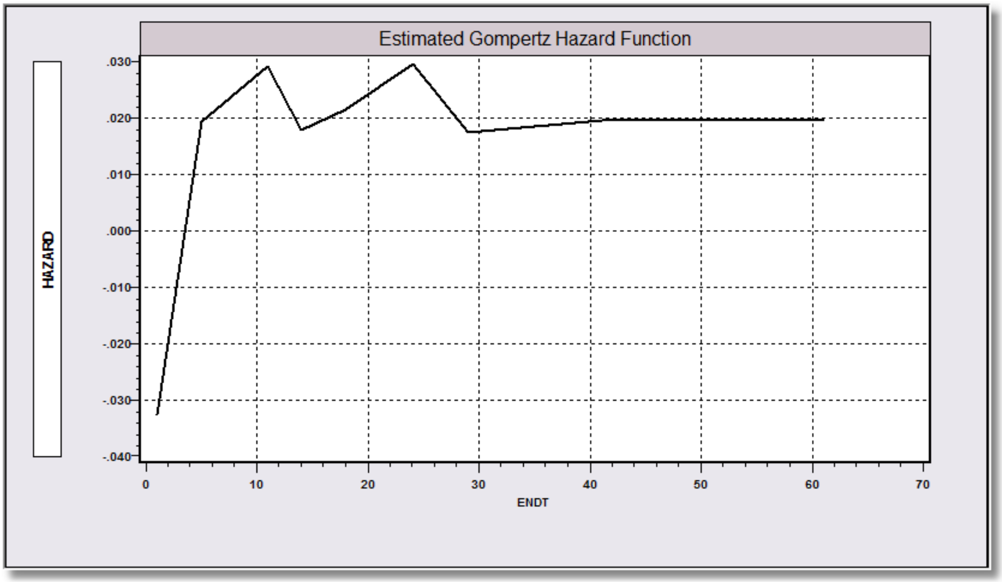

Figure E59.4 Han-Hausman Estimated Gompertz Hazard Function

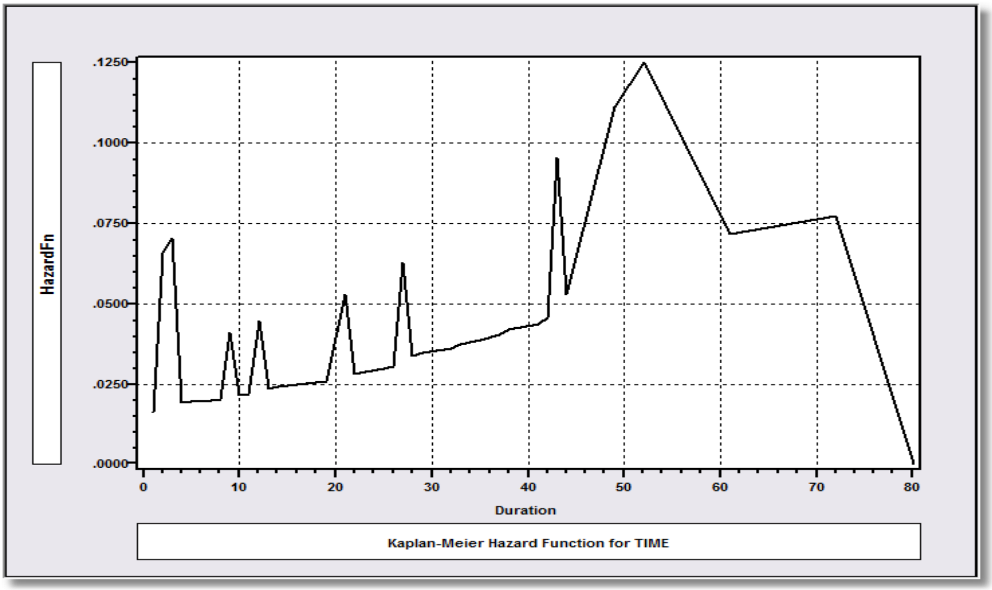

Figure E59.5 Kaplan-Meier Estimated Hazard Function

E60: Parametric Models for Duration

E60.1 Introduction

The models discussed in this chapter embody specific assumptions about the distribution of duration or failure times. *LIMDEP* includes many of the models which have been proposed in the literature. (See, e.g., Kalbfleisch and Prentice (1980), Lancaster (1990) and Cox and Oakes (1984).) This chapter presents a large number of variations of the models. The choice among the various models is sometimes made on the basis of the shape of the hazard function. As shown below, this can vary widely. In order to arrange the material in a convenient fashion, the basic formulations are first presented in full. Some of the more esoteric extensions are collected in later sections. We begin with basic models for duration, without covariates or heterogeneity. Later sections will extend the models.

The essential model command for estimating parametric survival models is

SURVIVAL ; Lhs = log of time variable [, censoring indicator (optional)]
; Rhs = covariates
; Model = type $

Type is one of Weibull, exponential, normal, loglogistic, inverse Gaussian, gamma, F, or Gompertz. Plots of hazard functions, integrated hazards and survival functions may also be requested. 'Residuals' in this model are the integrated hazard function. 'Fitted values' are the estimated hazard function values. Other specifications which may each (alone) modify the basic model include: latent heterogeneity in the location of the distribution, time varying covariates, panel data estimators, (fixed effects, random effects, random parameters, and latent class), split population models, truncation, variance heterogeneity, and sample selection. These extensions are treated in Chapter E61.

E60.2 Parametric Models for Survival Data

We denote by '*t*' the nonnegative random variable 'time until transition' (using Lancaster's term). In many familiar applications, *t* is time until failure, which produces the term 'failure time models.' But, other applications, for example, strike duration, involve time until recovery from a disease, elapsed time until a merger takes place or length of a spell of unemployment. In each of these, Lancaster's term seems more appropriate than 'failure time' so we will use this.

Parametric models may be defined in terms of the density, $f(t)$, the survival function, $S(t)$ = Prob[$T \geq t$], or the hazard function, $h(t) = f(t)/S(t)$. Note that $f(t) = -\text{d}S(t)/\text{d}t$ and $h(t) = -\text{dlog}S(t)/\text{d}t$. In *LIMDEP*'s set of specifications, each model is characterized, at minimum, by a positive location or rate parameter, λ, and a positive scale parameter, p. The parametric distributions supported by this program in *LIMDEP* are listed in Table E60.1.

The survival function for the gamma model must be written in implicit form because of the incomplete gamma integral. The hazard rate is likewise complicated. Note that the gamma model is an encompassing model for the Weibull and exponential models. If θ equals one, the Weibull model results. If θ and p both equal one, the exponential model results. As described below, the generalized *F* model is even more broad, as it encompasses all the above save for the Gompertz and inverse Gaussian models.

Authors differ on how useful the parametric models are. All assume a specific functional form, which is not necessarily good. On the other hand, all save for the exponential model allow for both positive and negative duration dependence, and all are fairly flexible functional forms. Moreover, some of the options discussed below, such as variance heterogeneity, latent heterogeneity and the presence of covariates, allow you a large amount of room to accommodate different patterns in the data that cannot be accommodated with the semiparametric or Kaplan-Meier approaches.

Distribution	**Density and Survival**	**Hazard Function**
exponential	$\lambda\exp(-\lambda t)$ $\exp(-\lambda t)$	λ
Weibull	$\lambda p(\lambda t)^{p-1}\exp[-(\lambda t)^p]$ $\exp[-(\lambda t)^p]$	$\lambda p(\lambda t)^{p-1}$
lognormal	$[p/(\lambda t)]\phi(-p\log(\lambda t))$ $\Phi(-p\log(\lambda t))$	$\phi(-p\log(\lambda t))/\Phi(-p\log(\lambda t))$
loglogistic	$\dfrac{\lambda p(\lambda t)^{p-1}}{[1+(\lambda t)^p]^2}$ $\dfrac{1}{[1+(\lambda t)^p]}$	$\dfrac{\lambda p(\lambda t)^{p-1}}{[1+(\lambda t)^p]}$
gamma	$\dfrac{(\lambda p)(\lambda t)^{P\theta-1}}{\Gamma(\theta)}\exp(-(\lambda t)^p)$ no closed form	no closed form
Gompertz	$p\exp(\lambda t)\exp\{(-p/\lambda)[\exp(\lambda t)-1]\}$ $\exp\{(-p/\lambda)[\exp(\lambda t)-1)]\}$	$p\exp(\lambda t)$
inverse Gaussian	$\phi\left[-(\lambda t-p)/\sqrt{t}\right]\dfrac{p}{t^{1.5}}$ $\Phi\left[-(\lambda t-p)/\sqrt{t}\right](1-\exp(2\lambda p)$	$\dfrac{\phi\left[-(\lambda t-p)/\sqrt{t}\right]}{\Phi\left[-(\lambda t-p)/\sqrt{t}\right]}\dfrac{p}{t^{1.5}(1-\exp(-2\lambda p))}$
generalized F	see below	
Weibull or exponential (p = 1) with gamma heterogeneity	$\{S(t)=\exp[-(\lambda t)^p]\}$ $\left[S(t)^{\theta+1}\right]\lambda p(\lambda t)^{p-1}\left[1+\theta(\lambda t)^p\right]^{-1/\theta}$ $\left[S(t)^{\theta}\right]\lambda p(\lambda t)^{p-1}$	$S(t)\left[1+\theta(\lambda t)^p\right]^{-1/\theta}$

Table E60.1 Parametric Survival Models

E60.2.1 Loglinear Models and Estimation Strategies

For the first five models listed above, estimation is facilitated by the transformation,

$$w = (\log t - \beta) / \sigma,$$

where $\lambda = e^{-\beta}$ and $p = 1/\sigma$.

With this change of variable, the densities and survival functions for w for the five distributions are as listed in Table E60.2.

Distribution	Density	Survival Function
Weibull:	$\exp(w - e^{w})$	$\exp(-e^{w})$
exponential:	$\exp(-e^{w})$	e^{-w}
lognormal:	$\phi(w)$	$\Phi(-w)$
loglogistic:	$e^{w}(1 + e^{w})^{-2}$	$1/(1 + e^{w})$
gamma:	$\exp(\theta w - e^{w} - \log\theta)$	$1- \gamma(\theta,e^{w})$, $\gamma(\theta,t)$ = incomplete gamma integral

Table E60.2 Loglinear Survival Models for Transformed Variables

The Gompertz model, $S(t) = \exp((-p/\lambda)(e^{\lambda t}-1))$ and $h(t) = pe^{\lambda t}$, is not loglinear, so we adopt a somewhat different estimation strategy. The inverse Gaussian model is log linear, but the transformation above does not produce a convenient functional form to use for optimization. The inverse Gaussian survival model is estimated as a particular form of the general loglinear model – see Chapter E55 for details.

The generalized F model, like the inverse Gaussian model, is not easily transformed to a simple functional form. Let $z = (\lambda t)^{p}$. Assume that z has a central F distribution with degrees of freedom parameters $2M1$ and $2M2$. ($M1$ and $M2$ need not be integers.) By the change of variable technique, the density of t is

$$f(t) = [(\lambda p)(\lambda t)^{(p-1)} / \beta(M1,M2)]\,[K(t)]^{M1}\{1 + [K(t)]\}^{-(M1+M2)}$$

where $K(t) = (M1/M2)(\lambda t)^{p}$

and $\beta(M1,M2)$ = the beta function, $\Gamma(M1)\Gamma(M2)/\Gamma(M1+M2)$.

The generalized F distribution has four structural parameters, λ, $p = 1/\sigma$, $M1$ and $M2$. The other parametric models have two (λ and p; lognormal, loglogistic, Weibull, Gompertz), one (λ; exponential), three (λ, θ, p; Weibull/heterogeneity), or three (λ, p, γ; gamma), so this is more general than the other models. Also, all of those listed except the Gompertz, mixed Weibull and inverse Gaussian models are special cases of the generalized F listed in Table E60.3.

Distribution	Form of the Generalized F Distribution		
loglogistic:	$M1 = 1$	$M2 = 1$	p free
lognormal:	$M1 \to +\infty$	$M2 \to +\infty$	p free
Weibull:	$M1 = 1$	$M2 \to +\infty$	p free
exponential:	$M1 = 1$	$M2 \to +\infty$	$p = 1$
gamma:	$M1$ free	$M2 \to +\infty$	p free

Table E60.3 Special Cases of the Generalized F Distribution

The survival and hazard functions do not exist in closed form and must be approximated. The survival function is computed using the CDF of the beta distribution:

$$S(t) = \text{Bds}\,[\,1/(1+K), M2, M1]$$

from which the hazard function may then be estimated. Lancaster (1990) has analyzed this model at length. Among his results is that the generalized F is a gamma weighted mixture of gamma models, which suggests that it can be interpreted as a gamma model with latent gamma distributed heterogeneity. Other models with heterogeneity are detailed below.

E60.2.2 Covariates and Log Likelihood Functions

The effect of external covariates, $\mathbf{x}_i$ on the survival rate or the hazard function can be incorporated by writing

$$\lambda_i = e^{-\boldsymbol{\beta}'\mathbf{x}_i}.$$

(This is labeled the 'accelerated failure time' model.) The model is otherwise the same as before. After transformation, the covariates enter w_i linearly, which, once again, makes estimation relatively simple. This formulation is used in all the models listed above, including those not handled as loglinear.

We note at this point a possible inconsistency in the literature. The formulations shown above correspond to Kalbfleisch and Prentice. Elsewhere, the signs and normalizations of the parameters may be different. For example, in terms of the original models, Kiefer (1988) writes the densities and hazard rates in terms of a 'γ' which would correspond to λ^p in our models. He also reverses the signs on the coefficients in the models. With both of these changes, where we have

$$\log t_i = \boldsymbol{\beta}'\mathbf{x}_i + \sigma w_i$$

Kiefer would have

$$\log t_i = -(1/\sigma)\boldsymbol{\beta}'\mathbf{x}_i - \sigma w_i.$$

For the present, we assume that the covariates, $\mathbf{x}_i$ have been fixed for the individual from time $T = 0$ to $T = t_i$, when we make our observation. Section E60.7 generalizes these models to allow $\mathbf{x}_i$ to evolve as a step function from time zero to the time of observation.

Data on observed transition times may be complete or censored. If an observation is censored, then t_i marks the time, relative to the origin, that the observation was made, not when the transition occurred. There is a presumption, dropped in the split population model, that the transition would occur some time after time t_i (but that for certain it would occur).

For the loglinear models, the likelihood function for N observations on

$$y_i = \log t_i = \sigma w_i + \beta$$

and right censoring indicator δ_i (one for complete observations, zero for censored) is

$$L \;=\; \Pi_i[\sigma^{-1} f(w_i)]^{\delta_i}[S(w_i)]^{1-\delta_i}.$$

Note that $\log L$ may be written

$$\log L \;=\; \Sigma_i\,[\delta_i\,(-\log\sigma + \log h(w_i)) \;+\; \log S(w_i)]$$

where $\quad h_i\,(w_i) \;=\; f(w_i)/S(w_i) \;=\;$ the hazard function.

Log likelihood functions are maximized by BFGS or Newton's method. The choice is discussed below. For discussions of interpretation of the parameters and the distributions, the reader is referred to Kalbfleisch and Prentice (1980), Lancaster (1990) or to Kiefer's (1988) survey.

The log likelihood for the loglinear models is the sum of individual terms of the form

$$\log L_i \;=\; \delta_i \log[f(w_i)/\sigma] \;+\; (1 - \delta_i)\log S(w_i)$$

where $\quad w_i \;=\; (\log t_i - \boldsymbol{\beta}'\mathbf{x}_i)/\sigma.$

The derivatives are: $\quad \partial\log L_i/\partial\boldsymbol{\beta} \;=\; [\delta_i\,\partial\log f/\partial w_i + (1-\delta_i)\partial\log S/\partial w_i\,](-\mathbf{x}_i/\sigma)$

$$\partial\log L_i/\partial\sigma \;=\; [\delta_i\,\partial\log f/\partial w_i + (1-\delta_i)\partial\log \mathrm{S}/\partial w_i\,](-1/\sigma) \;-\; \delta_i/\sigma.$$

Note that $\quad \delta_i \log f(w_i) \;+\; (1 - \delta_i)\log S(w_i) \;=\; \delta_i \log h_i\,(w_i) \;+\; \log S(w_i),$

where $h(w_i)$ is the hazard function. Let the bracketed term in the derivatives be denoted A_i. It follows from the first term that $\Sigma_i\,A_i\,\mathbf{x}_i = \mathbf{0}$ at the maximum of the log likelihood for the sample. Therefore, terms involving A_i times constants not involving w_i will fall out of the second derivatives matrix at the maximum. Making use of this result (and skipping some algebra), we have, at the maximum of the log likelihood,

$$\partial^2\log L/\partial\boldsymbol{\theta}\partial\boldsymbol{\theta}' \;=\; -\Sigma_i\,[\delta_i\,\partial^2\log h/\partial w_i^{\,2} + \partial^2\log S/\partial w_i^{\,2}]\mathbf{z}_i\,\mathbf{z}_i' \;+\; \mathbf{K},$$

where $\quad \mathbf{z}_i' \;=\; (1/\sigma)[\mathbf{x}_i', -w_i\,]$

$$\boldsymbol{\theta}' \;=\; [\boldsymbol{\beta}',\sigma]$$

and $\quad \mathbf{K}_{ij} \;=\; \Sigma_i\,\delta_i/\sigma^2$

in the lower right corner and zero everywhere else. We use this matrix as the weighting matrix in Newton's method. This is, therefore, a hybrid of Newton's method and the method of scoring, since we use the exact expectation for one part of the Hessian and estimate the expectation with the mean for the rest of the terms.

What differs from model to model are the bracketed terms in the second derivatives. For the four models for which this procedure is available, these terms denoted by C_i are listed in Table E60.4.

Model	Second Derivative
Weibull and exponential:	$C_i \;=\; \mathrm{e}^{\,w_i},$
loglogistic:	$C_i \;=\; [S(w_i)]^2(1 + \delta_i)\mathrm{e}^{w_i},$
lognormal:	$C_i \;=\; [h(w_i) - \delta_i\,w_i\,][h(w_i) - w_i)] + \delta_i\,.$

Table E60.4 Second Derivatives

The remaining models, mixed Weibull, gamma, generalized F, Gompertz and inverse Gaussian models are estimated using the original log likelihood in terms of observed t_i rather than log t_i. The log likelihood takes the same general form as for the loglinear models. For these cases, the BHHH method is used to estimate the asymptotic covariance matrix of the MLE.

E60.3 Commands for Parametric Duration Models

The model command is

SURVIVAL **; Lhs = logt,delta** (delta is optional and may be omitted)
; Rhs = one
; Model = Weibull $

Weibull may be replaced by **Loglogistic, Exponential, Normal, Gamma, InverseGauss** or **F**. To add additional covariates, simply add them to the Rhs list. (There is no default model. If you do not specify a particular model, the estimator reverts to the Cox model discussed in Chapter E59.) The censoring indicator, *delta*, is optional. The censoring indicator is set up as noted earlier, taking values one for complete observations, zero for censored.

NOTE: The Lhs variable in all models except the Gompertz model is the log of time. You must **CREATE** and use log time for the Lhs variable. The command, itself, may compute the log, as in **; Lhs = log(time)**.

When there are covariates on the Rhs, β in the preceding becomes $\boldsymbol{\beta}'\mathbf{x}$ where $\mathbf{x}$ is the covariate vector, including *one*. The first set of maximum likelihood estimates given is the complete parameter vector, $[\boldsymbol{\beta}',\sigma]$. Since λ now depends on $\mathbf{x}$ $[\lambda=\exp(-\boldsymbol{\beta}'\mathbf{x})]$, we compute it at the means of the variables. This value of λ, p (which is $1/\sigma$), and the median and several percentiles of this distribution are also displayed.

'Predictions' for survival models are computed as follows:

; List requests a listing of

- actual observation on t_i (not logt_i)
- prediction of $t_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$ (Note, in general this is neither the mean nor the median.)
- generalized residual = integrated hazard = $-\log S(t_i)$
- hazard function
- survival function

The survival probabilities or hazard rates may also be retained as new variables in the data set by including

; Keep = name to retain the hazard function

and **; Res = name** to retain the integrated hazard rate.

The preceding provide generic model forms that can be used for the exponential, Weibull, loglogistic, lognormal and inverse Gaussian models. The gamma, Gompertz and generalized F models require specific forms of the model commands. These are given below in Section E60.6.

Standard Model Specifications for the Parametric Duration Models

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps ancillary parameter σ with main parameter $\boldsymbol{\beta}$ vector in *b*.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

; Cluster = spec requests computation of the cluster form of corrected covariance estimator.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

You may provide your own starting values for the models if you wish. In all cases, the values you provide are parameters = $-\boldsymbol{\beta}$, σ. You may also impose fixed value and equality restrictions with

; Rst = list...

In the exponential model, σ equals one, so you should not include it in the list. Note that during estimation, *LIMDEP* is using the negative of the parameter vector during the iterations.

E60.4 Results for Parametric Models

Ordinary least squares is used to obtain the starting values. The iterations follow, then the maximum likelihood estimates are displayed. The estimates presented first are β and σ. In a subsequent table, estimates of λ, *p*, the median of the distribution, and four percentiles (.25, .50, .75, and .95) of the distribution of time (not log time) with these values of λ and *p* are listed. These are computed at the sample mean values of the covariates.

The CDFs of all models given above save the gamma and inverse Gaussian can be inverted (the lognormal distribution requires an approximation) to obtain percentiles of the distributions. In particular, where α is the probability of surviving to time *t* or longer, these are given in Table E60.5.

Model	Inverse CDF
Weibull	$t = [(-\log\alpha)^{1/p}]/\lambda$
Gompertz	$t = [\log(1.0 - \lambda\log\alpha)/p)]/\lambda$
lognormal	$t = \exp(-\Phi^{-1}(\alpha)/p)]/\lambda$
loglogistic	$t = [((1.0 - \alpha)/\alpha)^{1/p}]/\lambda$
exponential	$t = [-\log\alpha]/\lambda$

Table E60.5 Inverse CDF

The median of the gamma distribution is obtained by inverting the corresponding chi squared distribution (with noninteger degrees of freedom parameters). The median of each distribution above is obtained by setting $\alpha = .5$. This estimate is presented with an estimate of its asymptotic standard error with the earlier estimates of λ and p. The displayed results contains the values of *t* corresponding to $\alpha = .25$, .50, .75, and .95.

When you estimate any of the parametric survival models (Weibull, loglogistic, Gompertz, exponential, normal, inverse Gaussian or F), plots of the survival function, hazard function, and integrated hazard function can be produced by adding the following to your command,

; Plot

Results saved by the loglinear models are:

Matrices: *b* and *varb* contain the estimate of β and the asymptotic covariance matrix. **; Par** adds the ancillary parameters, σ, and for the gamma model, θ to *b* and *varb*.

Scalars: $s = \sigma$,
ybar and *sy* are descriptive statistics for $\log t_i$,
kreg and *nreg* give the dimensions of the estimation problem,
logl contains the log likelihood,
theta is the value of γ for the gamma model, θ for the heterogeneity models.

Last Model: *b_variables* and *sigma*.

Last Function: None

E60.5 Applications

We will illustrate several of the parametric models with Kennan's strike data. These are reported in Greene (2011). The two variables are *t* = duration in days of major strikes in several years and *prod*, a measure of 'unexpected' output in the economy in that year. Note that *prod* is the same for all observations in a given year. The data are listed in Table E60.6.

t	*prod*	*t*	*prod*

In order to compare the various models, one can examine the coefficients, log likelihoods, and various diagnostic statistics. A tool which can be used to diagnose model adequacy is the integrated hazard function, $ih(t)$ = -log$S(t)$ where $S(t)$ is the survival function. Under the hypothesis that the model specification is correct, the integrated hazard function should be a straight line emanating from the origin. Departures from this might signal model misspecification. For example, the figures below are produced by adding **; Plot** to the Weibull and inverse Gaussian models: The curvature of the integrated hazard for the inverse Gaussian model suggests (slightly) that the Weibull might be the preferred model.

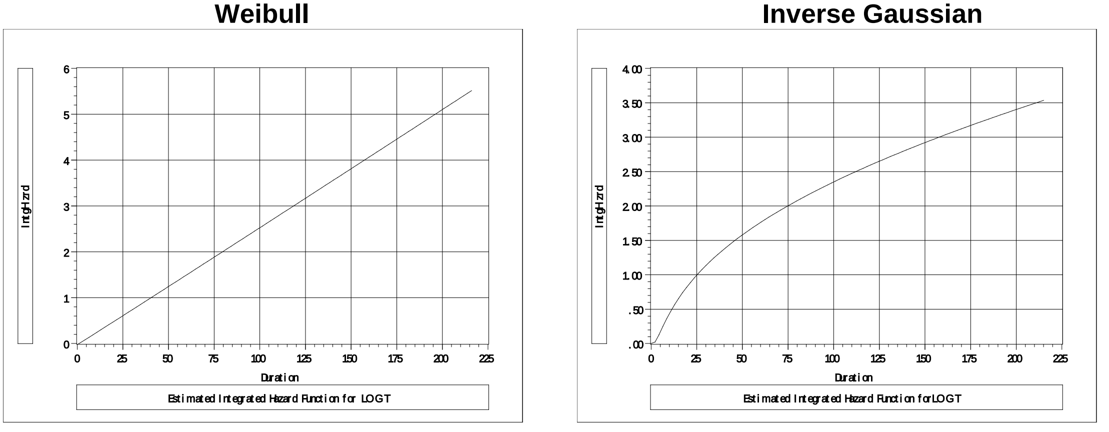

Figure E60.1 Comparison of Weibull and Inverse Gaussian Models

To examine the effect of censoring, we modify the data by censoring observations at T = 80. The results produced earlier with the uncensored data are repeated.

```
CREATE      ; ct = 80 ~ t ; d = (ct = 80) $

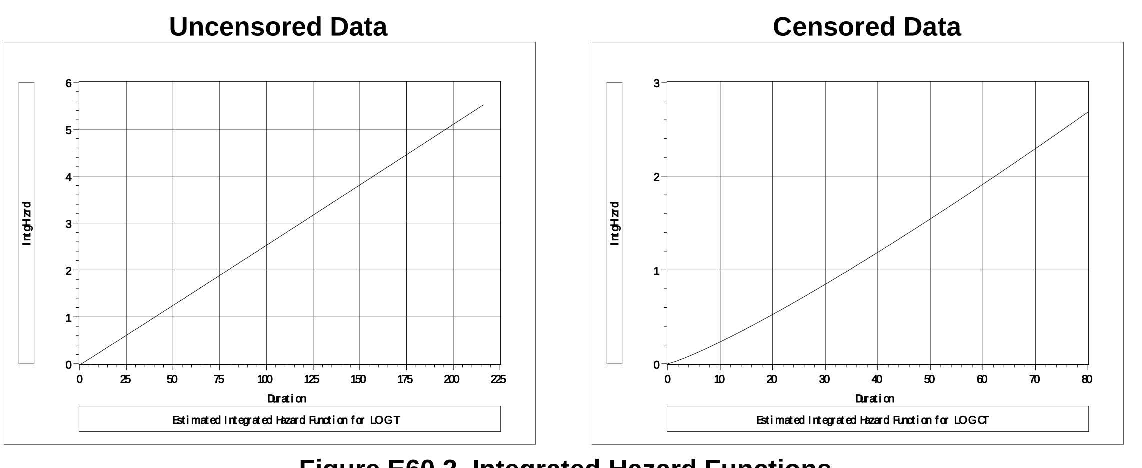

Figure E60.2 Integrated Hazard Functions

E60.6 Gamma, Gompertz and Generalized F Models

These three models generally require additional information specific to the model to set up the estimation command. The Gompertz model can be estimated using more than one procedure. Owing to the complexity of the model, a specific application may require use of different procedures to obtain a result.

E60.6.1 Estimating the Gamma Model

The gamma model must be treated differently from the other models. The parameter θ cannot be easily estimated simultaneously with the other parameters because of the difficulty of computing the derivative of the log likelihood. One method of estimation is to search over θ. You can provide the value of θ at the time the command is requested, as follows:

SURVIVAL ; Lhs = ... ; Rhs = ... ; Model = Gamma ; Theta = value $

Even though θ is supplied by you rather than searched for by the iterative algorithm, it is still treated as an unknown parameter. *LIMDEP* will compute an estimated standard error for the estimate of θ and factor this variance into the estimated covariance matrix for the other parameter estimates. I.e., it treats it just like the other parameters. Unlike the other parameters, though, we use a first difference approximation to estimate the derivative of the log likelihood with respect to θ.

You may specify that θ is to be treated as fixed in the preceding and not allow its variance to be factored into the estimated asymptotic covariance matrix. This will nearly always result in the remaining estimated standard errors being smaller than when θ is treated as having been estimated. To request this, add

; Fix

to the command. The output will clearly show the constraint.

Three alternative formulations may also be specified for the gamma model:

1. To fix σ at some value and allow θ to be freely estimated instead, use

   NAMELIST ; x = the set of Rhs variables $
   CALC ; k = Col(x) $
   SURVIVAL ; Lhs = ... ; Rhs = x ; Model = Gamma
   ; Rst = k_b, value for sigma, tt $

2. To fix both σ and θ, use the same as above, but instead of the free label *tt* above, insert the desired fixed value.

Experience suggests that estimation of the gamma model with one or both of the parameters fixed is fairly routine. The third approach is to allow both σ and θ to vary freely, and be estimated as free parameters. To request this, simply use

SURVIVAL ; Lhs = ... ; Rhs = ... ; Model = Gamma $

To continue, our experience with some carefully constructed data sets suggests that the model with free σ and θ is quite difficult to estimate. We found in most cases that θ and the slope parameters wandered off to extreme values, and ultimately, it was not possible to obtain convergence of the estimator. (It is quite well behaved with our sample data, however.)

A number of options discussed below are unavailable for the gamma model:

- truncation
- splitting model
- gamma heterogeneity
- time varying covariates

The following show several formulations of the gamma model. For the data analyzed here, the unrestricted model turns out to be fairly easily estimated.

SURVIVAL ; Lhs = logt ; Rhs = one,prod ; Model = Gamma $
SURVIVAL ; Lhs = logt ; Rhs = one,prod ; Model = Gamma ; Theta = .5 $
SURVIVAL ; Lhs = logt ; Rhs = one,prod ; Model = Gamma ; Theta = 1.5 $

E60.6.2 Estimating the Gompertz Model

Estimation of λ and p for a (possibly censored) set of observations on t = time is done as follows:

SURVIVAL ; Lhs = t[,status] ; Model = Gompertz $

The status variable is optional. Note that there are no covariates. Starting values for the parameters are obtained from the Kaplan-Meier estimates of the hazard function, based on

$$\log h_t = \log p + \lambda t.$$

We use the least squares coefficients in the regression of the estimated hazards on a constant and '*t*.' The log of the hazard, which has been tabulated for 10 or more values of t, is, theoretically, linear in t. Then, λ and p are estimated directly by maximum likelihood. They and the estimated median of the distribution are presented with standard errors. Several percentiles of the distribution are also presented. A listing by observation of time, the survival rate, density of the distribution, and hazard rate is obtained by adding

; List

to the model command.

NOTE: The input (Lhs) variable is *time* for this model, not log(*time*).

When the Gompertz model is estimated with covariates, you must provide starting values. They are optional with the other models. It is difficult to obtain good starting values for this model – it depends partly on the data. Here are two strategies:

1. Use the procedure described above to fit the model without the covariates. Then, use **; Start = *** in your later command to specify the starting values for the expanded model. This will result in an initial assumption of zero for all coefficients but the constant term. Thus, for example,

   SURVIVAL ; Lhs = time ; Model = Gompertz $
   SURVIVAL ; Lhs = time ; Rhs = one,sex
   ; Start = * ; Model = Gompertz $

2. Estimate some other functional form, such as the Weibull and use the estimates as the starting values for the Gompertz model. These will not be particularly good, but they will probably be better than zero as they will provide some information about relative sizes. If you do this, you must use the **; Par** option to make sure that an estimate of σ = 1/P gets passed as well. Thus, for example,

   SURVIVAL ; Lhs = Log(time) ; Rhs = one,sex ; Model = Weibull ; Par $
   SURVIVAL ; Lhs = time ; Rhs = one,sex ; Start = b ; Model = Gompertz $

We note, within our experience, regardless of the strategy chosen, estimate of the Gompertz model will be a challenge in most cases.

The following shows an exercise in which the Weibull and Gompertz hazard functions are compared. The **MAXIMIZE** command is used to fit the Gompertz model.

```
SAMPLE      ; 1-62 $

```

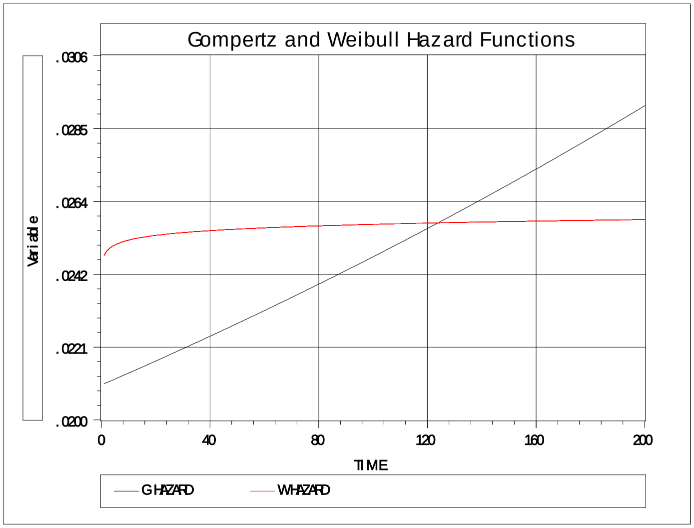

Figure E60.3 Gompertz and Weibull Hazard Functions

The hazard function for the Weibull model is essentially that of an exponential model. Since the estimated value of *p* is only 1.00786 for the Weibull model, this is to be expected.

E60.6.3 Estimating the Generalized F Model

This model is more general than the other models in the set, and may be used to help decide which is the best among the set to use as a modeling framework. The hazard function for the generalized F may display negative or positive duration dependence.

To request this model, the basic command is

```
SURVIVAL    ; Lhs  = ... as usual, including censoring if appropriate
            ; Rhs  = ... as usual
            [; Rh2= ... if the splitting model is desired (with the other
                        options for the splitting model)]
            [; Hfn = ... if the variance heterogeneity model is desired]
            ; Model  = F
            ... (other options) $
```

All options for the parametric survival models are available except the time varying covariates specification. The model may be estimated with *M*1 and *M*2 fixed or free. Two available setups are as follows:

1. *ML estimation of free M*1 *and M*2. If you wish to let the optimization procedure find *M*1 and *M*2, just use the **; Model = F** form of the command exactly as shown above.

2. *Fixed M*1 *and/or M*2: The likelihood for this model is a bit ill behaved in some data sets, as *M*1 and/or *M*2 begin to wander to the values for the special cases, i.e., +∞. You can fix one or both of the two parameters using a special form of the command. To fix both *M*1 and *M*2 at particular values, use

   ; Model = F (value1, value2)

For example, **; Model = F(1,1)** produces the loglogistic distribution. This will produce conditional maximum likelihood estimates of the other parameters in the model with $M1$ and $M2$ fixed at the specific values you give. To fix just one of them, use

; Model = F (M1, value2) to fix $M2$, for example, F($M1$,2.5)
; Model = F (value1, M2) to fit $M1$, for example, F(1.25,$M2$).

The estimator computes maximum likelihood estimates of all free model parameters.

The full parameter vector in the generalized F model is, in order,

β = slope parameters in index function (mandatory),
α = slope parameters in splitting model (optional),
γ = parameters in variance heterogeneity model (optional – see Section E61.4),
$M1,M2$ = degrees of freedom parameters in F distribution (mandatory),
σ = scale (variance parameter) for duration distribution (mandatory).

You may also fix $M1$ and/or $M2$ using the **; Rst** specification. But, you should not use this unless you are constraining other parameters in the model as well. For fixing only $M1$ and/or $M2$, **; Model = F(...,...)** does the same thing, and is much simpler.

The following are special cases of *LIMDEP*'s generalized F model.

Distribution	**Form of the Generalized F Distribution**		
loglogistic:	$M1 = 1$	$M2 = 1$	σ free
lognormal:	$M1 \to +\infty$	$M2 \to +\infty$	σ free
Weibull:	$M1 = 1$	$M2 \to +\infty$	σ free
exponential:	$M1 = 1$	$M2 \to +\infty$	$\sigma = 1$
gamma:	$M1$ free	$M2 \to +\infty$	σ free

Table E60.7 Special Cases of the Generalized F Distribution

To specify the limiting forms, you can use a large value for $M1$ and/or $M2$ (or, of course, use the form directly).

For an example of the generalized F, we use Kennan's strike data with the production data used earlier. Without the censoring, the results strongly support the Weibull specification – indeed the ML results are virtually identical to the Weibull model. $M2$ wanders off to an extreme value while $M1$ moves toward one, suggesting that the Weibull model gives the highest likelihood. However, the exponential model cannot be rejected based on its log likelihood of -97.285. Note that the standard errors for the estimated parameters of the Weibull model will be inflated by the presence of $M1$ and $M2$, compared to the estimates when the Weibull model is specified explicitly. Recall, the integrated hazard function plotted earlier also suggested that a Weibull model would be appropriate.

E60.7 Time Varying Covariates

As noted earlier, we have assumed thus far that the covariates are constant from the beginning of the measurement period, $T = 0$, to the time of the measurement, $T = t_i$. There will be circumstances in which this assumption must be relaxed. For example, a model of the duration of unemployment might include marital status, and the individual's marital status might change during the spell. A second example might be job tenure, during which rank or position in the firm might have changed. This section presents a method of incorporating true *time varying covariates* in the duration model. We draw heavily on Petersen (1986a, 1986b). Petersen and we differ on the definition of time varying as opposed to time dependent covariates. We use the latter to denote covariates which are written as explicit functions of time. We use the term *time varying covariates* to denote what he calls time dependent covariates.

Following Petersen, we formulate the model as follows: Let the interval 0 to t_i be divided into k exhaustive, nonoverlapping intervals, $t_0 < t_1 < ... < t_{k-1} < t_k$, where $t_0 = 0$ and $t_k = t_i$. The covariates are assumed to stay constant within each of the k intervals, but may change from one interval to the next. Let

$$h(t|\mathbf{x}_j) \; = \; \text{hazard function from time } t_{j-1} \text{ to } t_j,$$

since within that interval, the covariates are constant. We deviate slightly from Petersen's notation. His formulation includes both time varying covariates, denoted $\mathbf{x}(t)$ and time dependent covariates, $z(t)$. The models considered here allow only the former. Then, from the relationship between the hazard function and the survival rate,

$$h_t \; = \; -\text{dlog}S(t)/\text{d}t,$$

and

$$\text{Prob}[T \le t_j \mid T \ge t_{j-1}] \; = \; \exp -\int_{t_{j-1}}^{t_j} h(s \mid \mathbf{x}_j)\text{d}s.$$

The survival function for duration of t_k or more can then be written

$$S(t_k \mid \mathbf{x}_k) \; = \; \prod_{j=1}^{k} \text{Prob}[T \ge t_j \mid T \ge t_{j-1}].$$

Finally, the density at t_k is

$$f(t_k \mid \mathbf{x}_k) \; = \; h(t_k)S(t_k).$$

The log likelihood function for one observation is

$$\log L_i \; = \; \delta_i \log h(t_k \mid \mathbf{x}_k) \; + \; \log S(t_k).$$

Thus, each observation contributes the survivor function to the log likelihood function. For noncensored observations, we add the density, evaluated at the terminal point. Therefore,

$$\log L_i \; = \; \delta_i \log h(t_k \mid \mathbf{x}_k) \; - \; \sum_{j=1}^{k} \int_{t_{j-1}}^{t_j} h(s \mid \mathbf{x}_j)\text{d}s.$$

The hazard function is modeled as a step function, with different values of the covariates through several intervals between $t = 0$ and $t = t_i$, the terminal value in the observation, at which either censoring or exit takes place. This requires one or more lines of data per observation, since the covariates must be provided for each interval observed. The number may vary by observation. For example, suppose marital status and education are the covariates in a model of duration of unemployment. For an observation i, education is constant, $E = 12$, say, for the entire observation period, but marital status changes at $t = 10$. The observation period is 0 to 24. This would require two lines of data

	t	*e*	*m*	*status*	*nperiod*
1st	10	12	0	1	2
2nd	24	12	1	1	2

The censoring status is provided for all periods, even though only the one on the last record is needed. This is requested with **; Pds = nperiod**, where *nperiod* is a variable which tells how many lines of data are needed for the observation. The model command is

```
SURVIVAL    ; Lhs = time or logtime, censoring status
            ; Rhs = covariates
            ; Pds = nperiod
            ; Model = ... as usual, along with other options $
```

The only change is the addition of **; Pds = nperiod**. Note that this is the same setup as the discrete choice model with variable numbers of choices as well as the other panel data estimators in *LIMDEP*. As discussed earlier, only the Gompertz model uses actual time, as opposed to the logarithm of time as the Lhs variable.

NOTE: The number of periods, *nperiod*, was given as a third Lhs variable in previous versions of *LIMDEP*. (You may continue to use this format if you wish.)

This formulation is available for the following models: Weibull, loglogistic, exponential, Gompertz, and Weibull with heterogeneity. The excluded models are the normal, split population, gamma, and generalized F models.

Technical Details

For the model with time varying covariates, we construct the log likelihood as the sum of terms

$$\log L_i = \delta_i \log h(t_k \mid \mathbf{x}_k) - \sum_{j=1}^{k} \int_{t_{j-1}}^{t_j} h(s \mid \mathbf{x}_j) ds.$$

where, for the present, we have reverted back to expressing time in natural units. The hazard functions for the distributions which include this feature are listed below. To construct the second term in the log likelihood, we require the indefinite integrals of these functions. The terms in the likelihood functions for these models are listed in the table below.

Model	**Hazard Function**	**Indefinite Integral**
Weibull	$(\lambda p)(\lambda t)^{p-1}$	$(\lambda t)^p$
Weibull/gamma	$(\lambda p)(\lambda t)^{p-1} / [1 + \theta(\lambda t)^p]$	$(1/\theta)\log[1 + \theta(\lambda t)^p]$
exponential/gamma	$\lambda / [1 + \theta\lambda t]$	$(1/\theta)\log[1 + \theta(\lambda t)]$
exponential	λ	λt
loglogistic	$(\lambda p)(\lambda t)^{p-1} / [1 + (\lambda t)^p]$	$\log[1 + (\lambda t)^p]$
Gompertz	pe^{λ}	$(p/\lambda)e^{\lambda t}$

Table E60.8 Characteristics of Survival Distributions

For the Gompertz model, it is more convenient to leave the distribution in its original form. Petersen (1986a, 1986b) used a modified form of nonlinear least squares to estimate the parameters. We apply the BFGS method directly to the log likelihood. Derivatives with respect to $\boldsymbol{\beta}$ and σ are obtained as follows:

$$\partial \log L_i / \partial \boldsymbol{\beta} = (\partial \log L_i / \partial \lambda_i)\lambda_i \mathbf{x}_i,$$

$$\partial \log L_i / \partial \sigma = (\partial \log L_i / \partial p)(dp/d\sigma) = (\partial \log L_i / \partial p)(-1/\sigma^2).$$

E61: Panel Data and Heterogeneity in Parametric Duration Models

E61.1 Introduction

This chapter develops several extensions of the duration models for panel data and other nonstandard forms. The other extensions include heterogeneity, heteroscedasticity and a two part model for sample selection.

E61.2 Panel Data Models

The following are less natural for the parametric survival models than they are for, say, the linear regression model or the probit model. The notion of 'clustering' might be more applicable than panel data in this context. Consider a setting in which observations occur in naturally collected groups, in which group members have common attributes. For example, one might consider bank or business failures in which there is a strong regional or local influence shared within a group, but perhaps not between groups. Then, we consider a parametric model of the form

$$f(t_{ij}) = (1/\sigma)\, f(w_{ij})$$

where $$w_{ij} = (1/\sigma)\,(\log t_{ij} - \boldsymbol{\beta}_i'\mathbf{x}_{ij})$$

where 'i' indexes the group, 'j' indexes the member of group i, and there are N_i members of group i. *LIMDEP* provides four formulations for such a model:

1. Fixed effects
2. Random effects
3. Random parameters
4. Latent class

Extensive descriptions of these four modeling frameworks and how *LIMDEP* does the estimation appear elsewhere in this manual, e.g., in Chapters R22-R25, so at this juncture, we will present only the essential details. We emphasize, again, in this framework, the usual panel data interpretation is a bit ambiguous, since one would not normally observe the same individual repeatedly. The 'cluster of observations' seems a more appropriate application. As a consequence, covariance structures for observations should be 'exchangeable' – that is, any time sequencing operation, such as autocorrelation, would normally not be used in this context.

NOTE: These 'panel data models' are available only for the Weibull, loglogistic and lognormal models.

All models will contain the mandatory part of the specification

SETPANEL ; Group = identifier
; Pds = count variable $
SURVIVAL ; Lhs = the log of the time variable
; Rhs = the list of covariates
; Model = Weibull or Normal or Loglogistic
; Panel
; ... specification of the particular model form
; ... any other options $

Since the Kennan data are grouped by year, they can be viewed as a panel (by our earlier loose interpretation). To illustrate the different estimators, we will fit several different forms of the Weibull model which appears to be a good choice for these data.

E61.2.1 Fixed Effects Models

The fixed effects model would result from

$$\boldsymbol{\beta}_i'\mathbf{x}_i^* = \beta_i^0 + \boldsymbol{\beta}'\mathbf{x}_i$$

where $\mathbf{x}_i$* is the full covariate vector including a constant term while $\mathbf{x}_i$ is all variables not including a constant term, and where $\boldsymbol{\beta}_i$ is partitioned conformably. The fixed effects estimator is requested with

; FEM
; Panel

NOTE: The fixed effect cannot be estimated for any group in which all observations in the group are censored. These groups must be dropped from the analysis. The output for the estimator will indicate how many times this condition was encountered in the data set.

Since *prod* does not vary within each year, the fixed effects model must be fit with just the constant terms. Since there are no covariates, this might seem to be equivalent to fitting separate models for each year, however, the underlying variance parameter is constrained to be the same in every year. (We created the count variable, *ni*, by hand, since the sample is so small. Purely for this numerical example, we created nine groups with seven observations in each group save for the last, which has six.)

E61.2.2 Random Effects and Random Parameters Models

The random parameters model specifies that

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i$$

where β is the mean of the distribution, Δ is a matrix of coefficients, and $\boldsymbol{\Gamma}$ is a lower triangular matrix. By this specification, each coefficient in the model is

$$\beta_{ik} = \beta_k + \boldsymbol{\delta}_k'\mathbf{z}_i + \boldsymbol{\gamma}'\mathbf{v}_i.$$

Any coefficient can be assumed to be nonrandom. Correlation across parameters is achieved by having nonzero off diagonal elements in $\boldsymbol{\Gamma}$. The diagonal elements are the scales (not necessarily the standard deviations) for the random terms.

NOTE: A random effects model is obtained in this framework by allowing only the constant term to be random and not providing any '*z*' variables for the heterogeneous mean.

The random parameters models are specified by providing, for each random parameter desired:

; RPM [= list of variables in z if desired. This is optional.]
; Fcn = name of variable (n, u, t, etc.)
for normal, uniform, tent distribution, etc.

LIMDEP's Weibull and exponential models support heterogeneity with log-gamma density by writing the survival function as

$$S(t|v) = v \times \exp[(-\lambda t)^P]$$

where v has a gamma density with mean one.

The random parameters formulation of the parametric models allows the modeler to incorporate heterogeneity in the parametric survival models in the form of variation in the model parameters, β. Thus, for example, the hazard function for the Weibull model is

$$h(t_i) = \lambda_i \, p \, (\lambda_i t_i)^{p-1}$$

where $\lambda_i = \exp(\boldsymbol{\beta}_i{}'\mathbf{x}_i)$

and, we allow $\boldsymbol{\beta}_i = \boldsymbol{\beta}^0 + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\,\mathbf{v}_i$.

This builds individual heterogeneity into the hazard rate in a different manner than in the gamma model above. Note, however, that if only the constant term in $\boldsymbol{\beta}$ is so affected, then this random parameter model becomes the same as the gamma model above with a different distribution. Typically the heterogeneity would be assumed to arise from a normally distributed v_i, in which case, the gamma variable v in the earlier model would be changed to include a lognormal γv_i in this new formulation.

This formulation, available for the Weibull, exponential, lognormal and loglogistic survival models, adds these survival models to *LIMDEP*'s class of random parameter models. The full range of features for the random parameter models is available. The function definition may specify that any parameter in the model is random. The randomness may be 'pure' as in

$$\boldsymbol{\beta}_i = \boldsymbol{\beta}^0 + \boldsymbol{\Gamma}\,\mathbf{v}_i$$

which replicates (at least in spirit) earlier formulations, or heterogeneous,

$$\boldsymbol{\beta}_i = \boldsymbol{\beta}^0 + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\,\mathbf{v}_i.$$

We should note, the preceding heterogeneity model assumes (as all random 'effects models' do) that the heterogeneity is uncorrelated with the covariates. If this is not true, then parameter estimates are inconsistent and inference about them from that model is possibly problematic. In other settings, the 'fixed effects' model is the preferable alternative. *LIMDEP*'s fixed effects estimator is available for these models as well. However, it is unclear how viable an option this will be, because the fixed effects model requires panel data, and one typically does not observe panels of duration data.

The random parameters model with a random constant term is comparable to the latent heterogeneity models discussed in Section E61.3. We will treat the data as a panel here – there are nine years of data. For these treatments, we assume that the latent effect is common to all observations in the given year, as it would be in the spirit of Kennan's treatment in which the *prod* variable represents a macroeconomic shock that hits all industries. Thus, the treatment here assumes that there are other shocks that do likewise.

The first model is a simple random effects formulation. The second allows both parameters to be random.

E61.2.3 Latent Class Models

The latent class model specifies a complete parameter vector, including σ, for each of *J* latent classes. The model is specified with

; LCM ; Pts = the number of classes desired

We fit a three class model to the strike data. In view of the previous results, these should not be expected to amount to much. Surprisingly, the latent class model seems to work quite well. However, a closer look at the results suggests that we have overfit it. The second and third classes, while different from the first, are nearly identical to each other. When we refit the model with two classes, the results are virtually identical to those below, with the second and third classes simply combined to one class.

E61.3 Latent Heterogeneity

This section considers handling heterogeneity in the survival models. We first provide a robust covariance matrix for the case of uncorrected latent heterogeneity. Sections E61.3.2 to E61.3.4 consider explicit treatments for latent heterogeneity in survival models. The traditional approach has been to embed a gamma distributed latent effect in a Weibull or exponential model. In Section E61.3.2, we present a more general, flexible model that can be used in several of the parametric models. Sections E61.3.3 and E61.3.4 present the traditional models. The final part, discussed in Section E61.4, presents a model of scale heterogeneity, which would be a counterpart to heteroscedasticity in a regression context.

E61.3.1 A Heterogeneity Corrected Covariance Matrix

Under certain conditions (see Gourieroux, Monfort, and Trognon (1984)), an appropriate asymptotic covariance matrix for a ‘pseudo maximum likelihood estimator’ can be obtained by using

$$\mathbf{V} = \mathbf{H}^{-1}\,(\mathbf{BHHH})\,\mathbf{H}^{-1}$$

where **H** is the negative expected Hessian of the pseudo-log likelihood and **BHHH** is the expected outer product of the first derivatives, i.e., the inverse of the BHHH estimator of the asymptotic covariance matrix. The pseudo-log likelihood is the incorrectly assumed log likelihood for our purposes. This computation can be done for any of the parametric models by ‘tricking’ the cluster estimator. The right matrix emerges if the cluster estimator is invoked with clusters of one, so the command is

SURVIVAL ; Lhs = ... ; Rhs = ... ; Model = ... ; Cluster = 1 $

This is available for all of the parametric models described to this point.

To illustrate the estimator, we have reestimated the Weibull model with the correction to the covariance matrix. The evidence of heterogeneity below is mixed. However, the robust covariance matrix is substantially larger. The commands are

```
SURVIVAL    ; Lhs = logt
            ; Rhs = one,prod ; Model = Weibull
            ; Cluster = 1 $
SURVIVAL    ; Lhs = logt
            ; Rhs = one,prod ; Model = Weibull $
```

E61.3.2 Parametric Models with Heterogeneity

If one assumes the survival distribution is homogeneous when it is not, there are two likely consequences:

- parameter estimates will be inconsistent and/or
- inferences will be based on inappropriate standard errors.

The results of Gourieroux et al. suggest that in many settings, the primary effect of the misspecification will be the second of these, but not the first. (For extensive discussions of heterogeneity, see Kiefer (1988) and Heckman and Singer (1984).) The following will describe two estimators that deal with both possibilities by specifically incorporating heterogeneity in the model.

A familiar, traditional model of heterogeneity in the parametric survival models (see the next section), is of the form of a multiplicative term in the Weibull survival model,

$$S(t|v) = v\{\exp[(-\lambda t)^p]\}.$$

where v has a gamma density with mean one. (See, e.g., Hui (1991).) The unconditional survival function is found by

$$\begin{aligned} S(t) &= \int_0^\infty vS(t|v)f(v)\mathrm{d}v. \\ &= \left[1 + \theta(\lambda t)^p\right]^{-1/\theta} \end{aligned}$$

where θ is the parameter of the gamma distribution. There is no natural mechanism that produces this model; it is devised as a reasonable approach that is mathematically convenient.

Consider the alternative approach

$$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma\varepsilon_i),\ E[\varepsilon_i] = 0,\ \mathrm{Var}[\varepsilon_i] = 1,$$

where the unobserved heterogeneity enters the model in the same fashion that the observed heterogeneity does. (The assumption of zero mean is innocent if the model contains a constant term, while the unit variance is simply a scaling – the variance is carried by σ^2.) We use maximum simulated likelihood to estimate the model parameters. The term $\lambda_i(\varepsilon_i)$ enters any of the models in Table E60.1 – the estimator described here is available for the exponential, Weibull, lognormal, loglogistic and inverse Gaussian. The log likelihood, conditioned on ε_i is

$$\log L|\varepsilon_1,\ldots,\varepsilon_N = \sum_{i=1}^N \delta_i \log f[y_i,\lambda_i(\varepsilon_i),p] + (1-\delta_i)\log S[y_i,\lambda_i(\varepsilon_i),p].$$

The unconditional log likelihood to be maximized is obtained by integrating ε_i out of the conditional log likelihood;

$$\log L = \sum_{i=1}^N \int_{-\infty}^\infty \left\{\delta_i \log f[y_i,\lambda_i(\varepsilon_i),p] + (1-\delta_i)\log S[y_i,\lambda_i(\varepsilon_i),p]\right\} f(\varepsilon_i)d\varepsilon_i.$$

The integral does not exist in closed form, but there are two approaches that can be used to provide a satisfactory approximation. If ε_i has a standard normal distribution, the integral can be computed using Hermite quadrature. Alternatively, if ε_i has a distribution that can be simulated (such as the standard normal), the integral can be computed using Monte Carlo methods. The simulated log likelihood that is used here is

$$\log L = \sum_{i=1}^N \frac{1}{R}\sum_{r=1}^R \left\{\delta_i \log f[y_i,\lambda_i(\varepsilon_{ir}),p] + (1-\delta_i)\log S[y_i,\lambda_i(\varepsilon_{ir}),p]\right\}$$

where ε_{ir} is a random sample of R draws from the appropriate population.

The maximum simulated likelihood estimator for this model is available for the Weibull, exponential, lognormal, loglogistic and inverse Gaussian models. The command is

SURVIVAL ; Lhs = dependent variable, censoring indicator if any
; Rhs = covariates (should include one)
; Model = the desired model
; RPM ; Fcn = one(n)
; Pts = 1
[; Halton ; Pts = desired value of R] $

(The model is fit as a random parameter model with only a random constant term.)

To illustrate, we have fit the Weibull model with normally distributed heterogeneity.

SURVIVAL ; Lhs = logt ; Rhs = one,prod ; Model = Weibull
; Pds = 1 ; RPM ; Fcn = one(n) ; Output = 3 ; Halton $

E61.3.3 Weibull Survival Model With Gamma Heterogeneity

A modification of the Weibull (or exponential) model suggested by Hui (1991) is

$$S(t|\mathrm{v}) = v\{\exp[(-\lambda t)^p]\}.$$

The random variable, v, is the heterogeneity effect. We assume that v is distributed as gamma with parameters k and R;

$$f(v) \quad = \left[k^R / \Gamma(R)\right] e^{-kv} v^{R-1}.$$

If the duration model contains a constant, then no generality is lost by assuming that the mean of v is one. Thus,

$$\mathrm{E}[v] = k/R = 1 \text{ or } k = R.$$

Now, we find

$$S(t) \quad = \int_0^{\infty} vS(t|v)f(v)\mathrm{d}v.$$

The result for the Weibull model is

$$S(t) \quad = \left[1 + \theta(\lambda t)^p\right]^{-1/\theta}$$

and $$h(t) \quad = S(t)^{\theta} \text{ times Weibull hazard,}$$

where $\theta = 1/k$. The variance of v is $1/k$, so, $\theta = 0$ corresponds to the Weibull model. The further θ deviates from zero, the greater is the effect of the heterogeneity. The Weibull survival function emerges if the limit of $S(t)$ as θ goes to zero is taken.

To request this variant of the Weibull model, use

SURVIVAL ; Lhs = ... ; Rhs = ...
; Model = Weibull
; Heterogeneity (or just ; Het) $

All other options and features described for the other parametric models apply equally. The only difference is that the BFGS algorithm is always used for estimation and the estimated covariance matrix for the parameter estimates is always the BHHH estimator. Since the exponential is a minor modification of the Weibull model, you may also specify **; Model = Exponential** in the command. The other models (loglogistic, normal, etc.) are not available with this specification.

NOTE: The log likelihood is somewhat volatile in the parameter θ. You may find the diagnostic 'Unable to compute function at current estimates' appearing in the output for your iterations. This means that the current trial value of θ is not positive. This is a recoverable error; *LIMDEP* will now try a new value.

The normal and gamma models are not directly comparable. The gamma model is not obtained by changing the normality assumption to the log gamma model in our formulation. The heterogeneity enters in a different form in the gamma model. The normal model turns out to be much easier to fit with these data, and appears to produce better results. The gamma model is actually inestimable, and we stopped the iterations at 12 to show the intermediate results. At 'convergence,' θ has gravitated to zero.

SURVIVAL ; Lhs = logt ; Rhs = one,prod
; Model = Weibull
; Het
; Output = 3
; Maxit = 25 $

This is the outcome when the estimator is allowed to iterate to completion:

```
Itr 12 F=  .9729D+02 gtHg=  .5460D+02 chg.F=  .8193D-04 max|db|=  .7173D+08

Itr 13 F=  .9729D+02 gtHg=  .6801D+01 chg.F=  .4096D-04 max|db|=  .1869D+08
1st derivs.     .00000D+00   .00000D+00   .00000D+00   .00000D+00
Parameters:    -.37856D+01   .91768D+01  -.16856D-07   .99166D+00
Itr 14 F=  .0000D+00 gtHg=  .0000D+00 chg.F=  .9729D+02 max|db|=  .0000D+00
                         * Converged                           * Converged
Normal exit:  14 iterations. Status=0, F=    .0000000
Function=  .10472246124D+03, at entry,  .00000000000D+00 at exit
```

The estimator claims convergence, but note that the estimate of θ is zero, and the derivatives matrix has essentially vanished – the BHHH estimator is singular, so estimation is halted. The results consist, within rounding error, of the original Weibull model plus a parameter that is zero.

```

E61.3.4 Other Heterogeneity Mixtures

A variety of base models and heterogeneity distributions are contained within *LIMDEP*'s menu of parametric models. The table below lists some of these.

Conditional Density	Heterogeneity	Unconditional Density	Estimator
gamma	gamma	generalized F(M1,M2)	**; Model = F**
gamma	exponential	generalized F(M1,1)	**; Model = F(M1,1)**
exponential	gamma	Pareto	**; Model = E ; Het**
exponential	exponential		**; Model = F(1,1)**
Weibull	gamma	Burr	**; Model = W ; Het**
Weibull	exponential	loglogistic	**; Model = L**

Table E61.1 Models for Heterogeneity

E61.4 Heterogeneity in the Scale Parameter for Loglinear Models

The parametric survival models, Weibull, loglogistic, lognormal, Weibull/gamma, inverse Gaussian and generalized F and their time varying covariates counterparts are specified so that the parameter $\lambda = \exp(-\boldsymbol{\beta}'\mathbf{x})$ makes the location of the survival distribution heterogeneous across individuals. The scale of the distribution, as specified by the parameter σ, is generally fixed for all individuals. The modification described here allows σ to be a function of individual specific covariates as well.

The loglinear specifications are defined in terms of a transformation,

$$w = (\log t - \boldsymbol{\beta}'\mathbf{x}) / \sigma$$

where σ is the scale parameter. You may specify the same sort of multiplicative heteroscedasticity as in the regression, tobit, logit, and probit models,

$$\sigma_i = \sigma \exp(\boldsymbol{\gamma}'\mathbf{h}_i)$$

where $\mathbf{h}_i$ is a vector of covariates. This extension is provided for the following models, all with or without time varying covariates or split population: Weibull, Weibull with gamma heterogeneity, loglogistic, lognormal, inverse Gaussian and generalized *F*. It is provided for the lognormal with or without the optional split population specification. To request this specification, just add

; Hfn = list of variables in $\mathbf{h}_i$

NOTE: The list must not contain *one*. The variance model already contains a constant, σ.

For hypothesis testing and providing starting values, note that with this extension, the parameter vector in the full model become

$$\theta = \boldsymbol{\beta}, \boldsymbol{\alpha}, \boldsymbol{\gamma}, \theta, (M1,M2), \sigma.$$

Some parts are optional. If you do not specify the split population model, α will not be present, while the parameter θ is only present for the Weibull or exponential model with gamma heterogeneity or the generalized gamma model, and $(M1,M2)$ apply only to the generalized F model.

E61.5 Split Population Survival Models

The following describes a modification of the parametric survival models: Weibull (with or without gamma heterogeneity), lognormal, loglogistic, or exponential. (The models developed here are based on Schmidt and Witte (1989). The specification is not available for the Gompertz model.)

For analyzing survival time data with censoring indicator, δ_i (we use *LIMDEP*'s rather than Schmidt and Witte's notation), *LIMDEP*'s parametric survival models are based on the log likelihood

$$\log L = \Sigma_{\delta=1} \log\{(1/\sigma)f[\mu_i/\sigma]\} + \Sigma_{\delta=0} \log S(\mu_i/\sigma),$$

where, $\mu_i = \log t_i - \boldsymbol{\beta}'\mathbf{x}_i$

and, in all these models, $w_i = (\log t_i - \boldsymbol{\beta}'\mathbf{x}_i) / \sigma = \mu_i / \sigma$.

In the log likelihood, $(1/\sigma)f(w_i)$ is the density and $S(w_i)$ is the survival function (equal to one minus the CDF). The model as stated assumes that censored observations will all fail eventually. Schmidt and Witte suggest that the model be modified by allowing for the possibility that a censored observation might, in fact, never fail. Thus, they suggest that we model the probability of eventual failure as

$$\text{Prob}[R_i = 1] = P_i \quad \text{(our notation).}$$

Then, for an observed individual, the appropriate term which appears in the log likelihood is

$$\text{Prob}[R_i = 1] \times g(t_i \mid R_i = 1) + \text{Prob}[\delta_i = 0],$$

where $g(\bullet)$ is the original density above, and the probability attached to a censored observation ($\delta_i = 0$) is

$$\text{Prob}[R_i = 0] \text{ (i.e., never fail)} + \text{Prob}[R_i = 1] \times \text{Prob[fail at time t or later]}.$$

Let the determinants of the probability of eventual failure be $\mathbf{z}_i$ (in the Schmidt and Witte paper, $\mathbf{z}_i = \mathbf{x}_i$, which makes sense, though *LIMDEP* does not require it) and let

$$\text{Prob}[R_i = 1] = P_i = G(\boldsymbol{\alpha}'\mathbf{z}_i).$$

Combining terms, the revised log likelihood is now

$$\begin{aligned}\log L = \;& \Sigma_{\delta=1} \log\{ G(\boldsymbol{\alpha}'\mathbf{z}_i)(1/\sigma)f(w_i)\} \\ & + \Sigma_{\delta=0} \log\{[1 - G(\boldsymbol{\alpha}'\mathbf{z}_i)] + G(\boldsymbol{\alpha}'\mathbf{z}_i)S(w_i)\}.\end{aligned}$$

It remains to model $G(\boldsymbol{\alpha}'\mathbf{z}_i)$. Schmidt and Witte suggest a logistic model,

$$G(\boldsymbol{\alpha}'\mathbf{z}_i) = 1/[1 + \exp(\boldsymbol{\alpha}'\mathbf{z}_i)] = 1 - \Lambda(\boldsymbol{\alpha}'\mathbf{z}_i).$$

LIMDEP allows two models, the preceding logit model and a normal (probit) model,

$$G(\boldsymbol{\alpha}'\mathbf{z}_i) = 1 - \Phi(\boldsymbol{\alpha}'\mathbf{z}_i),$$

where $\Phi(\bullet)$ is the standard normal CDF. (There is no variance parameter, as it would not be identified in the model. The same principle as in the univariate probit model applies here.)

This augmented model is requested simply by adding

; Rh2 = list of variables in $\mathbf{z}_i$

The default model for $G(\bullet)$ is the normal model. Request Schmidt and Witte's logistic model by adding

; Logit

to the command with the **; Rh2** specification. No other changes are required in the command. This applies to **; Model = Weibull**, **; Model = Exponential**, **; Model = Normal**, or **; Model = Loglogistic** for the survival rate.

Schmidt and Witte discuss various models for G and the survival rate with and without individual effects. In your command, either (or both) of the models $S(\bullet)$ or $G(\bullet)$ may be specified to have just a constant term, *one* or may have covariates. As noted, there is no requirement that the Rhs and Rh2 models be the same. For example, to estimate their 'SPLIT' models (their Table 2, page 153), just specify **; Rh2 = one** and the rest of the command as usual. Likewise, by specifying both **; Rhs = one** and **; Rh2 = one**, you would obtain the models described on their page 147.

The additional output for this model consists of a header which displays the specification requested and an additional set of coefficients in the statistical output. In the table which is given after the coefficient estimates, there will now appear an additional row with an estimate of the average value of the probability of eventual failure. This is labeled 'SPLIT' in the table.

WARNING: This model is a bit quirky. If the model does not have much explanatory power, and if the censoring indicator is not explained very well by both the duration variable (*logtime*) and the covariates in the duration model, then the estimated probability of eventual failure will tend to gravitate toward 1.0 (as one might expect). This will show up in the model as extreme values of the coefficients in the equation for $G(\bullet)$. When this happens, the other coefficients will be identical to those which would be estimated if the 'splitting' model were ignored (i.e., as if you had not included the **; Rh2** specification). The model reported will appear to show coefficients in the $G(\bullet)$ equation, but it will not be possible to compute standard errors, and, in fact, the coefficients themselves will not be usable. If this occurs, the coefficients which were computed will be reported, along with zeros for their standard errors. A message will be given that the covariance matrix is singular (which it is). *LIMDEP* then uses a generalized inverse to invert the nonsingular submatrix.

E61.6 Left and Right Truncation

There are cases in which the natural limit point of zero is not actually appropriate for the duration data in hand. Consider, for example, an experiment in which duration measurement did not even begin until a certain amount of time had passed. The actual distribution of observed survival times will logically be constrained to some range other than zero to infinity. Presumably the truncation point will be somewhere above zero. In order to accommodate such a situation, the survival distribution, which is normally defined over $[0,+\infty)$, must be scaled up so that it integrates to one over the appropriate range.

Accounting for truncation can bring drastic changes in the estimated distribution. The relevant theory is exactly that underlying the truncated regression model. To account for truncation, modify the model command to

```
SURVIVAL    ; Lhs = ...
            ; Rhs = ...
            ; Model = ...
            ; other options if any
            ; Limit = limit point $
```

The default is lower (left) truncation. Specify upper truncation, instead, with

```
            ; Limit = limit ; Upper
```

(I.e., your data may be such that the observation is not observed if *T* exceeds a certain value. Consider, for example, observed failure times for a product with a warranty period of a fixed length.) The limit may be a constant or the name of a variable, if the truncation varies by observation. The model is otherwise unchanged. A header at the beginning of the output for the model will echo the specification of a model with truncation. But, there will be no further mention of the fact, since subsequent changes are all internal. The following restrictions apply:

- The model must be one of Weibull, exponential, lognormal, or loglogistic. This option is not available for the gamma, inverse Gaussian, generalized F, Gompertz, or the split population models.

- Newton's method is not available for this model. If you prefer a Newton-like method, you may still use BHHH. Note, though, that this extension makes calculation much more difficult. We have had our best success with BFGS.

E61.7 Sample Selection

The random parameters treatment noted above opens the possibility of a sample selection model for parametric survival models. The structure would be the base case parametric model, as modified above, using the Weibull model as the standard case,

$$h(t_i) = \lambda_i\, p\, (\lambda_i t_i)^{p-1}$$

where $$\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i + \sigma v_i)$$

We accommodate this case by treating the random component as a random constant term in the parametric model. The observation mechanism is now

$$d_i^* = \boldsymbol{\alpha}'\mathbf{z}_i + \varepsilon_i, \quad d_i = 1(d_i^* > 0)$$

where the correlation between v_i and ε_i is ρ. We assume that the data for the duration model are only observed when $d_i = 1$. The model is fit by full information maximum likelihood. (This means that there is no ‘lambda,’ the familiar inverse Mills ratio, added to the duration model. That treatment is only appropriate for the linear model fit by two step least squares.)

This model is requested by the following command set:

```
PROBIT      ; Lhs = d
            ; Rhs = variables in z
            ; Hold $
SURVIVAL    ; Lhs = logt [, and possibly a censoring indicator]
            ; Rhs = variables in x
            ; Model = one of Weibull, Normal, Loglogistic
            ; Selection
            ; RPM ; Fcn = one(n) $
```

(Other controls for the random parameters models, such as the number of replications, Halton draws, and so on, operate as with all other random parameters specifications.)

E62: Stochastic Frontier Models and Efficiency Analysis

E62.1 Introduction

Chapters E62-E65 present *LIMDEP*'s programs for two types of efficiency analysis, stochastic frontier analysis (SFA) and data envelopment analysis (DEA). To a large extent, these are competing methodologies. No formulation has yet been devised that unifies the two in a single analytical framework. Arguably, the former is a fully parameterized model whereas the latter is 'nonparametric,' albeit also atheoretical in nature.

The stochastic frontier model is used in a large literature of studies of production, cost, revenue, profit and other models of goal attainment. The model as it appears in the current literature was originally developed by Aigner, Lovell, and Schmidt (1977). The canonical formulation that serves as the foundation for other variations is their model,

$$y = \boldsymbol{\beta}'\mathbf{x} + v - u,$$

where y is the observed outcome (goal attainment), $\boldsymbol{\beta}'\mathbf{x} + v$ is the optimal, frontier goal (e.g., maximal production output or minimum cost) pursued by the individual, $\boldsymbol{\beta}'\mathbf{x}$ is the deterministic part of the frontier and $v \sim N[0,\sigma_v^2]$ is the stochastic part. The two parts together constitute the 'stochastic frontier.' The amount by which the observed individual fails to reach the optimum (the frontier) is u, where

$$u = |U| \text{ and } U \sim N[0,\sigma_u^2]$$

(change to $v + u$ for a stochastic cost frontier or any setting in which the optimum is a minimum). In this context, u is the 'inefficiency.' This is the normal-half normal model which forms the basic form of the stochastic frontier model.

Many varieties of the stochastic frontier model have appeared in the literature. A major survey that presents an extensive catalog of these formulations is Kumbhakar and Lovell (2000). (See, as well, Bauer (1990), Greene (2008) and several other surveys, many of which are cited in Kumbhakar and Lovell and in Greene.) The estimator in *LIMDEP* computes parameter estimates for most single equation cross section and panel data variants of the stochastic frontier model.

A large number of variants of the stochastic frontier model based on different assumptions about the distribution of the 'inefficiency' term, u have been proposed in the received literature. Most of these are available in *LIMDEP*, as suggested in the list below. The bulk of the received technology centers on cross section style modeling. However, recent advances include many extensions that take advantage of the features of panel data. A large array of panel data estimators are also supported by *LIMDEP* as well.

The conventional approach to deterministic frontier estimation is currently data envelopment analysis. This is usually handled with linear programming techniques. The analysis assumes that there is a frontier technology (in the same spirit as the stochastic frontier production model) that can be described by a piecewise linear hull that envelopes the observed outcomes. Some (efficient) observations will be on the frontier while other (inefficient) individuals will be inside. The technique produces a deterministic frontier that is generated by the observed data, so by construction, some individuals are 'efficient.' This is one of the fundamental differences between DEA and SFA. Data envelopment analysis is documented in Chapter E65.

The analysis of production, cost, etc. in the stochastic frontier framework involves two steps. In the first, the frontier model is estimated, usually by maximum likelihood. In the second, the estimated model is used to construct measures of inefficiency or efficiency. Individual specific estimates are computed that provide the basis of comparison of firms either to absolute standards or to each other. The sections of this chapter develop several model forms used in the first step. Efficiency estimation, the second step, appears formally in Section E62.8. The general methodology is then used in the already developed specifications and with several proposed in the sections that follow, as well as in Chapters E63 and E64.

E62.2 Stochastic Frontier Model Specifications

The stochastic frontier model is

$$y = \boldsymbol{\beta}'\mathbf{x} + v\text{-}u,\ u = |U|.$$

In this area of study, unlike most others, estimation of the model parameters is usually not the primary objective. Estimation and analysis of the inefficiency of individuals in the sample and of the aggregated sample are usually of greater interest. This part of the development will present tools for estimation of inefficiency.

Typically, the production or cost model is based on a Cobb-Douglas, translog, or other form of logarithmic model, so that the essential form is

$$\log y = \boldsymbol{\beta}'\mathbf{x} + v - u$$

where the components of **x** are generally logs of inputs for a production model or logs of output and input prices for a cost model, or their squares and/or cross products. In this form, then, at least for relatively small variation, u represents the proportion by which y falls short of the goal, and has a natural interpretation as proportional or percentage inefficiency. The numerous examples below will demonstrate. Users are also referred to the various survey sources listed earlier.

The results one obtains are, of course, critically dependent on the model assumed. Thus, specification and estimation of model parameters, while perhaps of secondary interest, are nonetheless a major first step in the model building process. In nearly all received formulations, the random component, v, is assumed to be normally distributed with zero mean. In some models, v may be heteroscedastic. But, in either form, the large majority of the different frontier models that have been proposed result from variations on the distribution of the inefficiency term, u. The range of specifications examined in this chapter includes the following:

- Distributional assumptions: half normal, exponential, gamma
- Partially nonparametric frontier function
- Sample selection model

The following extensions are presented in Chapters E63:

- Truncated normal with nonzero, heterogeneous mean in the underlying *U*
- Heteroscedasticity in *v* and/or *u*
- Heterogeneity in the parameter of the exponential or gamma distribution
- Alvarez, Amsler, Orea and Schmidt's (2006) 'scaling model'
- Alvarez, Arias and Greene's (2006) model of fixed, latent management

A number of treatments for panel data are presented in Chapter E64.

E62.3 Basic Commands for Stochastic Frontier Models

The command for all specifications of the stochastic frontier model is

FRONTIER ; Lhs = y ; Rhs = one, ... ; … other specifications $

NOTE: *One* must be the first variable in the Rhs list in all model specifications.

The default specification is Aigner, Lovell and Schmidt's canonical *normal-half normal model*. The default form is a production frontier model,

$$y = \boldsymbol{\beta}'\mathbf{x} + v - u, u = |U|.$$

That is, the right hand side of the equation specifies the *maximum* goal attainable. To specify a cost frontier model or other model in which the frontier represents a *minimum*, so that

$$y = \boldsymbol{\beta}'\mathbf{x} + v + u, u = |U|,$$

use

; Cost

This specification is used in all forms of the stochastic frontier model. As noted below, one additional specification you may find useful is

; Start = values for β, λ, σ.

(The meanings of the parameters are developed below.) ALS also developed the *normal-exponential model*, in which *u* has an exponential distribution rather than a half normal distribution. To request the exponential model, use

; Model = Exponential (or ; Model = E)

in the **FRONTIER** command. For this model, the parameters are (β,θ,σ_v). Further details appear below. There are also several model forms, and numerous modifications such as heteroscedasticity that are developed below.

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps ancillary parameters σ, λ, etc. with main parameter β vector in *b*.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix	displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Choice	uses choice based sampling (sandwich with weighting) estimated matrix.
; Cluster = spec	requests computation of the cluster form of corrected covariance estimator.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

E62.3.1 Predictions, Residuals and Partial Effects

Predicted values and ‘residuals’ for the stochastic frontier models are computed as follows: The same forms are used for cross section and panel data forms. The predicted value is $\boldsymbol{\beta}'\mathbf{x}$. (These are rarely useful in this setting.) The ‘residual’ is computed directly as

$$e_i = y_i - \hat{\boldsymbol{\beta}}'\mathbf{x}_i$$

This residual is usually not of interest in itself. It is, however, the crucial ingredient in the efficiency estimator discussed in Section E62.8. The estimator of u_i that we will use is computed by the Jondrow formula $E[u|v\text{-}u]$ or $E[u|v\text{+}u]$ if based on a cost frontier,

$$\hat{E}[u\,|\,\varepsilon] = \frac{\sigma\lambda}{1+\lambda^2}\left[\frac{\phi(w)}{1-\Phi(w)} - w\right],\ \varepsilon = v \pm u\ ,\ w = \varepsilon\lambda/\sigma,$$

$$\sigma = \sqrt{\sigma_v^2 + \sigma_u^2},\ \lambda = \frac{\sigma_u}{\sigma_v}.$$

In the JLMS formula, e_i is the estimator of ε_i. The formulas and computations are discussed in Section E62.8.

The frontier model is, save for its involved disturbance term, a linear regression model. The conditional mean in the model is

$$E[y_i|\mathbf{x}_i] = \boldsymbol{\beta}'\mathbf{x}_i - \mathrm{E}[u_i|\mathbf{x}_i].$$

In most cases, $\mathrm{E}[u_i|\mathbf{x}_i]$is not a function of $\mathbf{x}_i$, so the derivatives of $\mathrm{E}[y_i|\mathbf{x}_i]$ with respect to $\mathbf{x}_i$ are just $\boldsymbol{\beta}$. In other cases, we will consider, the conditional mean of u_i does depend on $\mathbf{x}_i$ or other variables, so the partial effects in the model might be more involved than this. Once again, however, these will usually not be of direct interest in the study. But, in all cases, $\hat{E}[u\,|\,\varepsilon]$ will be an involved function of $\mathbf{x}_i$ and any other variables that appear anywhere else in the model. We will examine the partial effects on the efficiency estimators in Section E62.8.

E62.3.2 Results Saved by the Frontier Estimator

The results saved by the frontier estimator are

Matrices: *b* = regression parameters, $\alpha,\boldsymbol{\beta}$
varb = asymptotic covariance matrix

Scalars: *sy*, *ybar*, *nreg*, *kreg*, and *logl*

Last Function: JLMS estimator of u_i.

Use **; Par** to add the ancillary parameters to these. The ancillary parameters that are estimated for the various models are as follows, including the scalars saved by the estimation program:

Half and truncated normal:	estimates λ, σ, saves *lmda* and $s = \sigma$,
Truncated normal:	same as half normal, estimates μ, saved as *mu*,
Exponential:	estimates θ, σ_v, saves *theta* and $s = \sigma_v$,
Heteroscedastic model:	average value of σ as s, average value of λ as *lmda*
Heterogeneity in mean:	estimates λ, σ, saves *lmda* and $s = \sigma$.

E62.4 Data for the Analysis of Frontier Models

We will use two data sets to illustrate the frontier estimators. The first, the data on U.S. airlines is a panel data set that we will use primarily for illustrating the stochastic frontier model. The second, the famous WHO data on health care attainment, will be used both for the stochastic frontier models and for the later work on data envelopment analysis.

E62.4.1 Data on U.S. Airlines

We will develop several examples in this section using a panel data set on the U.S. airline industry from the pre-deregulation period (airlines.dat). The observations are an unbalanced panel on 25 airlines. The original balanced panel data set contained 15 observations (1970-1984) on each of 25 airlines. Mergers, strikes and other data problems reduced the sample to the unbalanced panel of 256 observations The group sizes (number of firms) are 2 (4), 4(1), 7 (1), 9 (3), 10 (3), 11 (1), 12 (2), 13 (1), 14 (3) and 15 (6). The variables in the data set are

firm	= ID, 1,...,25	*year*	= 1970...1984	t = *year* - 1969 = 1,...,15	
cost	= total cost	*revenue*	= revenue	*output*	= total output
stage	= average stage length	*points*	= number of points served	*loadfct*	= load factor
cmtl	= materials cost	*mtl*	= materials quantity	*pm*	= price of material
cfuel	= fuel cost	*fuel*	= fuel quantity	*pf*	= fuel price
ceqpt	= equipment cost	*eqpt*	= equipment quantity	*pe*	= equipment price
clabor	= labor cost	*labor*	= labor quantity	*pl*	= labor price
cprop	= property cost	*property*	= property quantity	*pp*	= property price
k	= capital index	*pk*	= capital price index		

Transformed variables used in the examples are as follows:

lc	= log(*cost*)	*cn*	= *cost*/*pp*	*lcn*	= log(*cn*)
lpm	= log(*pm*)	*lpf*	= log(*pf*)	*lpe*	= log(*pe*)
lpl	= log(*pl*)	*lpp*	= log(*pp*)	*lpk*	= log(*pk*)
lpmpp	= log(*pm*/*pp*)	*lpfpp*	= log(*pf*/*pp*)	*lpepp*	= log(*pe*/*pp*)
lplpp	= log(*pl*/*pp*)	*lf*	= log(*fuel*)	*lm*	= log(*mtl*)
le	= log(*eqpt*)	*ll*	= log(*labor*)	*lp*	= log(*property*)
lq	= log(*output*)	*lq*2	= lq^2		

E62.4.2 World Health Organization (WHO) Health Attainment Data

The data used by the WHO in their 2000 *World Health Report* assessment of health care attainment by 191 countries have been used by many researchers worldwide both for developing frontier models and for analyzing health outcomes. The data are a panel of five years, 1993-1997, on health outcome data for 191 countries and a number of internal political units, e.g., the states of Mexico. The main outcome variables are *dale* and *comp* (an aggregate of such measures as efficiency and equity of health care delivery in the country). The main input variables are *hexp* and *educ*. A variety of other variables, listed below, were observed only in 1997. The following descriptive statistics apply to the entire data set of 840 observations:

Variable	**Mean**	**Std. Dev.**	**Description**
country	*	*	country number omitting internal units, 1...,191
year	*	*	year (1993-1997)
small	*	*	internal political unit, 0 for countries, else 1,...,6.
comp	75.0062726	12.2051123	composite health care attainment
dale	58.3082712	12.1442590	disability adjusted life expectancy
hexp	548.214857	694.216237	health expenditure per capita, PPP units
educ	6.31753664	2.73370613	educational attainment, years
oecd	.279761905	.449149577	OECD member country, dummy variable
gdpc	8135.10785	7891.20036	per capita GDP in PPP units
popden	953.119353	2871.84294	population density per square KM
gini	.379477914	.090206941	gini coefficient for income distribution
tropics	.463095238	.498933251	dummy variable for tropical location
pubthe	58.1553571	20.2340835	proportion of health spending paid by government
geff	.113293978	.915983955	World Bank government effectiveness measure
voice	.192624849	.952225978	World Bank measure of democratization

(The data were analyzed in Greene (2004a,b). Some of the variables, such as *popden* and *gdpc*, were augmented from other sources in these studies.) Although the data are a five year panel – a few countries were observed for fewer than five years – there is almost no cross year variation in any variable. (The proportion of total variation that is within groups is less than 1% for the four time varying variables.) We have created a cross section from these data as follows: First, we discarded the data on internal political units. We then averaged *comp, dale, hexp* and *educ* across the five years. We retained a sample of 191 cross sectional (country) units. The following command set creates the data set.

```
SAMPLE      ; 1-840 $
REJECT      ; small > 0 $
SETPANEL    ; Group = country ; Pds = ti $
RENAME      ; hc3 = educ $
CREATE      ; lpubthe = log(pubthe) $
CREATE      ; dalebar  = Group Mean(dale, Pds = ti) $
CREATE      ; compbar = Group Mean(comp, Pds  = ti) $
CREATE      ; educbar  = Group Mean(educ, Pds = ti) $
CREATE      ; hexpbar  = Group Mean(hexp, Pds = ti) $
CREATE      ; logdbar  = Log(dalebar) ; logcbar  = Log(compbar) $
CREATE      ; logebar  = Log(educbar) ; loghbar= Log(hexpbar) $
CREATE      ; loghbar2 = loghbar^2 $
REJECT      ; year # 1997 $
```

E62.5 Skewness of the OLS Residuals and Problems Fitting Stochastic Frontier Models

Before maximum likelihood estimation begins, the skewness of the OLS residuals in the regression of *y* on **x** is checked. Waldman (1982) has shown that when the OLS residuals are skewed in the wrong direction, a solution for the maximum likelihood estimator for the stochastic frontier model is simply OLS for the slopes and for σ_v^2 and 0.0 for σ_u^2. If this condition is found, a lengthy warning is issued. We emphasize, this is not a bug in the program, nor is it something to be 'fixed,' beyond changing the specification of the model or rethinking the stochastic frontier as the modeling platform. This is our single most frequently posed question, so we offer an application to demonstrate the effect. Consider the commands

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-500 $
CREATE      ; u = Abs(Rnn(0,2))
            ; v = Rnn(0,1)
            ; x = Rnn(0,1)
            ; y = x + v + u $
REGRESS     ; Lhs = y ; Rhs = one,x
            ; Res = e $
FRONTIER    ; Lhs = y ; Rhs = one,x $
KERNEL      ; Rhs = e $
```

The **CREATE** command generates *y* exactly according to the model, except note that *u* is not subtracted, it is added. Thus, we should expect this model to perform poorly. The estimation results from the **FRONTIER** command are shown below. Note the string of warnings. Estimation is allowed to proceed, but the results are not a 'frontier' as such. The final estimate of λ is essentially zero, with a huge standard error and the reported estimate of σ_u^2 in the box above the results is 0.0000. The other estimates are, in fact, the same as OLS. The kernel density estimator for the OLS residuals is clearly skewed in the positive, that is, the wrong direction. Once again, we emphasize, this is a failure of the data to conform to the model.

```
  Error   315: Stoch. Frontier: OLS residuals have wrong skew. OLS is MLE.
WARNING! OLS residuals have the wrong skewness for SFM
Other forms of the model models may also behave poorly.
In this case, one MLE for the half normal model is OLS
for beta and sigma and zero for the inefficiency term.

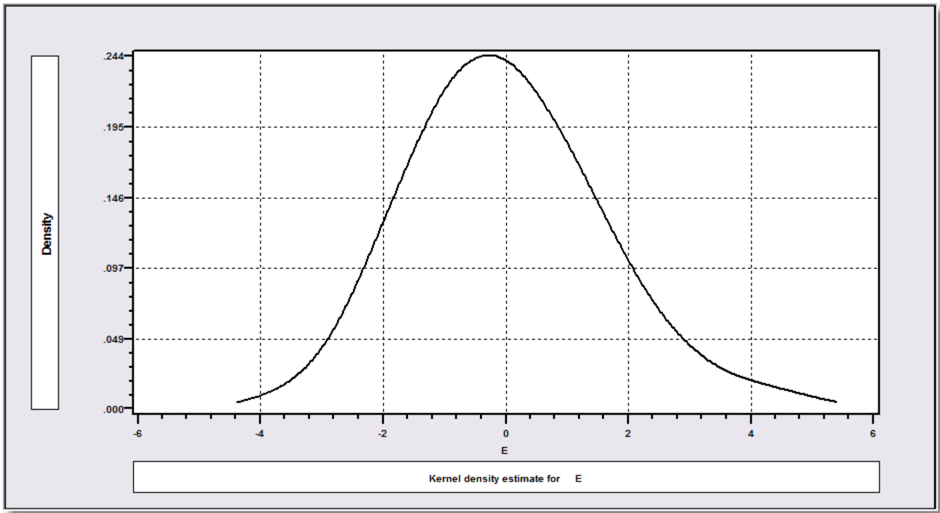

Figure E62.1 Kernel Density for Least Squares Residuals

Unfortunately, the Waldman result is a sufficient condition, not a necessary one. That is, it has been shown that when the OLS residuals have the 'right' skewness, then the MLE for the frontier model is unique, and you will have no trouble in estimation. When they have the 'wrong' skewness, it is only shown that the OLS results are a local stationary point of the log likelihood, not that they are the global maximizers. There may be another point that is yet better than OLS. Our airline data used below provide an example. Consider the following results, where we present both the stochastic frontier estimates and OLS. (The model, itself, is developed later, so we show only the useful results here.) As above, we receive the initial warning about the skewness of the OLS residuals. Then, estimation proceeds and an apparently routine solution emerges that is different from, and better than (has a higher log likelihood) OLS.

```
Error   315: Stoch. Frontier: OLS residuals have wrong skew. OLS is MLE.
WARNING! OLS residuals have the wrong skewness for SFM
Other forms of the model models may also behave poorly.
In this case, one MLE for the half normal model is OLS
for beta and sigma and zero for the inefficiency term.

```

There is no simple bullet proof strategy for handling this situation. You can try different starting values with **; Start = values for β, λ, σ** that differ from OLS, but it is hard to know where these will come from. Moreover, it is likely that you will end up at OLS anyway. As Waldman points out, this is a potentially ill behaved log likelihood function. We offer the preceding as a caution for the practitioner. For the particular data set used here, we can identify a specific culprit. The 'failure' of the model emerges in the presence of the variable *lm*, and does not occur when *lm* is omitted from the equation. We have no theory, however, for why this should be the case. Simply deleting variables from the model until one which does not have the skewness problem emerges does not seem like an effective strategy.

We do note, the failure might signal a misspecified model. For example, for our airlines example, the specification above omits the capital variable. When *lk* = log(*k*) is added to the model, we obtain the following quite routine results (albeit with the wrong signs on capital and labor inputs).

We emphasize, the Waldman result, and this particular theoretical outcome, is specific to the normal-half normal model. However, when it occurs, problems of a similar sort will often, *but not always*, show up in other models. Thus, in spite of a warning, your fitted exponential, or panel data model, may be quite satisfactory.

E62.6 The Ordinary Least Squares Estimator

For the simplest specification

$$y = \boldsymbol{\beta}'\mathbf{x} + v - u, u = |U|$$

in which $\boldsymbol{\beta}$ contains a constant term and both v and U are homoscedastic and have zero means, i.e., in the original half normal or exponential models, the OLS estimator of all elements of $\boldsymbol{\beta}$ except the constant term are consistent. It is convenient to rewrite the model as

$$y = \beta_0 + \boldsymbol{\beta}_1'\mathbf{x}_1 + v - u.$$

Under the assumptions, we can write the model as

$$y = (\beta_0 - E[u]) + \boldsymbol{\beta}_1'\mathbf{x}_1 + v - (u - E[u])$$

or

$$y = \alpha + \boldsymbol{\beta}_1'\mathbf{x}_1 + e$$

in which e has zero mean and constant variance, and is orthogonal to $(1,\mathbf{x}_1)$. Thus, the model as shown can be estimated consistently by OLS. The constant term estimates $\alpha = (\beta_0 - E[u])$. Assuming that $E[u]$ is estimable, therefore, estimation of β by MLE vs. OLS is a question of efficiency, not consistency. (However, we remain interested in estimation of u, so this may be a moot point.)

E62.6.1 Corrected Ordinary Least Squares – COLS

The COLS estimator is obtained by turning the least squares estimator into a deterministic frontier model. This is done by shifting the intercept in the OLS estimator upward (for a production frontier) or downward (for a cost frontier) so that all points lie either below or above the estimated function. Figure E62.2 shows the result for estimation of a simple cost frontier for the airlines data. The function is shifted so that it rests on the single most extreme point (residual) in the data. The COLS estimator is requested with

FRONTIER ; Lhs = goal variable
; Rhs = one, …
; Model = COLS $

Add **; Cost** if the model is a cost frontier.

Efficiency values, as discussed below, are obtained as follows:

; Eff = variable name

saves the residuals from the deterministic frontier. These are the estimates of u_i. Note in Figure E62.2, for a cost frontier, all values of u_i are positive. If you fit a production frontier, then all points will lie below the regression and all residuals will be negative. The estimated inefficiency that is saved will be $-e_i$. Thus, in both cases, the values saved by **; Eff = variable** are the positive estimates of the size of the deviation of the observation from the frontier. The estimator saved by **; Eff = variable name** is the inefficiency estimate, in this model, a direct estimate of u_i. The estimator of technical or cost efficiency is

$$Efficiency = \exp(-\hat{u}_i)$$

If you fit a production frontier, use

; Techeff = variable name

to save this variable. For a cost frontier, use

; Costeff = variable name

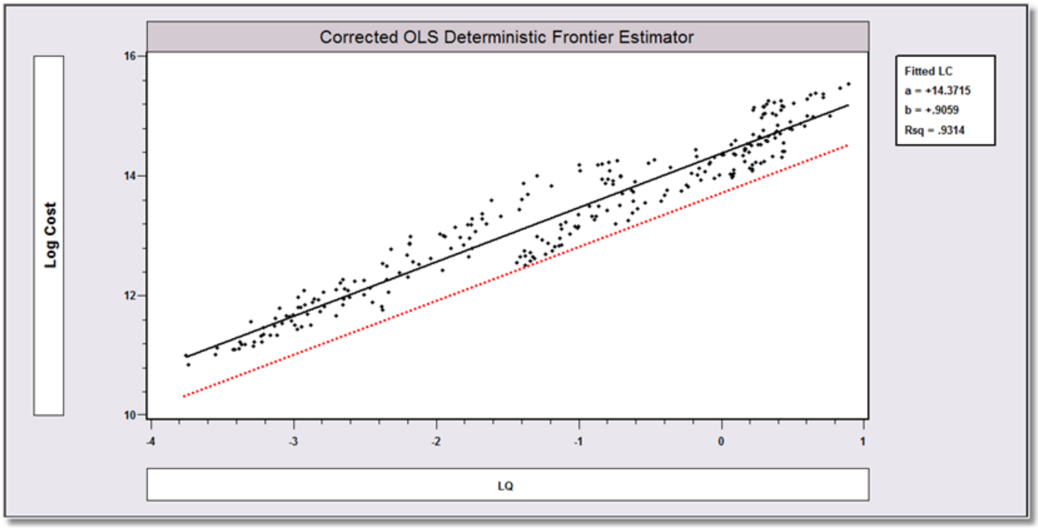

Figure E62.2 COLS Estimator of Cost Frontier Function

The following shows computation of a COLS estimator for the airlines. The **FRONTIER** command requests both the inefficiency estimates, *ui*, and the cost efficiency estimates, *eui_cost*. The kernel density estimate for the cost efficiency is shown in Figure E62.3. The results for the estimator begin with the standard output for least squares regression. The second panel includes some preliminary results for the stochastic frontier model, including the chi squared test for zero skewness (which is rejected); $\chi^2 = (n/6)(m_3/s^3)^2$. The standard normal statistic is the signed (based on m_3) square root of χ^2. The third panel presents descriptive statistics for u_i and $\exp(-u_i)$.

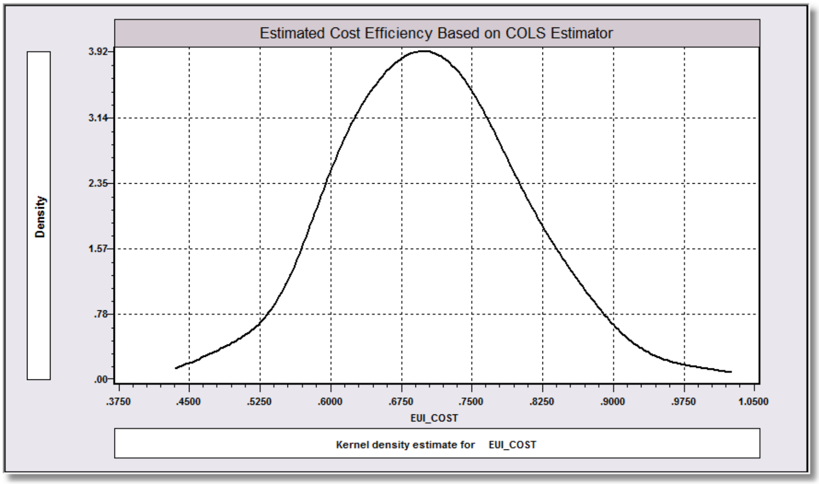

Figure E62.3 Kernel Estimator for Cost Efficiency

E62.6.2 Modified OLS and Starting Values for the MLE

Under the specific distributional assumptions of the half normal and exponential models, we do have method of moments estimators of the underlying parameters. They are based on the moment equations

$$\text{Var}[e] \;=\; \text{Var}[v] \;+\; \text{Var}[u]$$

and
$$\text{Skewness}[e] \;=\; \text{Skewness}[u]$$

since v is symmetric. The left hand sides can be consistently estimated using the OLS residuals:

$$m_2 \;=\; (1/n)\Sigma_i\, e_i^2$$

and
$$m_3 \;=\; (1/n)\Sigma_i e_i^3.$$

Both of the functions on the right hand side are known for the half normal and exponential models. In particular, for the half normal model, the moment equations are

$$m_2 \;=\; \sigma_v^2 \;+\; [1 - 2/\pi]\sigma_u^2\,,$$

$$m_3 \;=\; (2/\pi)^{1/2}[1 - 4/\pi]\sigma_u^3.$$

The solutions are:
$$\hat{\sigma}_u = \left[\frac{m_3\sqrt{\pi/2}}{1-4/\pi}\right]^{1/3} \text{ and } \hat{\sigma}_v = \sqrt{m_2 - (1-2/\pi)\hat{\sigma}_u^2}\,.$$

Note that there is no solution for σ_u if m_3 is not negative, which is the problem discussed in Section E62.5. Assuming that this problem does not arise, the corrected constant term is

$$\hat{\alpha} = a + \text{Est.}E[u] \;=\; a \;+\; \hat{\sigma}_u\sqrt{2/\pi}\,.$$

This is the 'modified least squares' (MOLS) estimator that is discussed in a number of sources, such as Greene (2005). These are the values used for starting values for the MLE, as well. Looking ahead, note that there is no natural method of moments estimator for the mean parameter in the truncated normal model discussed in Section E63.3. For this model, we use

$$\hat{\mu}/\sigma_u \;=\; 0.$$

For the normal-exponential model, the moment equations that correspond to the preceding are

$$m_2 \;=\; \sigma_v^2 \;+\; 1/\theta^2$$

$$m_3 \;=\; -2/\theta^3.$$

Therefore,
$$\hat{\theta} = \left[\frac{-2}{m_3}\right]^{1/3} \text{ and } \hat{\sigma}_v = \sqrt{m_2 - 1/\hat{\theta}^2}$$

and
$$\hat{\alpha} = a \;+\; 1/\hat{\theta}\,.$$

The header information in the results table will display the decomposition of the variance of the composed error in two parts. In the case of the half normal model,

$$\text{Var}[u] = [(\pi\text{-}2)/\pi]\sigma_u^2$$

not σ_u^2. Therefore, the estimated parameters might be a bit misleading as to the relative influence of u on the total variation in the structural disturbance.

We note, these estimators are sometimes quite far from the maximum likelihood estimators, particularly when the sample is small. But, they are generally quite satisfactory as starting values for the MLE. The following demonstrates these results for the airline data, where we use MOLS and MLE to fit a normal-half normal cost frontier. (Note, the signs of the OLS residuals are reversed because we are fitting a cost function.) In the results below, we have imposed the assumption of linear homogeneity in prices in the cost function by normalizing the six input prices, *pk*, *pl*, *pe*, *pp*, *pm*, *pf*, by the property price, *pp*. The model contains $\log(p_j/p_p)$. To complete the constraint, we have also normalized total cost by p_p before taking logs.

```

            ; sgma = Sqr(su^2 + sv^2) $
FRONTIER    ; Lhs = lc ; Rhs = x ; Cost $
```

The first set of results below are the OLS estimates with the correction to the constant term and the method of moments estimators of σ_u and σ_v used to start the MLE. The maximum likelihood estimators are shown next. The estimates for the stochastic frontier model include the log likelihood and the implied estimates of σ_u, σ_v and their squares, based on the estimates of $\lambda = \sigma_u/\sigma_v$ and $\sigma^2 = \sigma_u^2 + \sigma_v^2$, which are estimated by ML. (The reverse transformations are $\sigma_u^2 = \sigma^2\lambda^2/(1 + \lambda^2)$ and $\sigma_v^2 = \sigma^2/(1 + \lambda^2)$. The MLE is documented further in the next section.

E62.7 Estimating the Normal-Half Normal and Normal-Exponential Models

ALS's canonical form of the model is the *normal-half normal model*,

$$y = \boldsymbol{\beta}'\mathbf{x} + v - Su,\ u = |U|,\ S = +1 \text{ for production, -1 for cost,}$$
$$U \sim N[0,\sigma_u^2],$$
$$v \sim N[0,\sigma_v^2].$$

The command for estimating the stochastic frontier model is

FRONTIER ; Lhs = y ; Rhs = one, ... $

The default form is the normal-half normal model. In this form, model estimates consist of $\boldsymbol{\beta}$, $\sigma = \sqrt{\sigma_v^2 + \sigma_u^2}$ and $\lambda = \sigma_u/\sigma_v$, and the usual set of diagnostic statistics for models fit by maximum likelihood. The other basic form in the ALS model is the exponential model,

$$u \sim \theta \exp(-\theta u),\ u \geq 0,$$

which has mean inefficiency $E[u] = 1/\theta$ and standard deviation, $\sigma_u = 1/\theta$. The parameters estimated in the exponential specification are $(\boldsymbol{\beta},\theta,\sigma_v)$. The estimate of σ_u is reported in the results as well.

The following illustrate the estimator, with a normal-half normal cost frontier and a normal-exponential production frontier. The coefficient estimates for the exponential cost frontier are shown as well.

FRONTIER ; Cost ; Lhs = lcn ; Rhs = x $
FRONTIER ; Cost ; Lhs = lcn; Rhs = x; Model = Exponential $

The stochastic frontier results include the standard output for MLEs The derived estimates of σ_u, σ_v, σ_u^2, σ_v^2 and σ are shown as well. The value of $\gamma = \sigma_u^2/\sigma^2$ is given for comparability with other parts of the literature. This ratio, which lies in (0,1) is sometimes reported as a variance decomposition of ε. However, the variance of $u = |U|$ is $(1 - 2/\pi)\sigma_u^2$, so the appropriate decomposition is $(1 - 2/\pi)\sigma_u^2/[\sigma_v^2 + (1 - 2/\pi)\sigma_u^2]$. This is the value shown next under γ in the results.

A likelihood ratio test against the hypothesis of no inefficiency follows the variance estimates. The degrees of freedom for the test are accumulated in the table.. The first is for σ_u in the base case. The second is for the heteroscedasticity terms in Var[u] when they are introduced in the model. Heteroscedasticity is developed in Chapters E63. The third term is for the truncation parameters in the normal-truncated normal model, also developed in the next chapter. The 'degrees of freedom for the inefficiency model' are the sum of these three terms. The likelihood ratio statistic is presented next. This is a nonstandard test because the null value of σ_u is on the boundary of the parameter space. Appropriate tables for the mixed chi squared test used here are given in Kodde and Palm (1986). (A copy of the relevant parts of the table is kept internally by the program. (See, also, Coelli, Rao and Battese (1998) for further details.)

Results for the normal-exponential model appear below. It is not possible to use a LR test to choose between these two models. The test has zero degrees of freedom – neither model is obtained by a restriction on the other. One possibility might be a Vuong (1989) statistic, which would be computed as

$$V = \frac{\sqrt{n}\ \overline{m}}{s_m},\ m_i = \log(f_i \mid normal) - \log(f_i \mid exponential)\ .$$

Results of the test are shown below the model results. The statistic is well inside the inconclusive region.

E62.7.1 Log Likelihoods for the Half Normal and Exponential Models

As will be evident below, different formulations of the log likelihood are most convenient for estimation of the different forms of the frontier models. (And, different authors sometimes parameterize the models differently.) The base case is the normal-half normal model. In this form, $v_i \sim \mathrm{N}[0,\sigma_v^2]$ and $u_i = |U_i|$ where $U_i \sim \mathrm{N}[0,\sigma_u^2]$. It follows that $f(u_i) = 2\phi(u_i/\sigma_u)$, $u_i \geq 0$. The density of $\varepsilon_i = v_i - u_i$ has been shown to be

$$f(\varepsilon_i) = (2/\sigma)\phi(\varepsilon_i/\sigma)\Phi(-\varepsilon_i\lambda/\sigma).$$

The most common form of the individual term in the log likelihood function (and the one used in *LIMDEP*) is

$$\log L_i = \tfrac{1}{2}\log(2/\pi) - \log\sigma - \tfrac{1}{2}(\varepsilon_i/\sigma)^2 + \log\Phi[-S\varepsilon_i\lambda/\sigma]$$

where
$$\varepsilon_i = y_i - \boldsymbol{\beta}'\mathbf{x}_i$$
$$\lambda = \sigma_u / \sigma_v,$$
$$\sigma^2 = \sigma_u^2 + \sigma_v^2,\ \sigma_v^2 = \sigma^2/(1+\lambda^2),\ \sigma_u^2 = \sigma^2\lambda^2/(1+\lambda^2)$$
$$S = +1 \text{ for production frontier, } -1 \text{ for cost frontier}$$

Olsen's transformation is used for maximizing the log likelihood. We reparameterize the function in terms of $\eta = 1/\sigma$ and $\boldsymbol{\gamma} = (1/\sigma)\boldsymbol{\beta}$. Then,

$$\log L_i = \tfrac{1}{2}\log(2/\pi) + \log\eta + \tfrac{1}{2}\omega_i^2 + \log\Phi(-S\omega_i\lambda)$$

where
$$\omega_i = \eta y_i - \gamma'x_i.$$

Define the functions
$$a_i = -S\omega_i\lambda$$
$$\delta_i = \phi(a_i)/\Phi(a_i)$$
$$\Delta_i = -a_i\delta_i = \delta_i^2.$$

Then, the gradient and Hessian are

$$\partial\log L_i / \partial\begin{pmatrix}\boldsymbol{\gamma}\\ \eta\\ \lambda\end{pmatrix} = \omega_i\begin{pmatrix}\mathbf{x}_i\\ -y_i\\ 0\end{pmatrix} + \delta_i S\begin{pmatrix}\lambda\mathbf{x}_i\\ -\lambda y_i\\ \omega_i\end{pmatrix} + \begin{pmatrix}0\\ 1/\eta\\ 0\end{pmatrix}$$

$$\partial^2\log L_i / \partial\begin{pmatrix}\boldsymbol{\gamma}\\ \eta\\ \lambda\end{pmatrix}\partial\begin{pmatrix}\boldsymbol{\gamma}\\ \eta\\ \lambda\end{pmatrix}' = -\begin{pmatrix}\mathbf{x}_i\mathbf{x}_i' & \mathbf{0} & 0\\ -y_i\mathbf{x}_i' & y_i^2 & 0\\ \mathbf{0}' & 0 & 0\end{pmatrix} +$$

$$\Delta_i\begin{pmatrix}\lambda^2\mathbf{x}_i\mathbf{x}_i' & -\lambda^2 y_i\mathbf{x}_i & -\lambda\omega_i\mathbf{x}_i\\ -\lambda^2 y_i\mathbf{x}_i' & \lambda^2 y_i^2 & \lambda\omega_i y_i\\ -\lambda\omega_i\mathbf{x}' & \lambda\omega_i y_i & \omega_i^2\end{pmatrix} - \begin{pmatrix}\mathbf{0} & \mathbf{0} & -\delta_i S\mathbf{x}_i\\ \mathbf{0}' & 1/\eta^2 & \delta_i S y_i\\ -\delta_i S\mathbf{x}_i' & \delta_i S y_i & 0\end{pmatrix}$$

The log likelihood for the exponential model is

$$\log L_i = \log\theta + ½\theta^2\sigma_v^2 + \theta S\varepsilon_i + \log\Phi[-S\varepsilon_i/\sigma_v - \theta\sigma_v].$$

The parameter θ in the exponential model is $1/\sigma_u$. The Olsen transformation is not useful for this model. Define $c_i = -S\varepsilon_i/\sigma_v - \theta\sigma_v$, $\delta_i = \phi(c_i)$, $\Delta_i = -c_i\delta_i - \delta_i^2$ and $a_i = S\varepsilon_i/\sigma_v - \theta$. The gradient and Hessian for the exponential model are

$$\partial \log L_i / \partial \begin{pmatrix} \boldsymbol{\beta} \\ \theta \\ \sigma_v \end{pmatrix} = \delta_i \begin{pmatrix} S\mathbf{x}_i / \sigma_v \\ -\sigma_v \\ S\varepsilon_i / \sigma_v^2 - \theta \end{pmatrix} + \begin{pmatrix} -\theta S\mathbf{x}_i \\ 1/\theta + \theta\sigma_v^2 + S\varepsilon_i \\ \theta^2\sigma_v \end{pmatrix}$$

$$\partial^2 \log L_i / \partial \begin{pmatrix} \boldsymbol{\beta} \\ \theta \\ \sigma_v \end{pmatrix} \begin{pmatrix} \boldsymbol{\beta} \\ \theta \\ \sigma_v \end{pmatrix}' = \Delta_i \begin{pmatrix} \mathbf{x}_i\mathbf{x}_i' / \sigma_v^2 & -S\mathbf{x}_i & a_i S\mathbf{x}_i / \sigma_v \\ -S\mathbf{x}_i' & \sigma_v^2 & -a\sigma_v \\ a_i S\mathbf{x}_i' / \sigma_v & -a_i\sigma_v & a_i^2 \end{pmatrix}$$
$$+ \begin{pmatrix} 0 & -S\mathbf{x}_i & -\delta_i S\mathbf{x}_i \\ -S\mathbf{x}_i' & -1/\theta^2 + \sigma_v^2 & 2\theta\sigma_v - \delta_i \\ -\delta_i S\mathbf{x}_i' & 2\theta\sigma_v - \delta_i & \theta^2 - 2\delta_i S\varepsilon_i / \sigma_v^3 \end{pmatrix}$$

E62.7.2 Alternative Parameterization

Some treatments of the normal-half normal model (e.g., Coelli (1996b)) use the alternative parameterization $\gamma = \sigma_u^2 / \sigma^2$ in the formulation of the log likelihood. This does not change the model, since it is a one to one transformation of the parameters;

$$\lambda = \sqrt{\frac{\gamma}{1-\gamma}}\,.$$

The parameterization in terms of λ is more convenient but does not produce different results.

E62.7.3 Variance Estimator in Frontier 4.1

A number of researchers have used Tim Coelli's (1996b) Frontier 4.1 program for estimation of stochastic frontier models. Frontier 4.1 and *LIMDEP* use different methods for computing estimators of the asymptotic covariance matrix of the ML estimator. *LIMDEP* uses either the BHHH estimator or the negative inverse of the Hessian. Frontier 4.1 used the weighting matrix used by the DFP algorithm to approximate the inverse Hessian during the iterations. As a general proposition, we recommend against this 'estimator,' and never use it. There is no theoretical assurance of its accuracy if convergence is reached in a finite number of iterations. Nonetheless, we have been asked about this many times. In the interest of methodological advance, *LIMDEP* provides a command switch,

; F41

that will invoke this estimator. (This is only provided for the stochastic frontier estimators.) No indication is given in the output that this option has been used.

E62.8 Estimating Inefficiency and Efficiency Measures

The main objectives of fitting the frontier models is to estimate the inefficiency terms in the stochastic model, u_i, by observation. The Jondrow estimator of $E[u|v\text{-}u]$ is the standard estimator. This is

$$\hat{E}[u\,|\,\varepsilon] = \frac{\sigma\lambda}{1+\lambda^2}\left[\frac{\phi(w)}{1-\Phi(w)} - w\right],\ \varepsilon = v \pm u\ ,\ w = S\varepsilon\lambda/\sigma.$$

(This is an indirect estimator of u. Unfortunately, it is not possible to estimate u_i directly from any observed sample information. The various surveys noted earlier discuss the computation of and properties of this estimator.) The counterpart for the normal-exponential model is

$$\hat{E}[u\,|\,\varepsilon] = \sigma_v\left[\frac{\phi(w)}{1-\Phi(w)} - w\right],\ w = (S\varepsilon/\sigma_v + \theta\sigma_v).$$

These are computed and saved as new variables in your data set with

; Eff = variable name

The **; List** specification will also request a listing of this variable. This form is used for all distributions and all variations of the stochastic frontier model.

By adding **; Eff = u** to the frontier command, then

KERNEL ; Rhs = u $

we obtain the results below. (We also added the title to the command with **; Title = …**) Note an important element of the estimation. The 'Standard Deviation' reported below is 0.054895, whereas the estimate of σ_u is 0.13746. The difference arises because the 0.054895 is an estimate of the standard deviation of $E[u|\varepsilon]$, not the standard deviation of u.

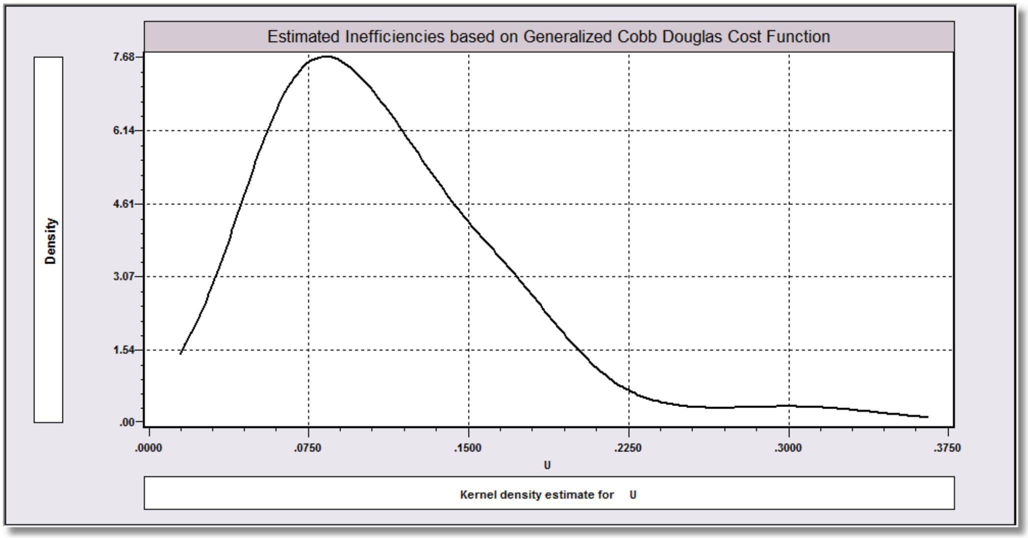

Figure E62.4 Analysis of Estimated Inefficiencies

E62.8.1 Estimating Technical or Cost Efficiency

One might be interested in estimating the 'efficiency' of the individuals in the sample. The model is usually specified in logs, of the form

$$\log y = \boldsymbol{\beta}'\mathbf{x} + v - u.$$

Under this assumption, the efficiency of the individual would be

$$EFF = \frac{y}{Optimal\ y} \approx \text{Exp}(-u)$$

This can be obtained with

; Techeff = the variable name

or **; Costeff = the variable name**

if you estimate a cost frontier instead. You may compute both inefficiencies and efficiency measures in the same command. Figure E62.5 was obtained by adding

; Costeff = ecu

to the **FRONTIER** command, then requesting the kernel density estimator as before (with the title changed accordingly).

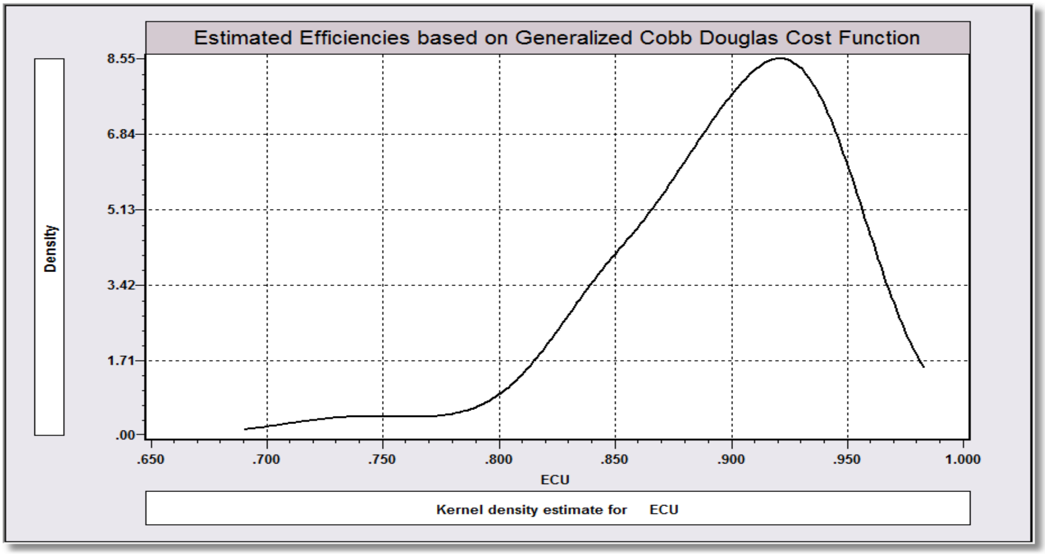

Figure E62.5 Estimated Cost Efficiencies

E62.8.2 Confidence Intervals for Inefficiency and Efficiency Estimates

Horrace and Schmidt (1996, 2000) suggest a useful extension of the Jondrow result. JLMS have shown that the distribution of $u_i|\varepsilon_i$ is that of a $N[\mu_i^*,\sigma^*]$ random variable, truncated from the left at zero, where $\mu_i^* = -\varepsilon_i\lambda^2/(1+\lambda^2)$ and $\sigma^* = \sigma\lambda/(1+\lambda^2)$. This result and standard results for the truncated normal distribution (see, e.g., Greene (2011)) can be used to obtain the conditional mean and variance of $u_i|\varepsilon_i$. With these in hand, one can construct some of the features of the distribution of $u_i|\varepsilon_i$ or $E[TE_i|\varepsilon_i] = E[\exp(-u_i|\varepsilon_i]$. The literature on this subject, including the important contributions of Bera and Sharma (1999) and Kim and Schmidt (2000) refer generally to ‘confidence intervals’ for $u_i|\varepsilon_i$. For reasons that will be clear shortly, we will not use that term – at least not yet, until we have made more precise what we are estimating.

For locating 100(1-α)% of the conditional distribution of $u_i|\varepsilon_i$, we use the following system of equations

$$\sigma^2 \;=\; \sigma_v^{\,2} + \sigma_u^{\,2}$$

$$\lambda \;=\; \sigma_u/\sigma_v$$

$$\mu_i^* \;=\; -\varepsilon_i\sigma_u^{\,2}/\sigma^2 = -\varepsilon_i\lambda^2/(1+\lambda^2)$$

$$\sigma^* \;=\; \sigma_u\sigma_v/\sigma = \sigma\lambda/(1+\lambda^2)$$

$$LB_i = \mu_i^* + \sigma^*\Phi^{-1}\left[1-(1-\tfrac{\alpha}{2})\Phi\left(\mu_i^*/\sigma^*\right)\right]$$

$$UB_i = \mu_i^* + \sigma^*\Phi^{-1}\left[1-\tfrac{\alpha}{2}\Phi\left(\mu_i^*/\sigma^*\right)\right]$$

Then, if the elements were the true parameters, the region $[LB_i,UB_i]$ would encompass 100(1-α)% of the distribution of $u_i|\varepsilon_i$. For constructing ‘confidence intervals’ for technical efficiency, $TE_i|\varepsilon_i$, it is necessary only to compute $TEUB_i = \exp(-LB_i)$ and $TELB_i = \exp(-UB_i)$.

We note two caveats about the estimator. First, the received papers based on classical methods have labeled this a *confidence interval* for u_i. However, it is a range that encompasses 100(1-α)% of the probability in the *conditional* distribution of $u_i|\varepsilon_i$. based on $E[u_i|\varepsilon_i]$, not u_i, itself. The interval is 'centered' at the estimator of the conditional mean, $E[u_i|\varepsilon_i]$, not the estimator of u_i, itself, as a conventional 'confidence interval' would be. The estimator is actually characterizing the conditional distribution of $u_i|\varepsilon_i$, not constructing any kind of interval that brackets a particular u_i – that is not possible. Second, these limits are conditioned on known values of the parameters, so they ignore any variation in the parameter estimates used to construct them. Thus, we regard this as a minimal width interval.

You can request computation of these lower and upper bounds by adding

; CI(100(1 - α)) = lower, upper

where 100(1-α) is one of 90, 95, or 99 and *lower*, *upper* are names for two variables that will be created. You may use this feature with **; Eff = variable** or **; Techeff = variable** (or **; Costeff = variable** for a cost frontier). If you have both **; Eff** and **; Techeff** in the command, the confidence intervals are computed for **; Techeff**. (You can obtain the interval for **; Eff** in this case by computing the negatives of the logs with **CREATE**.)

We obtained these bounds for our cost function with

; Costeff = euc ; CI(95) = eucl,eucu

We followed the estimation with

PLOT ; Rhs = eucl,ecu,eucu
; Title = Upper and Lower Bound Estimates of Cost Efficiency
; Vaxis = Cost Efficiency$

to obtain Figure E62.6.

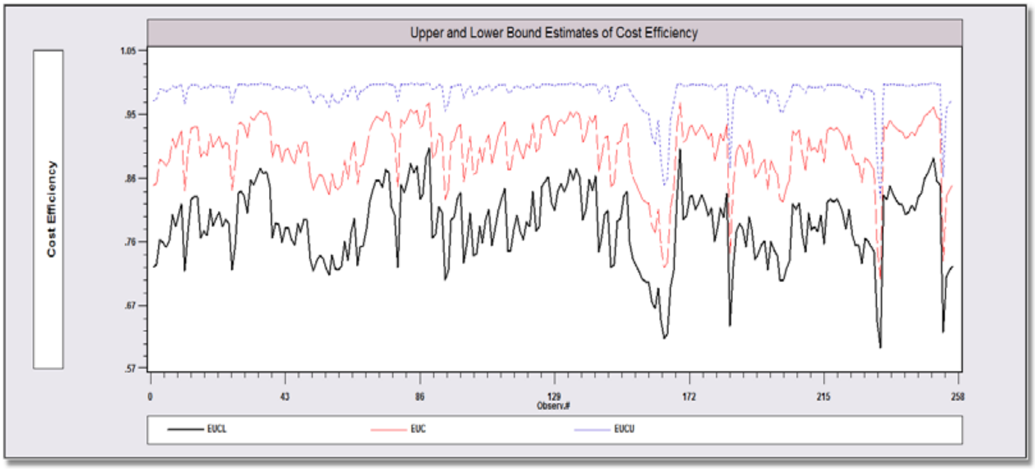

Figure E62.6 Lower and Upper Bound Estimates of Cost Efficiency

The centipede plot is also a useful device in this context. The following redraws Figure E62.6 using a different view for the lower and upper bounds

```
CREATE     ; Firm_i = Trn(1,1) $
PLOT       ; Lhs = firm_i ; Rhs = eucl,eucu
           ; Centipede ; Endpoints = 0,260 ; Grid
           ; Title = Confidence Limits for Cost Efficiency $
```

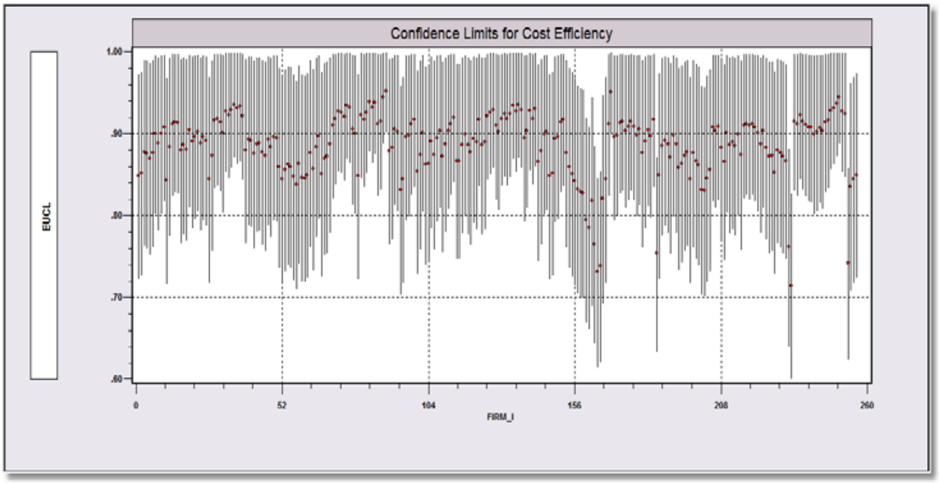

Figure E62.7 Centipede Plot of Efficiency Bounds

E62.8.3 Partial Effects on Efficiencies

The variables in the production or cost frontier function begin with either the inputs for the production model or input prices and outputs in the cost model. Analyses of how these variables affect technical or cost efficiency are not likely to be particularly revealing. However, if the function includes environmental variables (we call these z_i), it might be of interest to examine how variation in these impacts efficiency. For our example, we consider

$$\text{Log}(Cost/P_p) = \alpha + \beta_q \log Q + \beta_{qq} \log^2 Q + \Sigma_k\beta_k \log(P_k/P_p)$$
$$+ \delta_L \textit{load factor} + \delta_N \textit{nodes} + \delta_S \textit{Log stage length} + v + u$$

In this case, it might be interesting to examine how increased load factor, route complexity, or stage length impact efficiency.

Expressions for the technical inefficiency values appear at the beginning of Section E62.8. In those expressions, we will use

$$\textit{Efficiency} = \exp\{-\hat{E}[u\,|\,\varepsilon]\}.$$

The two expressions for the normal and exponential models are functions of a $w(\varepsilon)$ that is specific to the model. Each may be written as

$$\textit{Efficiency} = \exp\{-\tau_m A[w_m(\varepsilon)]\}$$

Where m = half normal or exponential, $\tau_m = \sigma\lambda/(1+\lambda^2)$ for the half normal and $1/\sigma_v$ for the exponential, and w_m is defined earlier. We now suppose that

$$\varepsilon = y - \boldsymbol{\beta}'\mathbf{x} - \boldsymbol{\delta}'\mathbf{z}$$

where **x** is the theoretical inputs to the goal and **z** are the environmental variables. We require the derivatives with respect to **z**. For convenience, let $W = -w$ and exploit the symmetry of the normal density. Then, $A[w_m(\varepsilon)] = [\phi(W)/\Phi(W) + W]$. The derivative is

$$\partial Efficiency/\partial\mathbf{z} = Efficiency \times -\tau_m \times dA(W)/dW \times -1 \times \partial w_m/\partial\varepsilon \times -\boldsymbol{\delta}.$$

The two terms that we need to complete the derivation are $\partial w_m/\partial\varepsilon = S\lambda/\sigma$ for the half normal model and S/σ_v for the exponential model and

$$\frac{dA(W)}{dW} = \left[1 - \frac{W\phi(W)}{\Phi(W)} - \left(\frac{\phi(W)}{\Phi(W)}\right)^2\right] = D(W).$$

Collecting terms,

$$\frac{\partial Efficiency}{\partial z} = Efficiency \times D(W) \times \begin{pmatrix} \lambda^2/(1+\lambda^2) \\ or \\ 1 \end{pmatrix} \times S \times (-\boldsymbol{\delta})$$

We can sign this result, though the magnitude will be empirical. The first three terms are all between zero and one, as is their product. S is either +1 for a production frontier or -1 for a cost frontier. Thus, in total, the derivative is a fraction of the corresponding coefficient, which takes the same sign for a cost frontier and the opposite sign for a production frontier.

Partial derivatives and simulations are computed with **PARTIALS** and **SIMULATE**. The general approach would be

```
FRONTIER    ; Cost (optional)
            ; Lhs = goal variable
            ; Rhs = one, x variables, z variables $
```

The command might also contain **; Eff = variable**, **; Techeff = variable** or **; Costeff = variable**. Then, you may follow it with

```
     PARTIALS    ; Effects: variables desired ; other options $
or   SIMULATE    ; Scenario … all options $
```

The function analyzed in these two commands is the technical or cost efficiency,

$$Efficiency = \exp\{-\hat{E}[u \mid \varepsilon]\}.$$

The following demonstrates using the cost frontier, with variables *z* = (*load factor*, *log stage length*, *points served*). Data on *z* are missing for one of the firms.

```
CREATE      ; logstage = Log(stage) $
NAMELIST    ; x = one,ly,ly2,,lpkp,lplp,lpmp,lpep,lpfp
            ; z = loadfctr,logstage,points $
FRONTIER    ; Cost ; Lhs = lc ; Rhs = x,z
            ; Eff = u ; Costeff = euc ; CI(95) = eucl,eucu $
SIMULATE    ; Scenario: & loadfctr = .4(.025)1 ; Plot(ci) $
```

E62.8.4 Partial Effects of Model Variables on Efficiencies

The preceding has examined the partial effects with respect to **z** in the model

$$y = \boldsymbol{\beta}'\mathbf{x} + \boldsymbol{\delta}'\mathbf{z} + v\text{-}Su.$$

It was noted that partial effects with respect to **x** are not likely to be particularly interesting. Nonetheless, they could be computed.

NOTE: Partial effects of variables in the stochastic frontier efficiency models may be computed with respect to any variable in any model, regardless of where those variables appear in the model. That includes **x** in the original frontier model, **z** in the means of the truncated regression formats, and **z** in the variances of the heteroscedasticity models.

To continue the earlier example, the partial effect of Log*Q* could be computed in the cost function using

```
NAMELIST    ; x = one,lq,lq^2,lpmpp,lpfpp,lpepp,lplpp,lpkpp $
NAMELIST    ; z = loadfctr,logstage,points $
FRONTIER    ; Cost ; Lhs = lcp ; Rhs = x,z  $
PARTIALS    ; Effects : lq ; summary $
```

Note that the specification will correctly account for the fact that the square of Log*Q* appears in the cost function when it computes the partial effects.

E62.8.5 Examining Ranks of Inefficiencies

Researchers often analyze outcome data in which the absolute values of the inefficiencies are not necessarily of interest. Rather, it is the ranking of observations that they wish to analyze. The WHO analysis of health care attainment (see Section E62.4.2) is a prominent example. *LIMDEP* provides several tools for examining ranks of inefficiencies.

First, to rank the raw observations on efficiency or inefficiency, use

```
CREATE      ; rank variable = Rnk(variable) $
```

The Rnk function sorts the data for you and creates the ranking variable. The observation with the highest value gets the rank of one. The lowest gets a rank of *n*. Note, tied observations do not get the same rank. Tied observations are ranked in the order in which they appear in the data. For example, in a sample of 100, if 10 observations are tied for third place, they will receive ranks 3 through 12.

Two **CALC** functions provide descriptive measures for ranks. For two sets of ranks, the Spearman rank correlation coefficient is computed as

$$\rho = 1 - 6\ \Sigma_i d_i^2\ /n(n^2 - 1),$$

$$d_i = variable1_i - variable2_i$$

The function for computing this is

```
CALC        ; List ; Rkc(variable1,variable2) $
```

The rank correlation is a correlation coefficient, so it has a natural range of measurement. (See the application below.) For more than two sets of ranks, a useful statistic is Kendall's coefficient of concordance,

$$W = 12 \sum_{i=1}^{n} (S_i - \bar{S})^2/[nK^2(n^2 - 1)]$$

where $S_i = \Sigma_k rank_{k,i}$.

To compute this measure, use

```
CALC        ; List ; Cnc(ranks1,...,ranksK) $
```

The concordance coefficient is not a correlation coefficient, so its magnitude is ambiguous. It can be used for a large sample test of discordance. Under the null hypothesis that the sets of ranks are independent, the statistic has a large sample chi squared distribution. In particular,

$$K(n\text{-}1)W \rightarrow \chi^2[K(n\text{-}1)].$$

To illustrate these computations, we have analyzed the WHO data described in Section E62.4.2. We have fit identical stochastic frontier models for the two attainment variables, *lcomp*, the log of the composite measure, and *ldale*, the log of disability adjusted life expectancy. We then computed the ranks for the 191 countries and plotted the ranks for the two measures as well as the raw efficiency measures. The simple correlation for the efficiency measures and the rank correlation for the ranks are displayed. The commands are as follows:

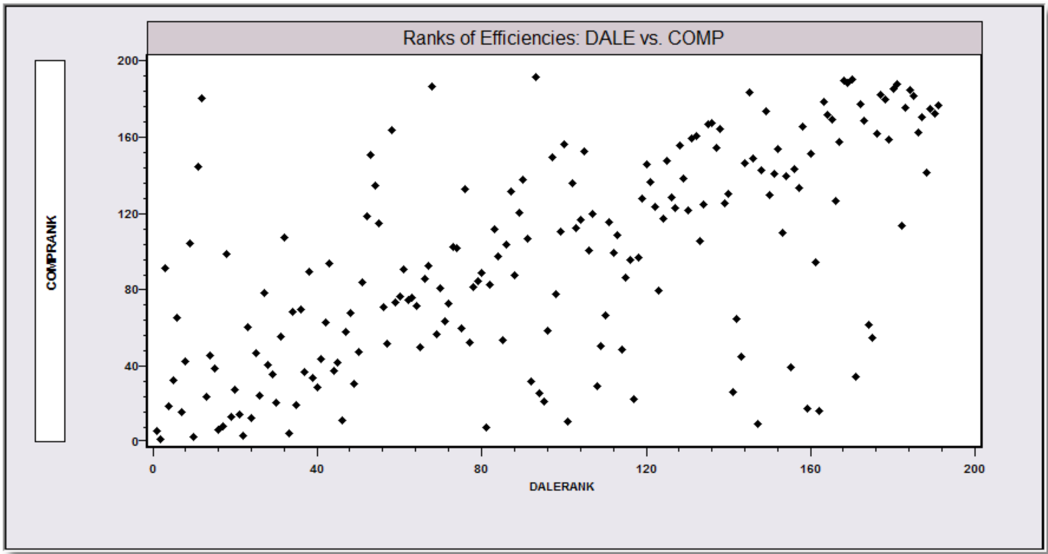

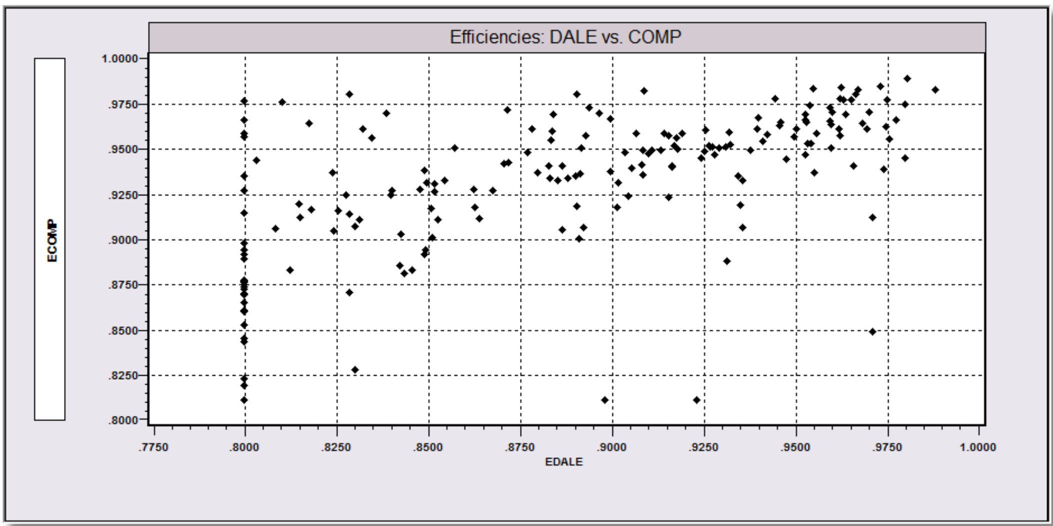

Figure E62.10 Ranks and Estimates of Efficiency

E62.9 Partially Nonparametric Stochastic Frontier Model

The stochastic frontier is fully parametric in both the deterministic part of the frontier and the distribution of the components of ε_i. This section examines a partially nonparametric model of the form

$$y = g(\mathbf{x},\mathbf{z}) + v - Su.$$

The estimator is based on the locally linear regression in Section E9.5. The underlying logic is the result that in the stochastic frontier model, apart from the constant term, OLS consistently estimates the slope parameters of the model and estimates the constant term with a known bias. For the constant, a, the bias is E[u], the unconditional mean, which in the stochastic frontier model is

$$\text{E}[u] = \sigma_u\sqrt{2/\pi}\,.$$

Continuing this approach, then, the least squares residuals estimate ε_i + E[u]. In addition, the least squares residual variance, $\mathbf{e}'\mathbf{e}/n$, consistently estimates Var[ε_i] = $\theta^2 = \sigma_v^2 + [(1 - 2/\pi)\sigma_u^2]$. The implication is that the only parameter remaining to estimate is σ_u^2. In Section E62.6.2, we used the third moment of the OLS residuals and the method of moments to estimate σ_u, then used this estimate to estimate α, the constant term in the frontier function.

The approach proposed here uses this same method with three differences.

1. The residuals used to compute the variance estimator are based on a locally linear, nonparametric estimator of the deterministic function.

2. The remaining parameter to be estimated in this case is λ rather than σ_u. We will base the estimation on the result $\sigma_u^2 = \sigma^2\lambda^2/(1+\lambda^2)$.

3. The approach will be based on a maximum likelihood estimator rather than the method of moments.

Estimation uses the following steps: We begin with estimation of the conventional normal-half normal frontier model with a linear frontier function in order to obtain an initial estimator of λ and of θ^2. The LOWESS estimator developed in Section E9.5 is then employed to estimate g(x,z) for each point in the sample. The residuals from the estimated functions are used with the estimate of θ^2 for estimation of λ. With θ^2 and λ in hand, we can compute the constant term, a set of residuals, and the JLMS estimators of technical or cost efficiency. Technical details appear in Section E62.9.2.

E62.9.1 Application

We have reestimated the airlines cost frontier with the semiparametric estimator. The frontier functions differ noticeably, primarily in the parameter estimates that are statistically insignificant. The kernel estimators suggest, however, that the difference in the estimates of inefficiency are quite modest. The descriptive statistics suggest the same pattern. The final plot shows more graphically how the nonparametric function has changed the estimates. The fact that most of the estimates from the nonparametric estimator lie below the 45 degree line is consistent with the appearance that generally, they are smaller than the parametric values. The last set of results are the ordinary (Pearson) correlation and Kendall's tau.

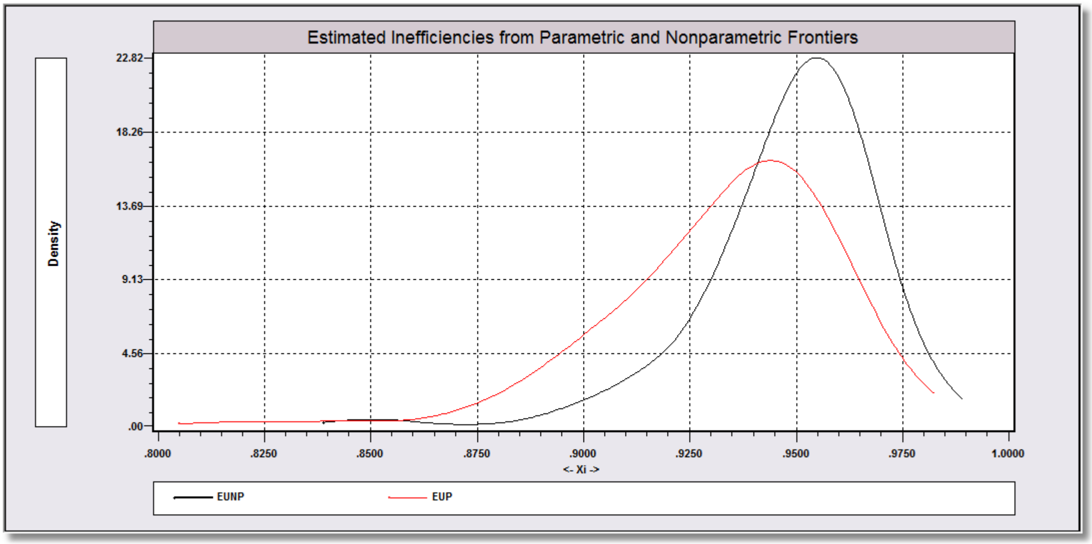

Figure E62.11 Kernel Estimators of Inefficiency Distributions

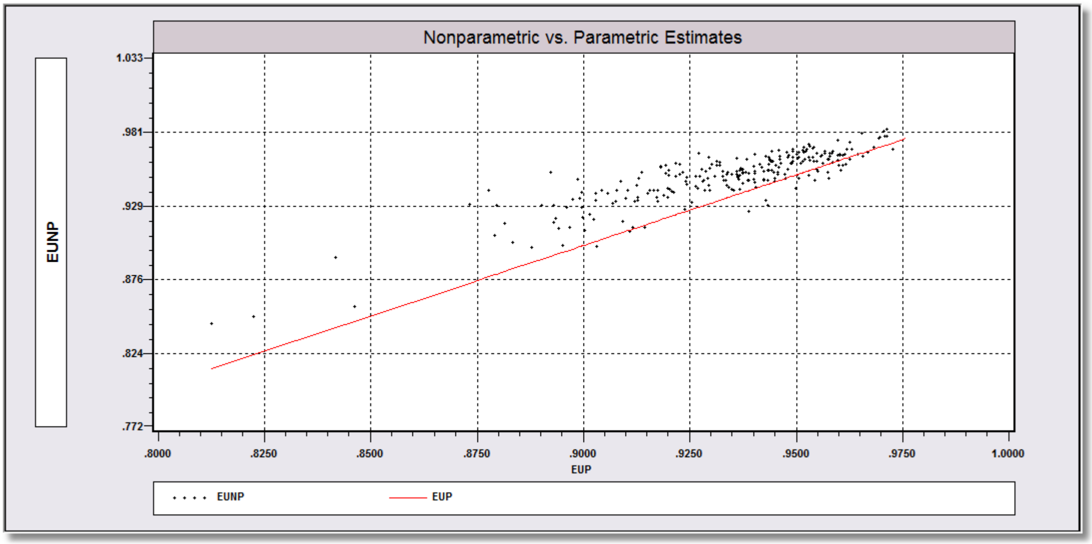

Figure E62.12 Plot of Nonparametric Estimates vs. Parametric Estimates

E62.9.2 Technical Details

The log likelihood function for the normal-half normal model is the sum of

$$\log L_i = \tfrac{1}{2}\log(2/\pi) - \log\sigma - \tfrac{1}{2}(\varepsilon_i/\sigma)^2 + \log\Phi[-S\varepsilon_i\lambda/\sigma].$$

The value of $\theta^2 = \sigma_v^2 + [(1 - 2/\pi)\sigma_u^2]$is estimated using the squared LOWESS residuals; it is the sample variance = q^2. The LOWESS residuals, themselves, are estimates of ε_i + E[u_i]. With q^2 and the residuals in hand, the log likelihood is a function only of λ. During the iteration, we compute

$$a = \lambda/(1+\lambda^2)^{1/2},$$

$$s^2 = q^2 / (1 - (2/\pi)a^2), \text{ then } s$$

$$m = as\sqrt{2/\pi}$$

$$e_i = \text{residual}_i - m.$$

These residuals and s are used to compute logL_i and the derivative with respect to λ. This estimation step provides the estimator of λ that we need to compute the efficiencies. After estimation of λ, computation of the JLMS estimates of inefficiency is done the same as in the parametric form of the model, using the LOWESS residuals.

E62.10 The Normal-Gamma Model

The normal-gamma model is the remaining distributional form of the stochastic frontier model. Under this specification,

$$u_i \sim \frac{\theta^P \exp(-\theta u_i) u_i^{P-1}}{\Gamma(P)}, \; u_i \geq 0, P > 0, \theta > 0.$$

This model is more flexible than the half normal or exponential model in that with two parameters, it allows the both the shape and location to vary independently. (The truncation model does likewise, but it is considerably more difficult to estimate.) To specify the gamma model, use

; Model = Gamma (or ; Model = G)

The normal-gamma model is estimated by the method of simulated maximum likelihood. (See Greene (2000b) and the details in Section E62.10.2.) The counterpart to the JLMS estimator of the inefficiency, $E[u|\varepsilon]$ must also be estimated by simulation.

E62.10.1 Application of the Normal-Gamma Model

We illustrate the gamma model by fitting a cost frontier model with normal-gamma inefficiency. For comparison, we have also fit the exponential model, which results when *P* is constrained to equal one. (The exponential model is fit directly by its own log likelihood, not by constraining *P* to equal one in the gamma model.) We have also computed the inefficiencies for the two models, and plotted kernel density estimators to compare them. The commands are

```
FRONTIER   ; Lhs   = lc ; Rhs = x ; Cost ; Model = Gamma ; Costeff = eucg
           ; Pts   = 50 ; Halton $
FRONTIER   ; Lhs   = lc ; Rhs = x ; Cost ; Model = Exponential ; Costeff = euce $
KERNEL     ; Rhs   = eucg,euce
           ; Title = Kernel Density Estimates for E[u|e,exponential and gamma] $
```

We note by the Wald and likelihood ratio tests, we cannot reject the hypothesis of the exponential model (*P* is close to one). The similarity of the kernel density estimators is consistent with this finding.

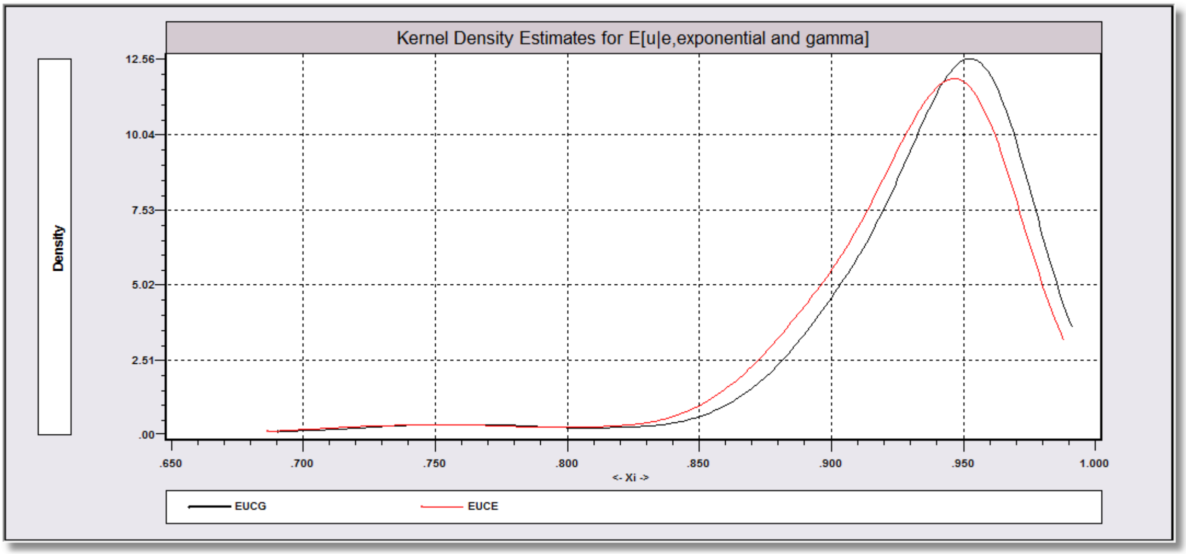

Figure E62.13 Kernel Density Estimates for Gamma and Exponential Inefficiencies

E62.10.2 Technical Details on Normal-Gamma Model

The log likelihood for this model is equal to the log likelihood for the normal-exponential model plus a term that is produced by the difference between the exponential and the gamma distributions;

$$\text{Log } L = \text{Log } L(\textit{exponential}) + n[(P\text{-}1)\log\theta - \log\Gamma(P)] + \Sigma_i \log h(P\text{-}1,\varepsilon_i)$$

where

$$h(r,\varepsilon_i) = \frac{\int_0^\infty z^r (1/\sigma_v)\phi((z-\eta_i)/\sigma_v)dz}{\int_0^\infty (1/\sigma_v)\phi((z-\eta_i)/\sigma_v)dz}, \ \eta_i = -\varepsilon_i - \theta\sigma_v^2.$$

The normal-exponential model results if $P = 1$. Computation of the function $h(r,\varepsilon_i)$ is the obstacle to estimation. Beckers and Hammond (1987) derived a closed form expression, but the result has never been operationalized – it is complex in the extreme. Greene (1990) attempted estimation by using a crude approximation with Simpson's rule, but failed to obtain reasonable results. (See Ritter and Simar (1997).)

A satisfactory solution is produced by the technique of maximum simulated likelihood. The integral and its derivatives can be estimated consistently by Monte Carlo simulation. The crucial result is that $h(r,\varepsilon_i)$ is the expectation of a random variable;

$$h(r,\varepsilon_i) = E[z^r \mid z \geq 0]$$

where

$$z \sim N[\eta_i, \sigma_v^2]$$

$$\eta_i = -\varepsilon_i - \theta\sigma_v^2$$

Therefore, $h(r,\varepsilon_i)$ is the expected value of z^r where z has a truncated at zero normal distribution. Thus, we estimate $h(r,\varepsilon_i)$ by using the mean of a sample of draws from this distribution. For given values of ε_i and η_i (i.e., y_i, $\mathbf{x}_i$, $\boldsymbol{\beta}$, σ_v, θ, r), $h(r,\varepsilon_i)$ is consistently estimated by

$$\hat{h}_i = \frac{1}{Q}\sum_{q-1}^{Q} z_{iq}^r$$

where z_{iq} is a random draw from the truncated normal distribution with mean parameter η_i and variance parameter σ_v. This produces the simulated log likelihood function

$$\text{Log } L_S = \text{Log } L(\textit{exponential}) + n[(P\text{-}1)\log\theta - \log\Gamma(P)] + \Sigma_i \log \hat{h}(P\text{-}1,\varepsilon_i)$$

which for a given set of draws is a smooth and continuous function of the parameters.

Random draws from the truncated distribution are obtained using Geweke's method as follows: Let

L = truncation point = 0 for this application

μ = the mean of untruncated distribution = $-\varepsilon_i - \theta\sigma_v^2$

σ = the standard deviation of the untruncated distribution = σ_v

$P_L = \Phi[(L - \mu) / \sigma]$

F = one draw from U[0,1]

$z = \mu + \sigma\Phi^{-1}[P_L + F\times(1 - P_L)]$

Then, z = the draw from the truncated distribution.

Collecting all terms, then, this produces the simulated log likelihood function:

$$\begin{aligned}\text{Log } L \;&=\; n\{\log\theta + \tfrac{1}{2}\sigma_v^2\theta^2\} + \Sigma_i\{\theta d\varepsilon_i + \log\Phi[-(d\varepsilon_i/\sigma_v + \theta\sigma_v)]\}\\ &+\; n[(P\text{-}1)\log\theta - \log\Gamma(P)]\\ &+\; \Sigma_i \log\left\{\frac{1}{Q}\sum_{q=1}^{Q}\left[\mu_i + \sigma_v\Phi^{-1}\left(F_{iq} + (1-F_{iq})\Phi\left(\frac{-\mu_i}{\sigma_v}\right)\right)\right]^{P-1}\right\}\end{aligned}$$

$$\varepsilon_i = y_i - \boldsymbol{\beta}'\mathbf{x}_i$$

$$\mu_i = -\varepsilon_i - \theta\sigma_v^2$$

and F_{iq} is a fixed set of Q draws from U[0,1] specific to the individual. Derivatives of $h(r,\varepsilon_i)$ and log $h(r,\varepsilon_i)$ are also estimated by simulation. The JLMS efficiency measure has the simple form

$$E[u|\varepsilon] = h(P,\varepsilon_i) / h(P\text{-}1,\varepsilon_i).$$

The final consideration is the method of obtaining the draws. The default method is to use the random number generators. Since this is a very computation intensive model, it is usually more efficient to use Halton draws – you can use many fewer Halton draws than random draws to obtain the same quality results. Halton draws are discussed in Section R24.7. To use Halton draws with this estimator, add

; Halton

to the command. The number of points for either method is specified with

; Pts = the desired number of draws

We have used this feature in the example in the previous section.

E62.11 Sample Selection in a Stochastic Frontier Model

This model is a counterpart to familiar models of sample selection. See Greene (2010) for details on the methodology. Additional results appear in Terza (2010). The model is a familiar sample selection form

$$\begin{aligned}
d^* &= \boldsymbol{\alpha}'\mathbf{z} + w, \; d = 1(d^* > 0) \\
y &= \boldsymbol{\beta}'\mathbf{x} + v - u \\
u &= |U| \text{ with } U \sim N[0,\sigma_u^2] \\
(v,w) &\sim \text{bivariate normal with } [(0,0),(\sigma_v^2, \rho\sigma_v, 1)] \\
(y,\mathbf{x}) & \quad \text{only observed when } d = 1.
\end{aligned}$$

Thus, the selection operates through the heterogeneity component of the production model, not the inefficiency. (Thus, observation is not viewed as a function of the level of inefficiency.)

The model is fit by maximum simulated likelihood. To request it, use *LIMDEP*'s usual format for sample selection models,

```
PROBIT     ; Lhs = d ; Rhs = variables in w ; Hold $
FRONTIER   ; Lhs = y ; Rhs = variables in x; Selection $
```

The model must be the base case, half normal, with no panel data application, no truncation, or heteroscedasticity, etc. You may control the simulations with **; Halton** and **; Pts** for the simulation. Efficiency and inefficiency estimates are saved as with other models with **; Eff** and **; Techeff**. However, observations in the nonselected part of the sample are given missing values (-999) for any of these computations. The **PARTIALS** and **SIMULATE** commands do not inherit the selection model – these commands are not available after fitting this model.

E62.11.1 Application

The following creates a data set that conforms exactly to the assumptions of the model.

```
CALC       ; Ran(123457) $
SAMPLE     ; 1-2000 $
CREATE     ; z1 = Rnn(0,1) ; z2 = Rnn(0,1) $
CREATE     ; v1 = Rnn(0,1) ; v2 = Rnn(0,1) $
CREATE     ; e1 = v1 ; e2 = .7071 * (v1+v2) $
CREATE     ; ds = z1 + z2 + e1 ; d = ds > 0 $
CREATE     ; u = Abs(Rnn(0,1)) ; x1 = Rnn(0,1) ; x2 = Rnn(0,1) $
CREATE     ; y = x1 + x2 + e2 - u $
PROBIT     ; Lhs = d ; Rhs = one,z1,z2 ; Hold $
FRONTIER   ; Lhs = y ; Rhs = one,x1,x2 ; Selection $
```

E62.11.2 Log Likelihood and Estimation Method

Write the model structure as

$$d^* = \boldsymbol{\alpha}'\mathbf{z} + w,\ w \sim N[0,1],\ d = 1(d^* > 0)$$

$$y = \boldsymbol{\beta}'\mathbf{x} + \sigma_v v - \sigma_u u$$

$$u = |U| \text{ with } U \sim N[0,1]$$

$$(v,w) \sim \text{bivariate normal with } [(0,0),(1,\rho,1)]$$

$$(y,\mathbf{x}) \quad \text{only observed when } d = 1.$$

(Note for convenience later, we have moved the scale parameters into the structural model.) To set up the estimator, we now write w in its conditional on v form,

$$w|v = \rho v + h \text{ where } h \sim N[0, (1 - \rho^2)] \text{ and } h \text{ is independent of } v.$$

Therefore, $d^*|v = \boldsymbol{\alpha}'\mathbf{z} + \rho v + h,\ d = 1(d^* > 0|v)$

Then, $\text{Prob}[d = 1 \text{ or } 0 \mid \mathbf{z},v] = \Phi\left[(2d-1)\left(\dfrac{\boldsymbol{\alpha}'\mathbf{z}+\rho v}{\sqrt{1-\rho^2}}\right)\right]$

For the selected observations, $d = 1$, conditioned on v, the joint density for y and d is the product of the marginals since conditioned on v, y and d are independent;

$$f(y, d = 1|\mathbf{x},\mathbf{z},v) = f(y|\mathbf{x},v)\ \text{Prob}(d = 1|\mathbf{z},v).$$

We have the second part above. For the first part,

$$y|\mathbf{x},v = (\boldsymbol{\beta}'\mathbf{x} + \sigma_v v) - \sigma_u u$$

where u is the truncation at zero of a standard normal variable, so $f(u) = 2\phi(u)$, $u \geq 0$. The Jacobian of the transformation from u to y is $1/\sigma_u$, so by the change of variable, the conditional density is

$$f(y \mid \mathbf{x},v) = \frac{2}{\sigma_u}\phi\left(\frac{(\boldsymbol{\beta}'\mathbf{x}+\sigma_v v)-y}{\sigma_u}\right), (\boldsymbol{\beta}'\mathbf{x}+\sigma_v v)-y \geq 0.$$

Therefore, the joint conditional density is

$$f(y, d=1 \mid \mathbf{x},\mathbf{z},v) = \frac{2}{\sigma_u}\phi\left(\frac{(\boldsymbol{\beta}'\mathbf{x}+\sigma_v v)-y}{\sigma_u}\right)\Phi\left(\frac{\boldsymbol{\alpha}'\mathbf{z}+\rho v}{\sqrt{1-\rho^2}}\right).$$

To obtain the unconditional density, it is necessary to integrate v out of the conditional density. Thus,

$$f(y,d=1\,|\,\mathbf{x},\mathbf{z}) = \int_v \frac{2}{\sigma_u}\phi\left(\frac{\sigma_v v-(y-\boldsymbol{\beta}'\mathbf{x}))}{\sigma_u}\right)\Phi\left(\frac{\boldsymbol{\alpha}'\mathbf{z}+\rho v}{\sqrt{1-\rho^2}}\right)f(v)dv.$$

The relevant term in the log likelihood is log $f(y,d=1|\mathbf{x},\mathbf{z})$. For the nonselected observations, the contribution to the log likelihood is the log of the unconditional probability of nonselection, which is

$$\text{Prob}(d = 0|\mathbf{z}) = \int_v \Phi\left[-\left(\frac{\boldsymbol{\alpha}'\mathbf{z}+\rho v}{\sqrt{1-\rho^2}}\right)\right]f(v)dv.$$

The integrals do not exist in closed form, so these terms cannot be evaluated as is. Before proceeding, we note the additional complication, $\boldsymbol{\beta}'\mathbf{x} + \sigma_v v - y = \sigma_u u > 0$, so the density $f(v)$ is not the standard normal that intuition might suggest; it is a truncated normal.

The integrals can be computed by simulation. By construction,

$$\int_v \frac{2}{\sigma_u}\phi\left(\frac{\boldsymbol{\beta}'\mathbf{x}+\sigma_v v-y)}{\sigma_u}\right)\Phi\left(\frac{\boldsymbol{\alpha}'\mathbf{z}+\rho v}{\sqrt{1-\rho^2}}\right)f(v)dv = E_v\left[\frac{2}{\sigma_u}\phi\left(\frac{\boldsymbol{\beta}'\mathbf{x}+\sigma_v v-y)}{\sigma_u}\right)\Phi\left(\frac{\boldsymbol{\alpha}'\mathbf{z}+\rho v}{\sqrt{1-\rho^2}}\right)\right]$$

so by sampling from the distribution of v, we can compute the function of v and average to obtain the integrals. In order to sample the draws on v, we note the implied truncation,

$$v \geq (y - \boldsymbol{\beta}'\mathbf{x})/\sigma_v \text{ or } v \geq \varepsilon/\sigma_v.$$

Draws from the truncated normal can be obtained using result (E-1) in Greene (2011). Let A equal a draw from the uniform (0,1) population. The desired draw from the truncated normal distribution will be

$$v_r = \Phi^{-1}\left[\Phi(\varepsilon/\sigma_v) + A_r\Phi(-\varepsilon/\sigma_v)\right].$$

Collecting all terms, then, the simulated log likelihood will be

$$\log L_S = \sum_i \log\frac{1}{R}\sum_{r=1}^{R}\left\{d_i\left[\frac{2}{\sigma_u}\phi\left(\frac{\boldsymbol{\beta}'\mathbf{x}+\sigma_v v_{ir}-y)}{\sigma_u}\right)\Phi\left(\frac{\boldsymbol{\alpha}'\mathbf{z}+\rho v_{ir}}{\sqrt{1-\rho^2}}\right)\right]+(1-d_i)\left[\Phi\left(\frac{-\boldsymbol{\alpha}'\mathbf{z}-\rho v_{ir}}{\sqrt{1-\rho^2}}\right)\right]\right\}$$

where the draws on v_{ir} are as shown above. Derivatives of this simulated log likelihood are obtained numerically using finite differences.

E63: Heteroscedasticity and Truncation in Stochastic Frontier Models

E63.1 Introduction

This chapter develops several extensions of the stochastic frontier model presented in Chapter E62. The four models considered here are as follows:

- Heteroscedasticity in v and/or u
- Truncated normal with nonzero, heterogeneous mean in the underlying U
- Heterogeneity in the parameter of the exponential or gamma distribution
- Amsler et al.'s 'scaling model'

E63.2 Heteroscedasticity and Heterogeneity

In the development of the frontier model, an important question concerns how to introduce observed heterogeneity into the specification. Suppose the vector of variables $\mathbf{z}_i$ contains the information. For example, in the airline data, we have data on load factor, stage length and number of points in the route map, that may also impact production, cost and efficiency. In the model proposed thus far, the only point at which one might introduce $\mathbf{z}_i$ appears to be in the goal function itself, which would become

$$y_i = \boldsymbol{\beta}'\mathbf{x}_i + \boldsymbol{\alpha}'\mathbf{z}_i + v_i - u_i.$$

This is a common approach. (See, e.g., Greene (2004a,b).) In this chapter, we present two other methods of introducing observed heterogeneity in the frontier model, in the variance parameters and in the mean of the underlying inefficiency.

E63.2.1 Heterogeneity in the Scale Parameters

A natural departure point is to allow observable variation in σ_v^2 and/or σ_u^2. For the first of these, the term heteroscedasticity is appropriate. (The papers by Hadri et al. (1999, 2003a,b) develop heteroscedasticity models for frontier specifications.) For the second of these, a result which seems routinely to be overlooked in the literature is that allowing σ_u^2 to vary over observations, call it $\sigma_{u,i}^2$, induces more than just heteroscedasticity. Unavoidably in all model specifications, when this parameter varies over individuals, then both the variance and the mean of u_i do also. For the half normal model, regardless of how $\sigma_{u,i}$ varies,

$$E[u_i] = \sigma_{u,i}\phi(0)/\Phi(0) = 0.79788\sigma_{u,i}.$$

A like result emerges in the truncated normal model. In the exponential model, the mean of u_i equals its standard deviation, while in the gamma model, it is a multiple, $P^{1/2}$, of it. Thus, in all cases, as regards u_i, the term heteroscedasticity, while not inappropriate, is nonetheless ambiguous. These models cannot be heteroscedastic without also having a heterogeneous mean. In what follows, therefore, we continue to use the familiar terminology, but we emphasize the nature of the model as well.

The models of scale heterogeneity may extend either variance parameter with the specification of the variance functions

$\mathrm{Var}[U|\mathbf{z}_i] = \sigma_{ui}^2 = \sigma_u^2 \exp(\boldsymbol{\gamma}'\mathbf{z}_i)$ (heteroscedastic)

$\mathrm{Var}[v|\mathbf{z}_i] = \sigma_v^2 = \sigma_v^2 \exp(\boldsymbol{\delta}'\mathbf{w}_i)$ (heteroscedastic)

$\mathrm{Var}[u|\mathbf{z}_i] = \sigma_u^2 \exp(\boldsymbol{\gamma}'\mathbf{z})$ and $\mathrm{Var}[v|\mathbf{z}_i] = \sigma_v^2 \exp(\boldsymbol{\delta}'\mathbf{w}_i)$ (doubly heteroscedastic)

There is no requirement that the same variables enter the two functions, and either or both may be heterogeneous. The model specification is

; Heteroscedasticity or ; Het

and either or both of

; Hfv = variables in the variance of v
; Hfu = variables in the variance of u

If either variance is not given, it is assumed to be constant. The variance function is the exponential format used throughout *LIMDEP* If either variance is unspecified, the implied model is $\sigma_{ji}^2 = \exp(\delta$ or $\gamma)$ which is the same as

; Hfv = one or ; Hfu = one

If both are unspecified, then the implied model

; Het ; Hfv = one ; Hfu = one

is the default, normal-half normal stochastic frontier model. It provides identical estimates. (Try it.) A constant (*one*) is automatically inserted into both lists if you do not include it. This form may be used with the normal-half normal and normal-truncated normal models.

E63.2.2 Exponential and Gamma Models with Heterogeneity

The one sided component of the normal-exponential and normal-gamma models is parameterized with a scale parameter, θ, which is thus far taken to be a constant. In these models,

$$E[u_i] = P/\theta = P\times\sigma_u$$

where $P = 1$ in the exponential model. The exponential heteroscedasticity model for u_i is extended to these two models by using

$$\theta_i = \theta \exp(-\boldsymbol{\delta}'\mathbf{z}_i).$$

With this parameterization, the estimates from this model will be comparable to those for the half normal and truncated normal models. (See the examples below.) To request this form, use

; Het ; Hfu = the list of variables.

The list should not contain a constant term, *one*. This may be used in all implementations of the exponential gamma model. Note, however, that in the panel data settings, the parameter is assumed to be time invariant. The values for $\mathbf{z}_i$ are taken from the data record for the last period for firm *i*. We will return to this subject below. The symmetric component, *v*, may also be heteroscedastic, as in the other models, with

; Hfv = list of variables.

E63.2.3 Efficiency Estimation with Heteroscedasticity

This extension does not change the computation of measures of efficiency or inefficiency. The central results are the JLMS estimators,

$$\hat{E}[u\,|\,\varepsilon] = \frac{\sigma\lambda}{1+\lambda^2}\left[\frac{\phi(w)}{1-\Phi(w)} - w\right],\ \varepsilon = v - u,\ w = S\varepsilon\lambda/\sigma$$

for the half normal models and

$$\hat{E}[u\,|\,\varepsilon] = \sigma_v\left[\frac{\phi(w)}{1-\Phi(w)} - w\right],\ w = (S\varepsilon/\sigma_v + \theta\sigma_v)$$

for the exponential models. These functions are evaluated for each observation at

$$\lambda_i = \sigma_{u,i} / \sigma_{v,i}$$

and

$$\sigma_i^2 = \sigma_{u,i}^2 + \sigma_{v,i}^2$$

for the half normal model and $\sigma_{v,i}$ and θ_i likewise in the exponential and gamma models.

E63.2.4 Application

The estimates below show a production frontier based on the six inputs. The second set of results presents the heteroscedastic model, with the variance of *v* a function of the log of the average stage length and the variance of *u* depending on the load factor and the log of the number of points served. We examine the efficiency results, then compute the average partial effects of the environmental variables on technical efficiency.

The figure below displays the kernel density estimators for the two sets of estimated inefficiencies. The upper one is for the heteroscedastic model. The figure shows clearly the influence of the heterogeneity. The means of the two distributions are virtually the same, but the variance in the heteroscedastic model is considerably higher.

E63.2.5 Technical Details

For the models with heteroscedasticity, we revert to the original structural form of the model to form the log likelihoods. For the normal-half normal model, for example, we use

$$\log L_i = -\log(2/\pi) - \log\sigma_i - ½(\varepsilon_i/\sigma_i)^2 + \log\Phi[-S\varepsilon_i\lambda_i/\sigma_i]$$

where

$$\sigma_i = \sqrt{\sigma_{ui}^2 + \sigma_{ui}^2}$$

$$\lambda_i = \sigma_{ui} / \sigma_{vi}$$

$$\sigma_{ui}^2 = \exp(\boldsymbol{\gamma}'\mathbf{z}_i)$$

$$\sigma_{vi}^2 = \exp(\boldsymbol{\delta}'\mathbf{w}_i),$$

where S = +1 for a production frontier and -1 for a cost frontier. Likewise, for the truncation model,

$$\log L_i = -½\log 2\pi - \log\sigma_i - ½[(S\varepsilon_i + \mu)/\sigma_i]^2$$

$$+ \log\Phi[(\mu/\lambda_i - S\varepsilon_i\lambda_i)/\sigma_i] - \log\Phi(\mu/\sigma_{u.i}).$$

We build the structure of the model with two freely varying variance parameters, $\sigma_{u,i}$ and $\sigma_{v,i}$, rather than the reduced form parameters λ and σ. The use of λ_i as a free parameter would not be appropriate because the numerator and denominator of λ_i must be allowed to vary freely and independently. A like consideration rules out the composed parameter σ_i. The formulation of the log likelihood and its derivatives follows the results given earlier for the homogeneous cases. Where the derivatives with respect to $\boldsymbol{\gamma}$ and $\boldsymbol{\delta}$ emerge, we use the chain rule to differentiate with respect to $\sigma_{u,i}$ and $\sigma_{v,i}$ first. Note that the independent parameter σ_u and σ_v have been absorbed into the exponential functions. Thus, σ_v is $\exp(\gamma_0)$. This ensures that the variances are always positive.

The normal-gamma and normal-exponential models are not reparameterized. The log likelihood for the exponential model with variance heterogeneity is

$$\log L_i = \log\theta_i + ½\theta_i^2\sigma_{i,v}^2 + \theta_i S\varepsilon_i + \log\Phi[-S\varepsilon_i/\sigma_{i,v} - \theta_i\sigma_{i,v}]$$

where

$$\theta_i = \theta\exp(-\boldsymbol{\gamma}'\mathbf{z}_i)$$

and

$$\sigma_{i,v} = \sigma_v\exp(\boldsymbol{\delta}'\mathbf{w}_i).$$

The sign change in θ_i is used to make the normal-exponential model comparable to the normal-half normal model, since $\text{Var}[u_i] = 1/\theta_i^2$.

E63.3 The Normal-Truncated Normal Model

The normal-truncated normal model relaxes an implicit restriction in the normal-half normal model, that the mean of the underlying inefficiency variable is zero. The extended model is obtained by allowing μ, the mean of U, to be nonzero;

$$y = \boldsymbol{\beta}'\mathbf{x} + v - u, u = |U|$$
$$U \sim N[\mu,\sigma_u^2]$$
$$v \sim N[0,\sigma_v^2]$$

(With a constant term in the model, no similar parameter can be introduced into the distribution of v.) The command for estimating this model is

```
FRONTIER    ; Lhs = dependent variable
            ; Rhs = one, other independent variables
            ; Model = Truncated Normal $ (or ; Model = T)
```

The specification of the cost frontier and the estimator of technical inefficiency are requested in the same fashion,

; Cost

and **; Eff = variable name**

Other optional parts of the command are the same as that for the normal-half normal model.

We note, this model is extremely volatile, owing to the rather weak identification of the parameter μ. It is difficult to distinguish the mean from the variance parameter in this model. In the truncation model,

$$E[u_i] = \mu + \sigma_u\phi(\mu/\sigma_u)/\Phi(\mu/\sigma_u).$$

This implies that σ_u and μ can covary so as to produce little or no variation in the expectation of u_i. The likelihood is not a function of the square of u_i, so this mean is the only source of information about these two parameters. (By totally differentiating the expected value, one can solve for the implicit relationship, $d\mu/d\sigma_u$ that produces $dE[u_i] = 0$.) The example below suggests how this aspect of the model influences (or fails to) the estimates of inefficiency. For purposes of the JLMS estimator for the half normal model, when the mean of U is a nonzero μ, the argument to the function is replaced with

$$w = S\varepsilon\lambda/\sigma - \mu/(\sigma\lambda).$$

The remaining part of the computation is the same.

E63.3.1 Application

The results below show estimates of a stochastic cost frontier with the half normal then the truncated normal specifications. The additional parameterization appears to have had a large impact on the results; the estimates are noticeably different. The plot of the two sets of inefficiency estimates suggest that the effect of the new specification has been little more than to double the estimated values from the model – the dashed line in the figure shows the function $u_{TN} = 2u_{HN}$. The extremely large estimates of μ and the standard error do suggest that something is amiss with the model, however.

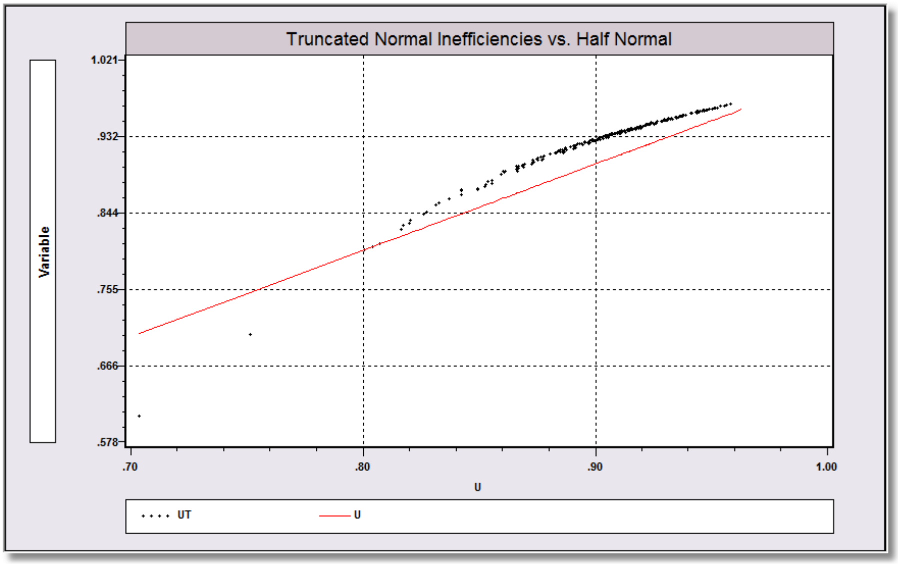

Figure E63.3 Inefficiency Estimates from Truncated Normal Model

E63.3.2 Battese and Coelli (1995) Formulation

There are (apparently) two formulations of the normal – truncated normal model in the literature. The formulated above,

$$y = \boldsymbol{\beta}'\mathbf{x} + v - u, u = |U|$$

$$U \sim N[\mu,\sigma_u^2] \leftarrow$$

$$v \sim N[0,\sigma_v^2]$$

is due to Stevenson (1980). Note that the inefficiency term is the absolute value of a normally distributed variable with a nonzero mean. Battese and Coelli proposed an apparently different formulation of the truncation model;

$$u = \mu + w$$

where w is a truncated normal, such that

$$w \geq -\mu.$$

This is actually the same model. You can obtain the estimates using this alternative formulation with

; Model = BC95

in place of **; Model = T**. The log likelihood for this formulation involves a one to one reparameterization of the Stevenson model, which has slightly different numerical properties. You can see this in the application below. The estimated inefficiency and efficiency values produced by the two models are the same to five or six digits, however.

E63.3.3 Technical Details on the Truncated Normal Model

The individual term in the log likelihood for the normal-truncated normal model is

$$\log L_i = -\tfrac{1}{2}\log 2\pi - \log\sigma - \tfrac{1}{2}[(S\varepsilon_i + \mu)/\sigma]^2 - \log\Phi(\mu/\sigma_u) + \log\Phi[(\mu/\lambda - S\varepsilon_i\lambda)/\sigma].$$

The definitions above imply that

$$\sigma_u = \sigma\lambda/\sqrt{1+\lambda^2}\ .$$

Using this and the reparameterization

$$\alpha = \mu/(\lambda\sigma)$$

produces the log likelihood for this model,

$$\text{Log } L_i = -\tfrac{1}{2}\log 2\pi - \log\sigma - \tfrac{1}{2}(d\varepsilon_i/\sigma + \alpha\lambda)^2 - \log\Phi\left(\alpha\sqrt{1+\lambda^2}\right) + \log\Phi(\alpha - d\varepsilon_i\lambda/\sigma).$$

The function is then maximized with respect to β, σ, λ and α. After optimization, the structural parameter μ is recovered from the result $\mu = \alpha\sigma\lambda$. For the model with heterogeneity in the mean presented in Section E63.3.4,

$$\mu_i = \boldsymbol{\theta}'\mathbf{z}_i$$

we simply replace α with $\alpha_i = \boldsymbol{\alpha}'\mathbf{z}_i$, then recover the parameter vector $\boldsymbol{\theta}$ from the same transformation as before, $\boldsymbol{\theta} = \sigma\lambda\boldsymbol{\alpha}$.

For purposes of the JLMS estimator for the half normal model, when the mean of U is a nonzero μ, the argument to the function is replaced with

$$w = S\varepsilon\lambda/\sigma - \mu/(\sigma\lambda).$$

The remaining part of the computation is the same.

E63.3.4 Heterogeneity in the Mean in the Truncation Model

The models listed above are all ‘homogeneous.’ Both the means and the variances of the underlying disturbance distributions are constant. There are several models of heterogeneity available as well. Use

; Model = T ; Rh2 = list of variables that enter the mean

to specify the heterogeneity in mean model, $U_i \sim N[\boldsymbol{\alpha}'\mathbf{z}_i, \sigma_u^2]$. In formulating this model, though it is not required, you should include a constant in $\mathbf{z}_i$ (the Rh2 variables) so that the homogeneous model becomes a special case. Also, if you are fitting a panel data version of this, note that the assumption underlying the model is that the same u_i occurs in every period. Therefore, the $\boldsymbol{\alpha}'\mathbf{z}_i$ should be the same in every period. *LIMDEP* will assume this is the case, and only use the Rh2 variables provided for the first period.

E63.3.5 Truncation and Heteroscedasticity

The doubly heteroscedastic model is also available for the truncated normal stochastic frontier model. In

$$y_i = \boldsymbol{\beta}'\mathbf{x}_i + v_i - u_i$$

you may specify **; Model = Truncated Normal; Rh2 = list of variables**

and $\text{Var}[u_i] = \sigma_u^2 \exp(\boldsymbol{\delta}'\mathbf{z}_i)$ with

; Het ; Hfu = list of variables in $\mathbf{z}_i$

and/or $\text{Var}[v_i] = \sigma_v^2 \exp(\boldsymbol{\gamma}'\mathbf{w}_i)$ with

; Het ; Hfv = list of variables in $\mathbf{w}_i$

Note that since both variance functions have a free multiplicative constant, you should not include *one* in either variable list.

In the absence of the Rh2 list, the mean of the underlying truncated variable is taken to be a constant to be estimated. This formulation encompasses all of Stevenson (1980), Reifschneider and Stevenson (1991), Huang and Liu (1994), and Battese and Coelli (1995). (Notwithstanding the assertion in the Battese and Coelli paper, the latter is not a panel data treatment as observations are still assumed to be independent.)

To illustrate the truncated normal estimator, we have refit the stochastic frontier production function with a complete set of firm dummy variables (less the last one) and the load factor variable in the mean of the underlying distribution. In the second model below, we have made the variance of *v* a function of the log of the average stage length. The command set begins with a small repair to the data set. One of the firms has no observations for the load factor, stage length or points served variables – they are coded as zero in the data. These observations are bypassed, then the firm dummies for the fixed effects model are assembled.

```
SAMPLE     ; All $
REJECT     ; loadfctr = 0 $
CREATE     ; i = Seq(firm) $
CREATE     ; Expand(i,0) $
CREATE     ; lk = Log(k) $
NAMELIST   ; xp = one,lf,lm,le,ll,lp,lk $
FRONTIER   ; Lhs = lq ; Rhs = xp ; Model = T ; Rh2 = loadfctr,_i_ $
FRONTIER   ; Lhs = lq ; Rhs = xp ; Model = T ; Rh2 = loadfctr,_i_
           ; Het ; Hfv = lstage $
```

(These are ‘true fixed effects’ models.)

```

E63.4 Alvarez et al. – Equality Constrained Scaling Model

Alvarez, Amsler, Orea and Schmidt (2006) have suggested a form of the truncation model which encompasses a number of ideas in stochastic frontier modeling. Their formulation is a normal-truncated normal frontier model with

$$\mu_i = \mu\times\boldsymbol{\delta}'\mathbf{z}_i \text{ and } \sigma_{u,i} = \sigma_u\times\boldsymbol{\delta}'\mathbf{z}_i.$$

The mean and standard deviation of the underlying truncated normal variable u_i are scaled by the same linear function of the data. We are skeptical of the linear scaling of the variance, and propose our usual exponential form instead. The linear form may be natural for the mean, but it allows the variance to be negative, which is unacceptable. The model used here is

$$\mu_i = \mu\times\exp(\boldsymbol{\delta}'\mathbf{z}_i) \text{ and } \sigma_{u,i} = \sigma_u\times \exp(\boldsymbol{\gamma}'\mathbf{z}_i).$$

The Alvarez model results if $\boldsymbol{\delta} = \boldsymbol{\gamma}$. Otherwise, we allow these to be free and to produce another variant of the frontier model. Note that as stated, this model is now merely a change of the normal-truncated normal model with heteroscedasticity in which the variables enter the truncation mean function in the exponential function rather than linearly.

The equality constrained scaling model is requested with

```
FRONTIER   ; Lhs  = y ; Rhs = one, x...
           ; Model = Scaling
           ; Heteroscedasticity
           ; Rh2 = variables in mean of truncated distribution
           ; Hfu  = the same list of variables $
```

Note in this case, Rh2 and Hfu give the same list. To obtain the scaling model without forcing the equality of $\boldsymbol{\delta}$ and $\boldsymbol{\gamma}$, use

```
FRONTIER   ; Lhs  = y ; Rhs = one, x...
           ; Model = S
           ; Heteroscedasticity
           ; Rh2 = variables in mean of truncated distribution
           ; Hfu  = the same list of variables $
```

Note, **; Model = Scaling** in the equality constrained case and **; Model = S** when the equality constraint is relaxed. (In this formulation, the variable lists could differ.) To constrain $\boldsymbol{\delta} = \mathbf{0}$, which just produces the heteroscedasticity model, use

```
FRONTIER   ; Lhs  = y ; Rhs = one, x...
           ; Model = T
           ; Heteroscedasticity
           ; Hfu  = list of variables $
```

To constrain γ = **0**, you would use the available setup for the truncated normal form, but **; Model = S** rather than **; Model = T** to obtain the exponential scaling of the mean.

```
FRONTIER    ; Lhs = y ; Rhs = one, x...
            ; Model = S
            ; Rh2 = variables in mean of truncated distribution $
```

Finally, with both δ = **0** and γ = **0**, this is just the standard normal-truncated normal model.

Technical Details

The implementation of the scaling model in *LIMDEP* is just a version of the truncation model with heteroscedasticity. The modifications of that model are:

- The constant terms in the mean and variance are enforced by the program.
- The mean function is exponential.
- In the first form of the model, a constraint is imposed that the coefficients in the mean and variance functions are the same.

As Alvarez et al. note in their paper, this model is not supported by any particular theory of the frontier framework. They suggest it as a natural extension of the familiar model with truncation. Rather, they argue that the unnatural form of the model would be the one with different scaling factors in the mean and variance functions.

Application

To illustrate the scaling model, we use the airlines cost data. The cost function is fit with truncation mean and variance functions that depend on the load factor and (log of) the average stage length. The equality constraint is imposed in the first model and relaxed in the second.

```
FRONTIER    ; Lhs  = lc ; Cost ; Rhs  = x
            ; Model = Scaling ; Het
            ; Rh2 = loadfctr,lstage
            ; Hfu  = loadfctr,lstage $
FRONTIER    ; Lhs  = lc ; Cost ; Rhs  = x
            ; Model = S ; Het
            ; Rh2 = loadfctr,lstage
            ; Hfu  = loadfctr,lstage $
```

```

E64: Panel Data Stochastic Frontier Models

E64.1 Introduction

The stochastic frontier model as it appears in the current literature was originally developed by Aigner, Lovell, and Schmidt (1977). The canonical formulation that serves as the foundation for other variations is their model,

$$y = \boldsymbol{\beta}'\mathbf{x} + v - u,$$

where y is the observed outcome (goal attainment), $\boldsymbol{\beta}'\mathbf{x} + v$ is the optimal, frontier goal (e.g., maximal production output or minimum cost) pursued by the individual, $\boldsymbol{\beta}'\mathbf{x}$ is the deterministic part of the frontier and $v \sim N[0,\sigma_v^2]$ is the stochastic part. The two parts together constitute the 'stochastic frontier.' The amount by which the observed individual fails to reach the optimum (the frontier) is u, where

$$u = |U| \text{ and } U \sim N[0,\sigma_u^2]$$

(change to $v + u$ for a stochastic cost frontier or any setting in which the optimum is a minimum). In this context, u is the 'inefficiency.' This is the normal-half normal model which forms the basic form of the stochastic frontier model. Chapters E62 and E63 developed several versions of the stochastic frontier model suitable for cross section and pooled data sets. This chapter will develop versions of the model constructed specifically for panel data.

E64.2 Panel Data Estimators for Stochastic Frontier Models

The stochastic frontiers literature has steadily evolved since the developments of basic random and fixed effects models by Pitt and Lee (1981) and by Cornwell, Schmidt and Sickles (1990). All of the generally used forms of panel data models are supported in *LIMDEP*. The following will document them in detail. These sections are arranged as follows:

- Pitt and Lee – Time Invariant Inefficiency, Random Effects,
- Cornwell, Schmidt and Sickles – Time Invariant Inefficiency, Fixed Effects,
- Battese and Coelli – Time Dependent Inefficiency Models,
- True Fixed Effects Models with Time Varying Inefficiency,
- True Random Effects Models with Time Varying Inefficiency,
- Random Parameters Stochastic Frontier Models,
- Alvarez et al. – Fixed Management (Random Parameters) Model,
- Latent Class Stochastic Frontier Models.

The panel models developed here will share features with other panel models in *LIMDEP*, as presented in Chapters R22-R25. As in other settings, panels in all models may be unbalanced. Panels are identified by

SETPANEL ; … $

then **; Panel**
in the command, or **; Pds = group count**

Nearly all of the models to be presented here actually require panel data, but a few will work, albeit not as well as otherwise, with **; Pds = 1**, i.e., with a cross section. This will be specifically noted below when it is the case. Second, in all models, the cost form as opposed to the production form is requested with

; Cost

This and other model specifications are generally the same as the cross sectional cases.

E64.3 Pitt and Lee – Time Invariant Inefficiency, Random Effects

The panel data, random effects specifications based on the model of Pitt and Lee (1981) are

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - Su_i$$

with S = +1 for a production model and -1 for a cost model. The inefficiency component is assumed to be time invariant. The base case is the normal-half normal model

$$u_i = |U_i|,\ U_i \sim \text{N}[0,\sigma^2].$$

This is a direct extension of the cross section variant discussed earlier. Several model formulations are grouped in this class. The command for the Pitt and Lee group of models is given by changing the base case specifications to

FRONTIER ; Lhs = y ; Rhs = one, ... ; Panel $

Pitt and Lee is the default panel data model. The only necessary change for the default case is specification of the panel with **; Panel**. As in the cross section case, the normal-exponential case is requested with

; Model = Exponential

while the normal-truncated normal is requested with

; Rh2 = one or ; Rh2 = one, additional variables

(The **; Model = T** is not needed.) The truncation model may not be combined with the exponential specification; it is only supported for the normal-truncated normal form.

NOTE: The gamma model does not have a random effects (panel data) version. The model extensions, such as the scaling model and sample selection described in Chapter E63 likewise do not support a Pitt and Lee style random effects version.

There is an important consideration for the truncation version with heterogeneous mean. If you are fitting a panel data version of this model, note that the assumption underlying the model is that the same u_i occurs in every period. Therefore, the $\boldsymbol{\alpha}'\mathbf{z}_i$ must be the same in every period. *LIMDEP* will assume this is the case, and only use the Rh2 variables provided for the first period.

When the random effects model is estimated, maximum likelihood estimates of the cross section models are always computed first to obtain the starting values. This will produce a full set of results which will ignore the panel nature of the data set. A second full set of results will then follow for the random effects model.

The model estimates retained for all cases are

b = regression parameters, α,$\boldsymbol{\beta}$
varb = asymptotic covariance matrix.

Use **; Par** to retain the additional parameters in *b* and *varb*. As seen in the applications below, the parameters estimated in each case will differ depending on the model formulation. The ancillary parameters that are estimated for the various models are the same ones saved by the cross section versions. All models save *sy*, *ybar*, *nreg*, *kreg*, and *logl* as well as *s*, *b*, *varb*, etc.

WARNING: Numerous experiments and applications have suggested that the normal-truncated normal model is a difficult one to estimate. Identification appears to be highly variable, and small variations in the data can produce large variation in the results. The model often fails to converge even when convergence of the restricted model with zero underlying mean is routine.

E64.3.1 Model Specifications

There are many different combinations of the components of the random effects model listed above. The following shows the different possibilities for the Pitt and Lee model. (There are also many combinations of these that do not use the panel data random effects form.):

NAMELIST ; x = one, … $
CREATE ; y = the outcome variable $
SETPANEL ; … $

Model 1 = pooled
FRONTIER ; Lhs = y ; Rhs = x $

Model 2 = random effects half normal
FRONTIER ; Lhs = y ; Rhs = x ; Panel $

Model 3 = random effects exponential
FRONTIER ; Lhs = y ; Rhs = x ; Panel ; Model = Exponential $

Model 4 = random effects normal heteroscedastic in *u* or *v* only
FRONTIER ; Lhs = y ; Rhs = x ; Panel ; Het ; Hfv = … $
FRONTIER ; Lhs = y ; Rhs = x ; Panel ; Het ; Hfu = … $

Model 5 = random effects normal doubly heteroscedastic
FRONTIER ; Lhs = y ; Rhs = x ; Panel ; Het ; Hfv = … ; Hfu = … $

Model 6 = random effects truncated normal
FRONTIER ; Lhs = y ; Rhs = x ; Panel ; Rh2 = one, … $

Model 7 = random effects truncated normal, singly or doubly heteroscedastic
FRONTIER ; Lhs = y ; Rhs = x ; Panel ; Rh2 = one, …
; Het ; Hfv = … ; Hfu = … $

The Pitt and Lee model forms assume that the inefficiency is time invariant. Thus, the estimate of u_i is repeated for each observation in the group. An example below illustrates.

E64.3.2 Applications

The following illustrates a few of the numerous formats of the random effects frontiers. The data set used is the Swiss railroad data used in Greene (2011, Table F19.1). These data are provided with the program as Swiss-railroads.lpj. The variables used here are

ct	= total cost
pk	= capital price
pe	= electricity price
pl	= labor price
q2	= passenger output – passenger km
q3	= freight output – ton km
rack	= dummy variable for 'rack rail' in network
tunnel	= dummy variable for network with tunnels over 300 meters on average
virage	= dummy variable for networks with narrow radius curvature
narrow_t	= dummy variable for narrow track (1m as opposed to standard 1.435m).

Preparing the data set includes bypassing one firm for which there is only a single year of data. For the remaining 49 firms, T_i is a mixture 3, 7, 10, 12 or 13. Figure E64.1 details the distribution of group sizes.

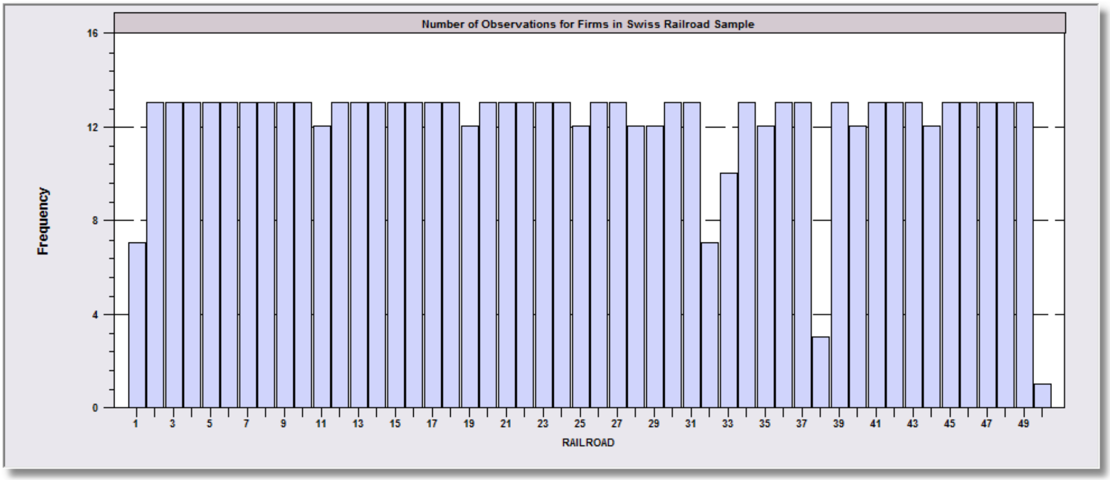

Figure E64.1 Groups Sizes for Swiss Railroad Sample

Descriptive statistics for the data are shown below. Variables with names beginning with 'M' are firm means, repeated for each year for the firm.

We fit four models to illustrate the estimator, the pooled normal-half normal, pooled normal-truncated (heterogeneous), basic Pitt and Lee and a full model with time invariant inefficiency, truncation (heterogeneous) and double heteroscedasticity.

The commands are as follows:

```
SETPANEL    ; Group = id ; Pds = ti $
REJECT      ; ti = 1 $
CREATE      ; lple = Log(pl/pe) ; lpke = Log(pk/pe) ; lnc = Log(ct/pe)$
NAMELIST    ; x = one,lnq2,lnq3,lple,lpke $
FRONTIER    ; Lhs = lnc ; Cost ; Rhs = x ; Costeff = eusfpool $
FRONTIER    ; Lhs = lnc ; Cost ; Rhs = x $
FRONTIER    ; Lhs = lnc ; Cost ; Rhs = x ; Panel ; Costeff = eusfp_l $
FRONTIER    ; Lhs = lnc ; Cost ; Rhs = x ; Rh2 = rack,tunnel
            ; Het ; Hfu = virage ; Hfv = virage ; Costeff = eushet_t $
FRONTIER    ; Lhs = lnc ; Cost ; Rhs = x ; panel ; Rh2 = rack,tunnel
            ; Het ; Hfu = virage ; Hfv = virage ; Costeff = fullmodl $
```

```

This is the original Pitt and Lee normal-half normal model with time invariant inefficiency. In comparison to the pooled model above, σ_u has tripled and σ_v has decreased by two thirds. The assumption of time invariance of the inefficiency produces a large reallocation of the random components between noise and inefficiency. This is evident in the kernel estimate below as well.

```

The kernel estimator compares the estimated cost efficiency distributions for the pooled and basic Pitt and Lee model. The pattern suggested earlier is clearly evident. The same comparison appears for the truncated normal/heteroscedasticity models. (The estimated cost efficiency results for the basic Pitt and Lee model and the expanded one are the same to three or four digits.) The partial listing below shows the estimates for the four models, noting the time invariance of the Pitt and Lee estimates.

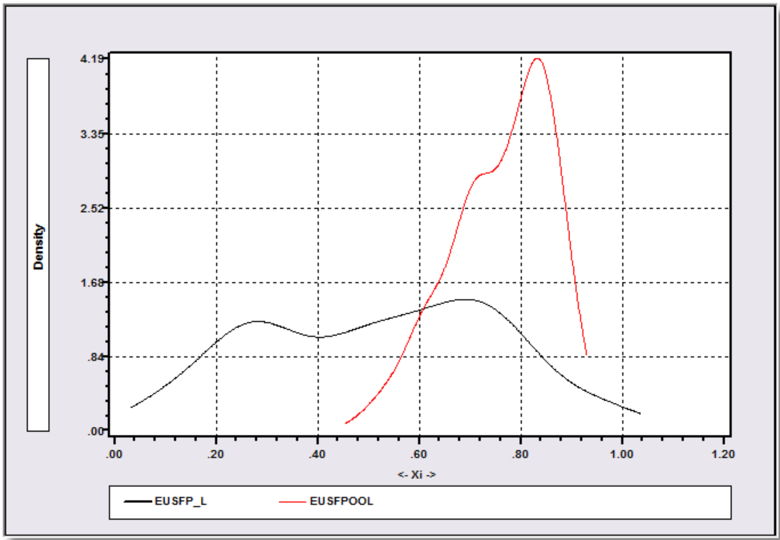

Figure E64.2 Kernel Estimators for Cost Efficiency

Figure E64.3 Estimated Cost Efficiency

E64.3.3 Technical Details

For the three forms of the normal mixture models, we use the following: Let

$\gamma = \sigma_u^2 / \sigma_v^2$

$\tau_i = \mu_i/\sigma_u$

$\mu_i = \boldsymbol{\theta}'\mathbf{z}_i$ for the heterogeneous mean model

$\mu,$ = a constant (0) for the simple truncated (half) normal model

$A_i = 1 + \gamma T_i$

$h_i = \tau_i / A_i - S\gamma T_i \bar{\varepsilon}_i /(\sigma_u A_i)$

$\bar{\varepsilon}_i = (1/T_i)\sum_{t=1}^{T_i}(y_{it} - \boldsymbol{\beta}' x_{it})$.

Then, the contribution of individual i to the log likelihood function for the normal-half normal model is

$$\log L_i = -(Ti/2)\log 2\pi - T_i \log\sigma_u - ½ \log A_i - (T_i/2) \log \gamma$$
$$- ½(\gamma / \sigma_u^2)\sum_{t=1}^{T_i} \varepsilon_{it}^2 + ½ A_i h_i^2 + ½ \log\Phi\left(h_i\sqrt{A_i}\right) - ½ \tau_i^2 - \log\Phi(\tau_i)$$

For the normal-exponential model, let

$h_i = -(\theta\sigma_v/T_i + \mathrm{d}\,\bar{\varepsilon}_i /\sigma_v)$

Then, $\log L_i = -½ \log T_i - (T_i - 1)\log 2\pi + \log\theta - (T_i - 1)\log\sigma_v$

$$- ½(1/\sigma_v^2) \sum_{t=1}^{T_i} \varepsilon_{it}^2 + ½ T_i h_i^2 + \log\Phi\left(h_i\sqrt{T_i}\right)$$

The Jondrow estimator, as formulated in Battese and Coelli (1988) in as follows: Let

$\gamma_i = 1 / (1 + \lambda^2 T_i)$,

$\psi_i^2 = \sigma_u^2\gamma_i$,

$E_i = \gamma_i\mu + (1 - \gamma_i)(-\bar{\varepsilon}_i)$,

and $\bar{\varepsilon}_i = (1/\mathrm{T_i})\Sigma_t\varepsilon_{it}$.

Then, $E[u_i|\varepsilon_{i1},\varepsilon_{i2},...] = E_i + \psi_i[\phi(E_i/\psi_i) / \Phi(E_i/\psi_i)]$.

For the exponential model, replace ψ_i with σ_v and E_i with $\sqrt{T_i}\,(-\bar{\varepsilon}_i - \theta\sigma_v^2/T_i)$.

E64.4 Cornwell, Schmidt and Sickles – Time Invariant Inefficiency, Fixed Effects

Cornwell, Schmidt and Sickles (1990) suggested a modification of the familiar fixed effects linear regression,

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it}.$$

The estimated model is

$$\begin{aligned} y_{it} &= a_i + \mathbf{b}'\mathbf{x}_{it} + v_{it} \\ &= \max(a_i) + \mathbf{b}'\mathbf{x}_{it} + v_{it} + [a_i - \max(a_i)] \\ &= a + \mathbf{b}'\mathbf{x}_{it} + v_{it} - u_i \end{aligned}$$

where $$u_i = \max(a_i) - a_i > 0.$$

(To change this to a cost frontier, change u_i to $[a_i - \min(a_i)]$ This bears resemblance to a stochastic frontier model, though in fact, it is a 'deterministic' frontier model. The signature feature is that u_i equals zero for the 'most efficient' firm in the sample. A natural interpretation of this is that what we measure with the model is not the absolute inefficiency, but inefficiency of firm *i* relative to the other firms in the sample. From the modeler's point of view, this approach has several substantive advantages and disadvantages: The main advantage is

- It is distribution free. It requires only the assumptions of the linear model.

The disadvantages are:

- It does not allow any time invariant variables in the model.
- It labels as inefficiency any and all omitted time invariant effects.
- It can only measure firms relative to each other.

As illustrated in the results below, this approach tends to produce very large estimates of u_i. The invariance assumption about u_i has been criticized elsewhere. Attempts to relax this assumption are a recurrent theme in the literature, including the Battese and Coelli and true fixed and random effects approaches described later. Other early work on the model suggested direct manipulation of the fixed effects, for example,

$$\alpha_{it} = \theta_{i0} + \theta_{i1}t + \theta_{i2}t^2.$$

Other more recent research (Han, Orea and Schmidt (2005)) has proposed factor analytic forms for α_{it}. The sections to follow will include several of these different approaches.

Application

This Cornwell, Schmidt and Sickles (CSS) approach requires only a linear fixed effects regression and a few instructions to manipulate the fixed effects. The following analyzes the airline data with this approach. The following computes the CSS estimates and compares them to the unstructured pooled estimates (using the normal-half normal model from Chapter E62) and the Pitt and Lee model introduced above. The commands for the analysis are as follows:

```
SAMPLE     ; All $
CREATE     ; Railroad = id $
CREATE     ; If(railroad > 20)railroad = railroad - 1 $ (There is a gap in the data)
HISTOGRAM  ; Rhs = railroad
           ; Title = Number of Observations for Firms in Swiss Railroad Sample $
SETPANEL   ; Group = id ; Pds = ti $
REJECT     ; ti = 1 $
FRONTIER   ; Lhs = lnc ; Cost ; Rhs = x ; Costeff = eusfpool $
CREATE     ; pooled = Group Mean(eusfpool, Pds = ti) $
FRONTIER   ; Lhs = lnc ; Cost ; Rhs = x ; Panel ; Costeff = pittlee $
REGRESS    ; Lhs = lnc ; Rhs = x ; Panel ; Fixed Effects $
CREATE     ; ai = alphafe(railroad) $
CALC       ; minai = Min(ai) $
CREATE     ; css = Exp((minai - ai)) $
CREATE     ; Period = Ndx(id,1) $
REJECT     ; period#1 $
PLOT       ; Lhs = railroad ; Rhs = pooled,css ; Grid ; Fill ; Limits = 0,1
           ; Vaxis = Estimated Cost Efficiency
           ; Title = Half Normal vs. Cornwell, Schmidt, Sickles FE Cost Efficiencies $
PLOT       ; Lhs = railroad ; Rhs = css,pittlee ; Grid ; Fill ; Limits = 0,1
           ; Vaxis = Estimated Cost Efficiency
           ; Title = Pitt and Lee RE vs. Cornwell, Schmidt, Sickles FE Cost Efficiencies $
```

The results below show the considerable differences in the parameter estimates produced by the three models. Figure E64.4 demonstrates the expected quite large differences between the time varying estimates (using the group means) and the time invariant results based on the CSS model. Figure E64.5 also shows a striking, albeit commonly observed result – the CSS and Pitt and Lee estimates are virtually identical.

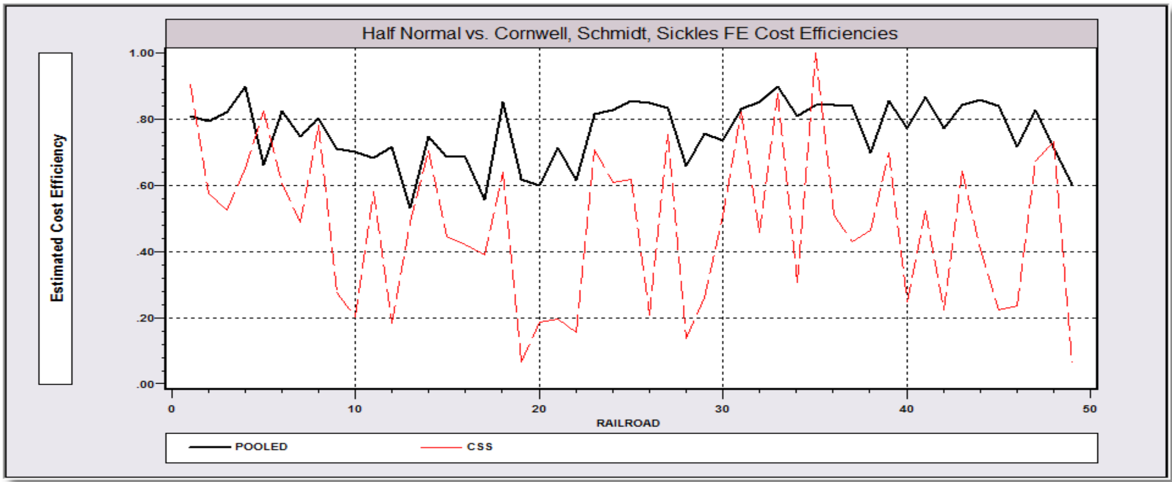

Figure E64.4 Cornwell et al. Estimates vs. Normal-Half Normal

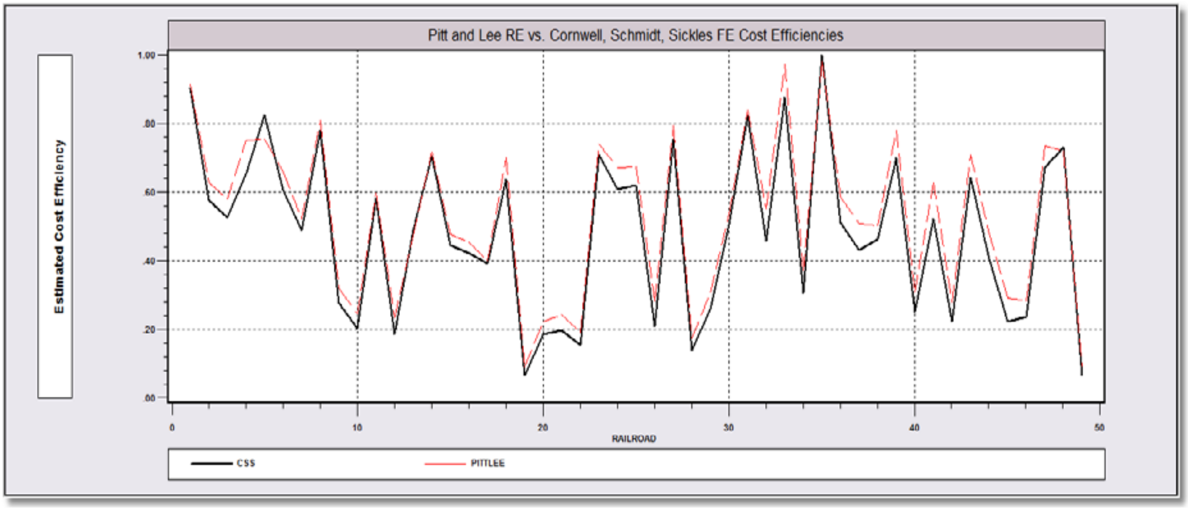

Figure E64.5 Estimated Inefficiencies from Cornwell et al. and Pitt and Lee Models

E64.5 Battese and Coelli – Time Dependent Inefficiency Models

Battese and Coelli (1992) proposed a series of models that can be collected in the general form

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it}$$

$$u_{it} = g(\mathbf{z}_{it})\,|U_i| \text{ where } U_i \text{ is half normal or truncated normal.}$$

Several formulations are available. In Battese and Coelli's original formulation, the distribution was half normal and the base specification was

$$g(z_{it}) = \exp[-\eta(t - T)]$$

where T is the number of periods in their balanced panel. (Here it would be T_i.) They also suggested

$$g(z_{it}) = \exp[-\eta_1(t - T) + -\eta_2(t - T)^2].$$

The first (linear) form is taken to be the default case for this model. The second is not provided in this package. The BC92 model is requested with

```
FRONTIER    ; Lhs = ... ; Rhs = one,...
            ; Model = BC
            ; Panel $
```

A truncated normal version is requested by adding

```
            ; Rh2 = list of variables which may (generally should) include one
```

(The **; Model = T** is not needed here.)

We note a warning to practitioners. When the data are very consistent with the model, the Battese and Coelli model produces quite satisfactory results. The framework has been employed in many recent empirical applications. But, when the data are not of particularly good quality, or this is the wrong model, extreme results can emerge. The airline data examined in Chapter E63 (and the WHO data), for example, are a poor fit to this model.

We have labeled this model as 'time dependent' rather than time varying. While the inefficiency component in the model does vary through time, the variation is systematic with respect to time. A question pursued in the ongoing literature is the extent to which this model actually moves away from the time invariant specification of Pitt and Lee. Since there is actual variation, the result is clearly somewhere between Pitt and Lee and what we have labeled the unstructured 'pooled' model. If η equals zero, Pitt and Lee emerges, so it depends entirely on this parameter. We have found in some investigations that the end result is actually closer to Pitt and Lee than it is to the pooled model – that is, there is quite a lot of structure involved in the BC92 model. The example below illustrates.

E64.5.1 Application

To illustrate the Battese and Coelli models, we return to the railroad data used previously. The base case is the pooled data stochastic cost frontier. This is followed by the Pitt and Lee model and, finally, by the original Battese Coelli 'time decay' model,

$$g(\mathbf{z}_{it}) = \exp[-\eta(t - T_i)].$$

The commands are

```
SAMPLE      ; All $
REJECT      ; ti = 1 $
FRONTIER    ; Lhs = lnc ; Cost ; Rhs = x ; Costeff = eusfpool $
FRONTIER    ; Lhs = lnc ; Cost ; Rhs = x ; Model = BC ; Panel ; Costeff = eucbc92 $
DSTAT       ; Rhs = eucbc92,eusfpool $
KERNEL      ; Rhs = eucbc92,eusfpool
            ; Title = Estimated Cost Efficiencies - Battese-Coelli 1992 vs. Pooled $
KERNEL      ; Rhs = eucbc92,pittlee
            ; Title = Estimated Cost Efficiencies - Battese-Coelli 1992 vs. Pitt and Lee $
```

The kernel density estimators are used to compare the efficiency estimates from the pooled data model to the Battese and Coelli model. The estimates of $\exp(-E[u_{it}|\varepsilon_i])$ from the Battese and Coelli model are far larger than those from the pooled model. The assumption of time invariance of the random term is a major component of this model. The second kernel estimator below compares Battese-Coelli to Pitt-Lee. The correspondence of the two results is striking, albeit to be expected given the small estimated value of η.

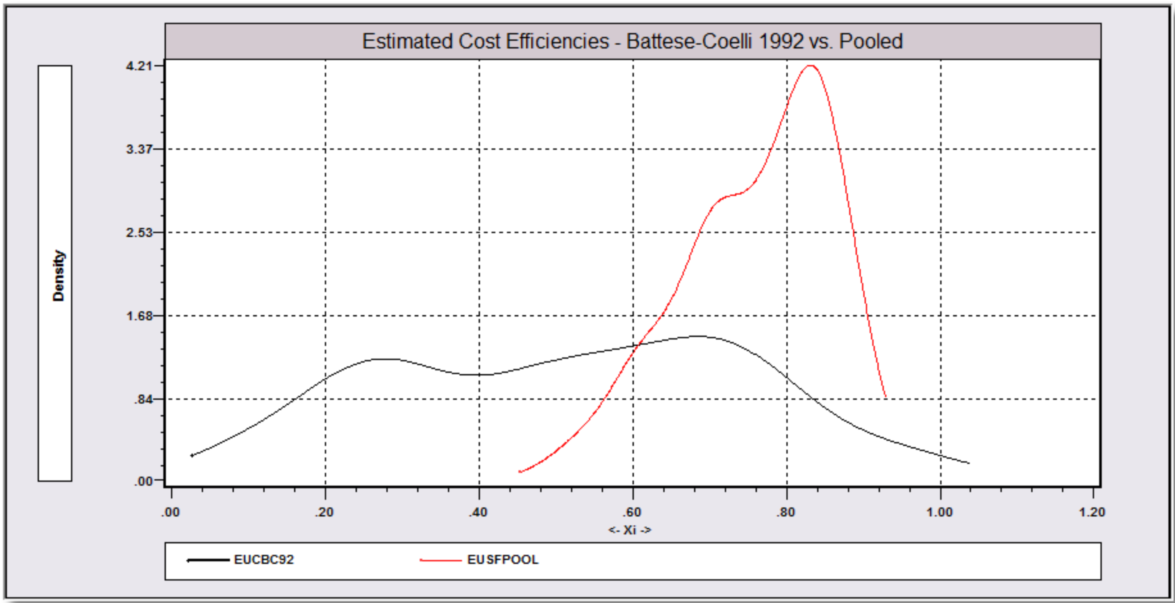

Figure E64.6 Kernel Density Estimates for Inefficiencies from Battese and Coelli Model

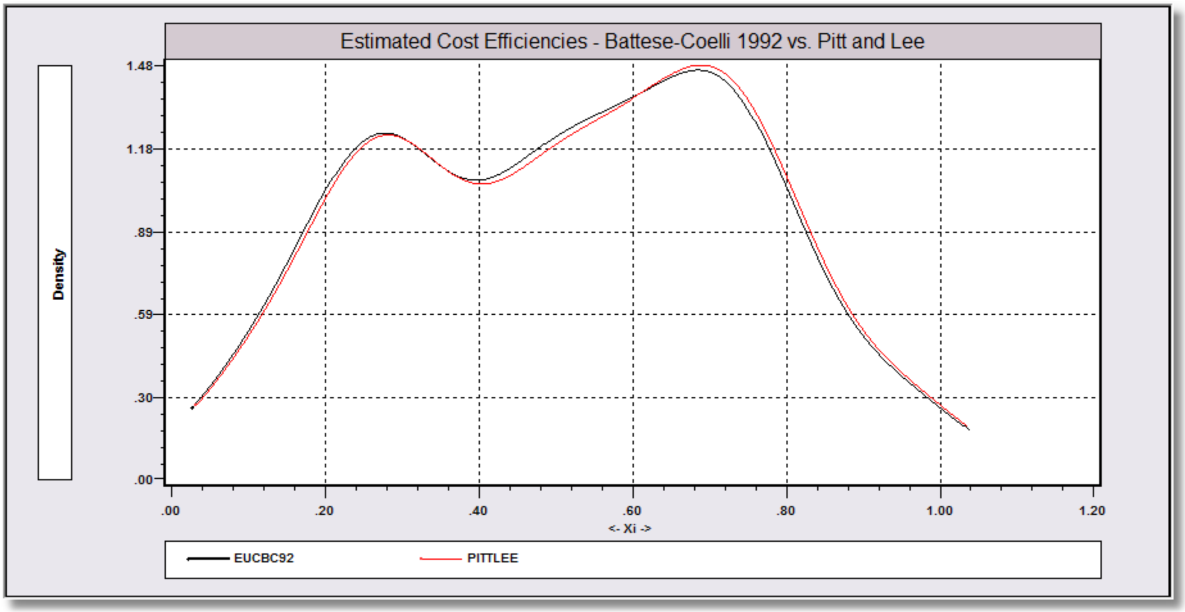

Figure E64.7 Kernel Density Estimates for Inefficiencies

E64.5.2 Technical Details

To form the log likelihood function for the model, we use Battese and Coelli's parameterization of the model. The contribution of the *i*th individual (firm, group, etc.) to the log likelihood is

$$\begin{aligned}\log L_i = &-\frac{T_i}{2}(\log 2\pi + \log\sigma^2) - \frac{(T_i-1)\log(1-\gamma)}{2} - \frac{1}{2}\sum_{t=1}^{T_i}\frac{\varepsilon_{it}^2}{(1-\gamma)\sigma^2}\\ &-\frac{1}{2}\log\left[1+\gamma\left(\left(\sum_{t=1}^{T_i} g_{it}^2\right)-1\right)\right]\\ &-\frac{1}{2}\left(\frac{\mu_i}{\sigma\sqrt{\gamma}}\right)^2 - \log\Phi\left(\frac{\mu_i}{\sigma\sqrt{\gamma}}\right) + \frac{A_i^2}{2} + \log\Phi(A_i)\end{aligned}$$

$$\begin{aligned}\sigma^2 &= \sigma_u^2 + \sigma_v^2\\ \gamma &= \sigma_u^2/\sigma^2\\ \varepsilon_{it} &= y_{it} - \boldsymbol{\beta}'\mathbf{x}_{it}\\ \mu_i &= 0 \text{ or } \mu \text{ or } \boldsymbol{\delta}'\mathbf{w}_i\\ g_{it} &= \exp[-\eta(t-T_i)] \text{ or } \exp(\boldsymbol{\eta}'\mathbf{z}_{it})\\ S &= +1 \text{ for a production model and -1 for a cost model}\\ A_i &= \frac{(1-\gamma)\mu_i - \gamma S\Sigma_{t=1}^{T_i} g_{it}\varepsilon_{it}}{\sqrt{\gamma(1-\gamma)\left[1+\gamma\left(\left(\Sigma_{t=1}^{T_i} g_{it}^2\right)-1\right)\right]}}\end{aligned}$$

Derivatives of this function are complicated in the extreme, and are omitted here. (Some useful results for obtaining them are found in Battese and Coelli (1992, 1995).)

The Jondrow estimator of u_{it} is

$$\begin{aligned}E[u_{it} \mid \varepsilon_{i1},\varepsilon_{i2},...] &= g_{it}\, E[u_i \mid \varepsilon_{i1},\varepsilon_{i2},...]\\ &= g_{it}\left[\tilde{\mu}_i + \tilde{\sigma}_i\left(\frac{\phi(\tilde{\mu}_i/\tilde{\sigma}_i)}{\Phi(\tilde{\mu}_i/\tilde{\sigma}_i)}\right)\right]\end{aligned}$$

where
$$\tilde{\mu}_i = \frac{(1-\gamma)\mu_i - \gamma\Sigma_{t=1}^{T_i} g_{it}(S\varepsilon_{it})}{(1-\gamma)+\gamma\Sigma_{t=1}^{T_i} g_{it}^2}$$

$$\tilde{\sigma}_i^2 = \frac{\gamma(1-\gamma)\sigma^2}{(1-\gamma)+\gamma\Sigma_{t=1}^{T_i} g_{it}^2}$$

E64.6 Time Varying Inefficiency in the Battese Coelli Model

The general form of the Battese and Coelli model is,

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it}$$

$$u_{it} = g(\mathbf{z}_{it})\,|U_i| \text{ where } U_i \text{ is half normal or truncated normal.}$$

The default form used earlier is $g(\mathbf{z}_{it}) = \exp[-\eta(t - T_i)]$. You may also use a more general form,

$$g(\mathbf{z}_{it}) = \exp(\boldsymbol{\eta}'\mathbf{z}_{it})$$

where $\mathbf{z}_{it}$ contains any desired set of variables. For this extension, use

```
FRONTIER     ; Lhs = ... ; Rhs = one,...
             ; Model = BC ; Hfu = the variables in z
             ; Pds = the panel specification $
```

As before, the truncated normal version of the model is also supported. For an example, we have used

```
FRONTIER     ; Lhs = lnc ; Cost ; Rhs = x ; Model = BC ; Panel ; Costeff = eucbc92h
             ; Hfu = rack,virage,tunnel $
```

The estimates of cost efficiency produced by this model are identical to those from the base model in the previous section.

```

E64.7 True Fixed Effects Models

The received applications of fixed effects to the stochastic frontier model, primarily Cornwell, Schmidt and Sickles have actually been reinterpretations of the linear regression model with fixed effects, not frontier models of the sort considered here. The estimators described below apply the fixed effects to the stochastic frontier. We label these 'true fixed effects models' to distinguish them from the linear regression models as discussed in Section E64.3. (This is not meant to apply that these are 'false fixed effects models.' Had we used 'real fixed effects models,' then the contrasting 'unreal fixed effects models' would arise which is likewise problematic. We use this purely as a concise term of art, not a characterization of the types of estimators considered.)

The stochastic frontier model with fixed effects may be fit in several forms. The base case applies the heterogeneity to the normal-half normal production function model;

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - Su_{it},$$

where S = +1 for a production frontier and -1 for a cost frontier, and

$$u_i = |\,N[0, \sigma_u^2]\,|.$$

This model (as are the others) is fit by maximum likelihood, not least squares. The normal-half normal model is applied to the stochastic part of the model. Note that the inefficiency term in this model is time varying. The heterogeneity may appear in Stevenson's truncated normal model as follows. This is a true fixed effects, normal-truncated normal model.

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it},$$

$$u_i = |\,N[\mu_i, \sigma_u^2]\,|$$

$$\mu_i = \boldsymbol{\delta}'\mathbf{z}_i.$$

In this form, the heterogeneity is still retained in the production function part of the model. Another possibility is to allow the heterogeneity to enter the mean of the inefficiency distribution rather than the production function – this seems the most natural of the three forms. In this case,

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it},$$

$$u_{it} = |\,N[\mu_{it}, \sigma_u^2]\,|$$

$$\mu_{it} = \alpha_i + \mu \text{ (nonzero) or } \boldsymbol{\delta}'\mathbf{z}_i.$$

The mean of the inefficiency distribution shifts in time, but also has a firm specific component. Finally, the heterogeneity may be shifted to the variance of the inefficiency distribution. In this form, we have

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it},$$

$$u_{it} = |\,N[0, \sigma_{ui}^2]\,|$$

$$\sigma_{uit}^2 = \sigma_u^2 \times \exp(\alpha_i + \boldsymbol{\delta}'\mathbf{z}_{it}).$$

The variables in the variance term may be omitted if only a groupwise heteroscedastic model is desired. Note this is a half normal model. A model with nonzero underlying mean and variation in the variance appears to be inestimable. Note that in order to secure identification, this model must have time varying inefficiency, induced by time variation in the variance.

NOTE: We have had extremely limited success with the second and third forms of the model. The likelihood function is quite volatile in the parameters of the underlying mean of the truncated distribution with the result that the estimated variance parameters λ and σ generally become negative in the early iterations and estimation must be halted. This occurs even when very good starting values are used, which suggests that estimation of this model as stated is likely to be extremely problematic in all but the most favorable of cases. An alternative approach which is simple, but can be used only with small panels (up to 100 groups), is suggested below.

In terms of implementation, we note that these forms of the models, though they are new with *LIMDEP*, have long been feasible. The panels typically used by researchers in this setting are often fairly small – our airline data for example have only 25 units and the Swiss railroad data has 49 firms. It would always have been possible to create these models simply by adding dummy variables to the familiar model. However, *LIMDEP*'s implementation of the model obviates this by using the methodology described in Chapter R23. In principle, this allows up to 100,000 firms in the data set.

Results that are kept for this model are

Matrices: *b* = estimate of **β**
varb = asymptotic covariance matrix for estimate of **β**.
alphafe = estimated fixed effects (if **; Par** is in the command)

Scalars: *kreg* = number of variables in Rhs
nreg = number of observations
logl = log likelihood function

Last Model: *b_variables*

The upper limit on the number of groups is 100,000.

E64.7.1 Commands for the Fixed Effects Stochastic Frontier Model

The command for fitting the normal-half normal model with fixed effects is as follows:

FRONTIER ; Lhs = ... ; Rhs = one,... $
FRONTIER ; Lhs = ... ; Rhs = one,...
; FEM ; Pds = specification $

The model must be fit twice. The first model is a pooled data model which provides the starting values for the second. The second command is identical to the first save for the addition of the panel data specification. In order to set up the initial values correctly, it is essential that your initial model include the constant term first in the Rhs list and that the second model specification be identical to the first. Other options and specifications for the fixed effects models are the same as in other applications. (See Chapter R23 for details.) The fixed effects command also contains the constant term, but this will be removed by the command processor later. See the example below for the operation of the command.

NOTE: Starting values must be provided by the first estimator. The specification **; Start = list of values** is not available for this model. You must fit both models each time you fit an FEM. The starting values are not retained after the FEM is estimated.

All fixed effects forms are estimated by maximum likelihood. You may also fit a two way fixed effects model

$$y_{it} = \alpha_i + \gamma_t + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_i, \text{ (change to } v + u \text{ for a stochastic cost frontier)},$$

$$u_i = |\,N[0, \sigma_u^2]\,|$$

where γ_t is an additional, time (period) specific effect. The time specific effect is requested by adding

; Time

to the command if the panel is balanced, and

; Time = variable name

if the panel is unbalanced.

For the unbalanced panel, we assume that overall, the sample observation period is t = 1,2,..., T_{max} and that the time variable gives for the specific group, the particular values of t that apply to the observations. Thus, suppose your overall sample is five periods. The first group is three observations, periods 1, 2, 4, while the second group is four observations, 2, 3, 4, 5. Then, your panel specification would be

; Pds = Ti, for example, where *Ti* = 3, 3, 3, 4, 4, 4, 4
and **; Time = Pd**, for example, where *Pd* = 1, 2, 4, 2, 3, 4, 5.

E64.7.2 Model Specifications for Fixed Effects Stochastic Frontier Models

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par keeps ancillary parameter σ in main results vector *b*.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list gives starting values for a nonlinear model.
; Tlg[= value] sets convergence value for gradient.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.

E64.7.3 Application of the True Fixed Effects Model

We have fit the fixed effects model with the airline data used in the previous chapter. These are simple models that do not use the observed heterogeneity in load factor, stage length or number of points served. Additional variables which vary over time can also be included in the function. The commands employed for the example are

```
SETPANEL    ; Group = firm ; Pds = ti $
FRONTIER    ; Lhs = lq ; Rhs = one,lf,lm,le,ll,lp,lk$
FRONTIER    ; Lhs = lq ; Rhs = one,lf,lm,le,ll,lp,lk,
            ; FEM ; Panel ; Techeff = euitfe ; Par $
REGRESS     ; Lhs = lq ; Rhs = one,lf,lm,le,ll,lp,lk
            ; Panel ; Fixed Effects $
CREATE      ; ai = alphafe(firm) $
CALC        ; maxai = Max(ai) $
CREATE      ; euicss = exp(-(maxai - ai)) $
CREATE      ; meuitfe = Group Mean(euitfe, Pds = ti) $
SAMPLE      ; All $
CREATE      ; Period = Ndx(firm,1) $
PLOT        ; For[period=1] ; Lhs = firm ; Rhs = euitfe,euicss
            ; Fill ; Symbols ; Limits = 0,1 ; Grid
            ; Title = Technical Efficiency Estimates, CSS vs. True Fixed Effects
                      (Group Means)
            ; Vaxis = Estimated Technical Efficiency $
```

This command recovers the estimated fixed effects from the Cornwell et al. model. then replicates them for each year in the data set. This is used to create the plot of the two sets of estimates of u_i shown below.

Figure E64.8 plots the Jondrow estimates of exp(-$E[u_{it}|\varepsilon_{it}]$) from the true fixed effects model and the estimates of u_i from the Cornwell, Schmidt and Sickles model of Section E64.4 for each firm. Since the true FE estimates vary by period, we have plotted the group means. The implication of the regression based model is clear in the figure. The estimates of technical efficiency from the true FEM are generally considerably larger than those from the deterministic model.

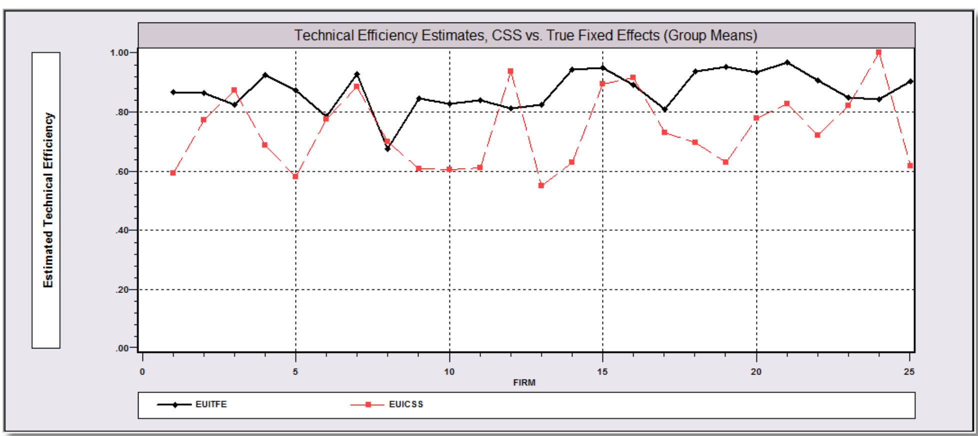

Figure E64.8 True Fixed Effects vs. Fixed Effects Estimates of u_i

E64.7.4 Fixed Effects in the Normal-Truncated Normal Model

The preceding may be extended to the truncated normal (with earlier caveats) as follows: For a model with heterogeneity appearing in the production (or cost) function,

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it},$$

$$u_{it} = |\, N[\mu_{it}, \sigma_u^2]\,|$$

$$\mu_{it} = \mu \text{ (nonzero) or } \boldsymbol{\delta}'\mathbf{z}_{it},$$

use **FRONTIER ; Lhs = ... ; Rhs = one, ... ; Rh2 = one, ...**
; Model = T $
FRONTIER ; Lhs = ... ; Rhs = one, ... ; Rh2 = one, ...
; FEM ; Panel $

The Rh2 is optional in the first equation if you have only a constant term in the mean of the truncated distribution. But, you should include it nonetheless so as to insure the match between the first and second commands. Also, it is essential that both Rhs and Rh2 include constant terms in the first positions.

To move the heterogeneity to the mean of the underlying truncated normal distribution,

$$y_{it} = \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it},$$

$$u_i = |\, N[\mu_{it}\sigma_u^2]\,|$$

$$\mu_{it} = \alpha_i + \boldsymbol{\delta}'\mathbf{z}_{it},$$

use **FRONTIER ; Lhs = ... ; Rhs = one, ... ; Rh2 = one, ...**
; Model = T $
FRONTIER ; Lhs = ... ; Rhs = one, ... ; Rh2 = one, ...
; Model = T
; FEM ; Panel $

Note that this version differs from the earlier one only in the presence of **; Model = T** in the second form and its absence in the first. Again, the variable specifications in the two commands must be identical, and both must include constant terms in the first position in both lists. As before, you may use **; Rh2 = one** if you do not require variables $\mathbf{z}_{it}$ in the mean. (This constant term will be removed from the fixed effects model, but this common value is used as the starting value for the firm specific estimates.)

We note, we have had scant success with this model even with a carefully constructed data set and good starting values. The problem appears to be Newton's method, which must be used for the general fixed effects program which this is part of. If you have a small panel with no more than 100 groups, an alternative approach appears to work better. You may provide a stratification variable in the cross section template to request that a set of dummy variables be inserted directly into the function.

To fit a model of the first form above, use

```
FRONTIER    ; Lhs = ... ; Rhs = one,...
            ; Model = T [ ; Rh2 = list is optional ]
            ; Str = a variable which provides a group indicator for the panel $
```

The stratification variable must take the full set of values from 1 to N up to 100 and all groups must have at least two observations. For the second form, with the heterogeneity embedded in the mean of the truncated normal distribution, add

```
            ; Mean
```

to the command.

This provides four possible forms of the model, which we illustrate with the airline data:

```
NAMELIST    ; x = one,lf,lm,le,ll,lp,lk $
```

This is a true fixed effects model with normal-truncated normal structure for u_{it}.

```
FRONTIER    ; Lhs = lq ; Rhs = x
            ; Model = T
            ; Str = firm $
```

This model is the same as the preceding one except now $\mu_i = \delta_1 + \delta_2 loadfctr_i$.

```
FRONTIER    ; Lhs = lq ; Rhs = x
            ; Model = T
            ; Rh2 = one,loadfctr
            ; Str = firm $
```

This is a true fixed effects model with the fixed effects appearing in μ_i rather than in the production function.

```
FRONTIER    ; Lhs = lq ; Rhs = x
            ; Model = T
            ; Mean
            ; Str = firm $
```

This model is the same as the preceding model except that *loadfctr* now also appears in the mean of the truncated variable.

```
FRONTIER    ; Lhs = lq ; Rhs = x
            ; Model = T
            ; Rh2 = one,loadfctr ; Mean
            ; Str = firm $
```

E64.7.5 Fixed Effects in the Heteroscedasticity Model

The firmwise heteroscedasticity model,

$$
\begin{aligned}
y_{it} &= \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it},\\
u_{it} &= |\,N[0, \sigma_{uit}^2]\,|\\
\sigma_{uit}^2 &= \sigma_u^2 \times \exp(\alpha_i + \boldsymbol{\delta}'\mathbf{z}_{it})
\end{aligned}
$$

is requested in the same fashion as the normal-truncated normal model, using a stratification variable in the cross section formulation. (This likelihood function is likewise quite ill behaved, though less so than the truncation form.) The command is

```
FRONTIER    ; Lhs = ... ; Rhs = one, ...
            ; Het
            ; Hfu = list of variables ; Hfv = one
            ; Str = stratification variable $
```

This model also allows for the doubly heteroscedastic form,

$$
\begin{aligned}
y_{it} &= \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} - u_{it},\\
u_{it} &= |\,N[0, \sigma_{uit}^2]\,|\\
\sigma_{uit}^2 &= \sigma_u^2 \times \exp(\alpha_i + \boldsymbol{\delta}'\mathbf{z}_{it})\\
v_{it} &\sim N[0,\sigma_{vit}^2]\\
\sigma_{vit}^2 &= \sigma_v^2 \times \exp(\boldsymbol{\gamma}'\mathbf{w}_{it})
\end{aligned}
$$

The command would be

```
FRONTIER    ; Lhs = ... ; Rhs = one, ...
            ; Het
            ; Hfu = list of variables ; Hfv = list of variables
            ; Str = stratification variable $
```

To continue the earlier example, the following fits a model of heteroscedasticity to the airline data. The first model has heteroscedasticity and the fixed effects in the variance of u_i. The second is doubly heteroscedastic, again with the fixed effects in the variance of u_i.

```
NAMELIST    ; x = one,lf,lm,le,ll,lp,lk $
FRONTIER    ; Lhs = lq ; Rhs = x
            ; Het ; Hfu = one,loadfctr ; Hfv = one ; Str = firm $
FRONTIER    ; Lhs = lq ; Rhs = x
            ; Het ; Hfu = one,loadfctr ; Hfv = one,loadfctr ; Str = firm $
```

```

E64.8 True Random Effects Models

We call the stochastic frontier model with a random as opposed to a fixed effect term a 'true random effects' model. The structure is the normal-half normal stochastic frontier model,

$$y_{it} = w_i + \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} + u_{it}$$
$$v_{it} \sim N[0,\sigma_v^2]$$
$$u_{it} = |U_{it}|,\ U_{it} \sim N[0,\sigma_u^2]$$
$$w_i \sim N[0,\sigma_w^2].$$

At first look, this appears to be a model with a three part disturbance, which would surely be inestimable. But, that is incorrect. It is a model with a traditional random effect, but with the additional feature that the time varying disturbance is not normally distributed. Specifically, the model may be written in our familiar form for the stochastic frontier model,

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + \varepsilon_{it} + w_i$$
$$\varepsilon_{it} \sim (2/\sigma)\phi(\varepsilon_{it}/\sigma)\Phi(-\varepsilon_{it}\lambda/\sigma)$$
$$w_i \sim N[0,\sigma_w^2].$$

The model is estimable by maximum simulated likelihood, as shown below. Contrast this to the Pitt and Lee form,

$$y_{it} = \alpha + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} + u_i$$
$$v_{it} \sim N[0,\sigma_v^2]$$
$$u_i = |U_i|,\ U_i \sim N[0,\sigma_u^2].$$

In this form, u_i, the time invariant effect, is the inefficiency. In the true random effects model, u_{it} is the inefficiency, and it is time varying. The latent heterogeneity, the random effect, is w_i. Thus, in the Pitt and Lee model, the 'inefficiency' term also contains all other time invariant unmeasured sources of heterogeneity. In the true random effects model, these effects appear in w_i, and u_{it} picks up the inefficiency. By this interpretation, we will expect (and always find) that estimated inefficiencies from the Pitt and Lee are larger than those from the true random effects model, sometimes far larger. The same result is at work in the difference between the Cornwell et al. fixed effects model and the true fixed effects model. Figure E64.8 clearly shows the effect at work.

The true random effects model is estimated as a form of random parameters (RP) model, in which the only random parameter in the model is the constant term. Thus, we write the model in the canonical RP form

$$y_{it} = \alpha_i + \boldsymbol{\beta}'\mathbf{x}_{it} + v_{it} + u_{it}$$
$$v_{it} \sim N[0,\sigma_v^2]$$
$$u_{it} = |U_{it}|,\ U_{it} \sim N[0,\sigma_u^2]$$
$$\alpha_i = \alpha + w_i$$
$$w_i \sim N[0,\sigma_w^2]$$

Details on estimating random parameters models appear in Chapter R24, so they will be omitted here.

The command structure for the true random effects model is similar to that for the true fixed effects model. The frontier model must be fit twice, first with no effects to generate the starting values, then with the effect specified. The commands are

FRONTIER ; Lhs = ... ; Rhs = one,... ; Par $
FRONTIER ; Lhs = ... ; Rhs = one,...
; RPM ; Fcn = one(n) $

If desired, the Jondrow estimates are requested as usual with

; Eff = the variable name

The computation of random parameters models is fairly time consuming because of the simulations. You can control this in part with

; Pts = the number of replications

For exploratory work (or for examples in program documentation), small values such as 25 or 50 are sufficient. For final results destined for publication, larger values, in the range of several hundred are advisable. Also, we advise using Halton sequences rather than pseudorandom numbers for the simulations (see Chapter R24). The parameter is

; Halton

The random parameters formulation also allows a variety of specifications for the mean of the underlying u_{it} – the normal-truncated normal model – and for heteroscedasticity. These are discussed in Section E64.9.

Application

To illustrate the true random effects model, we continue the analysis of the airline data. The commands below estimate the pooled model, then the true RE model. In like fashion to the analysis of fixed effects, we then compare the true random effects estimates of inefficiency to the Pitt and Lee estimates. Figure E64.8 illustrates the general result that the estimated inefficiencies in the true fixed effects model will differ considerably from those produced by the Cornwell et al. approach to fixed effects. Figure E64.9 shows the same result for the two approaches to random effects. Numerous studies in the literature (see Greene (2005) for discussion) have documented the similarity of the random and fixed approaches – when the same overall structure is used. Thus, Figure E64.10 shows similar results for the true fixed and random effects models and for the Pitt and Lee and Cornwell et al. models.

The commands used for this application are as follows:

```
NAMELIST    ; x = one,lf,lm,le,ll,lp,lk $
FRONTIER    ; Lhs = lq ; Rhs = x ; Panel ; Eff = uplre $

These are the estimates of the true random effects model. Note that the variation of the random terms in the model has been rearranged. In the pooled model, s_v = 0.138 and s_u = 0.130. In the random effects model, we have s_v = .099 and s_u= .100. But, s_w = .140. The proportional allocation of the total to u and v has stayed roughly the same, but some additional variation is now attributed to the random effect. Note that the production function parameters have changed substantially as well.

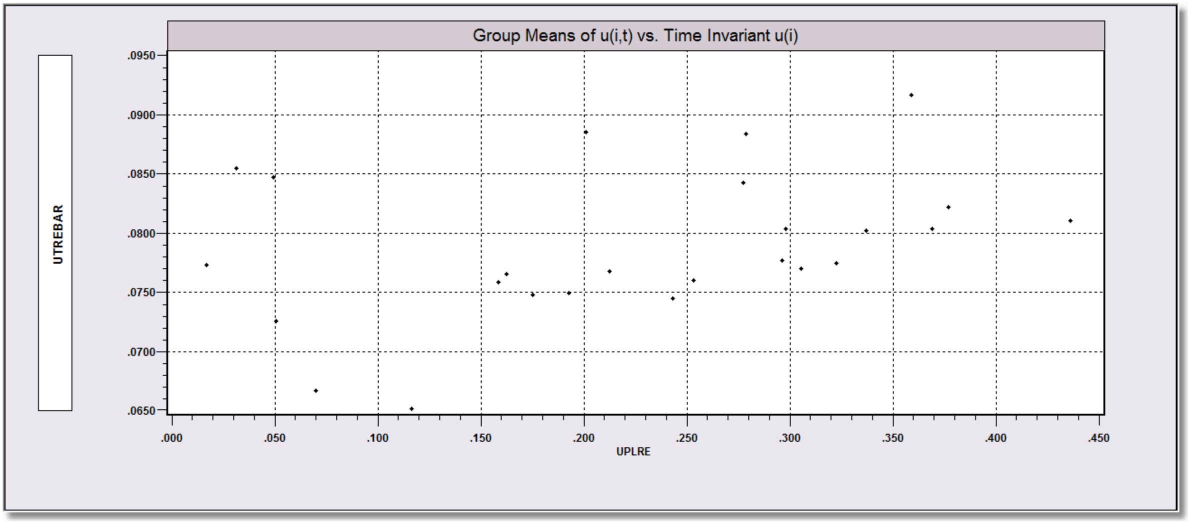

Figure E64.9 Time Varying vs. Time Invariant Estimates of u(i)

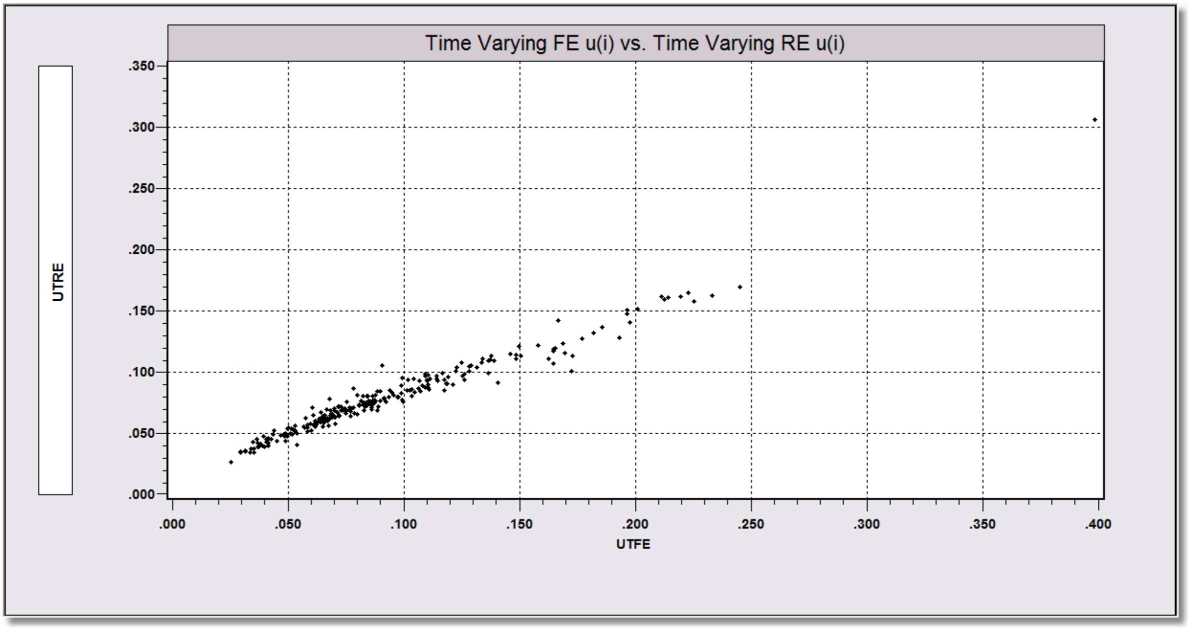

Figure E64.10 Comparison of Time Varying Fixed and Random Effects Estimates

E64.9 Random Parameters Stochastic Frontier Models

The random parameters stochastic frontier model in *LIMDEP* is very general, and embodies all three of the formulations discussed in the preceding sections on fixed and random effects.

$$
\begin{aligned}
y_{it} &= \boldsymbol{\beta}_i'\mathbf{x}_{it} + v_{it} - u_{it},\\
u_i &= |\, \text{N}[\mu_{it}, \sigma_{uit}^2] \,|\\
\mu_{it} &= \boldsymbol{\delta}_i'\mathbf{m}_{it}.\\
\sigma_{uit}^2 &= \sigma_u^2 \times \exp(\boldsymbol{\gamma}_i'\mathbf{w}_{it}).
\end{aligned}
$$

The model allows, all at once, half normal or truncated normal distribution for u_i and firmwise and/or timewise heteroscedasticity in u_{it}. The model form allows parameters to be random in all three parts of the specification with the single restriction noted below. (Only the variance of the 'disturbance,' v_{it} is assumed to be constant. In addition, this model form does not accommodate heteroscedasticity in v_{it}.) As will be clear in what follows, the true random effects model developed in the previous section is a special case of this model with nonrandom parameters in μ_{it} and σ_{uit}^2 and only a random constant term in $\boldsymbol{\beta}_i$.

NOTE: The random parameters normal-truncated normal model with heteroscedasticity (in u_{it}) at the same time is not identified. Only one of these two should be specified. The command parser will not prevent you from specifying such a model, but it will ultimately be impossible to obtain the parameter estimates.

The general structure of the random parameters stochastic frontier model is based on the conditional density

$$f(y_{it}|\, \mathbf{x}_{it}, \boldsymbol{\beta}_i) = f(\boldsymbol{\beta}_i'\mathbf{x}_{it}),\ i = 1,...,N,\ t = 1,...,T_i$$

where

$$\boldsymbol{\beta}_i = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i + \boldsymbol{\Gamma}\mathbf{v}_i$$

and $f(.)$ is the density for the stochastic frontier regression model. The model assumes that parameters are randomly distributed with possibly heterogeneous (across individuals) means

$$\text{E}[\boldsymbol{\beta}_i|\, \mathbf{z}_i] = \boldsymbol{\beta} + \boldsymbol{\Delta}\mathbf{z}_i,$$

(the second term is optional – the mean may be constant), and

$$\text{Var}[\boldsymbol{\beta}_i|\, \mathbf{z}_i] = \boldsymbol{\Sigma}.$$

As noted earlier, the heterogeneity term is optional. In addition, it may be assumed that some of the parameters are nonrandom by placing rows of zeros in the appropriate places in $\boldsymbol{\Delta}$and $\boldsymbol{\Gamma}$. The general form of random parameter vector $\boldsymbol{\beta}_i$ is also extended to $\boldsymbol{\delta}_i$ and $\boldsymbol{\gamma}_i$. The general aspects of random parameters model estimation in *LIMDEP* are described in Chapter R24.

Command for the Random Parameters Model

The model command for the random parameters form of the stochastic frontier model is as follows. The first **FRONTIER** command is mandatory, and is needed to obtain the starting values. This is a pooled data version of the model. Note that it does not include the heteroscedasticity or truncation specification, even if the second command does.

FRONTIER ; Lhs = dependent variable ; Rhs = independent variables
; Parameters $
FRONTIER ; Lhs = dependent variable
; Rhs = independent variables
[; Rh2 = list is optional for the truncated normal model]
[; Hfn = list is optional for the heteroscedasticity model]
; Pds = fixed periods or count variable
; RPM (may include = variables in z)
; Fcn = random parameters specification $

(Note, again, only one of the two optional specifications noted should be specified.)

NOTE: For this model, your Rhs list must include a constant term. Though not strictly necessary, you should also include constants in Rh2 or Hfn if they are specified.

Specifying Random Parameters

The **; Fcn = specification** is used to define the random parameters. It is constructed from the list of Rhs names as follows: Suppose your model is specified by

; Rhs = one, x1, x2, x3, x4

This involves five coefficients. Any or all of them may be random; any not specified as random are assumed to be constant. For those that you wish to specify as random, use the following for production (cost, profit) function parameters,

; Fcn = variable name (distribution),
variable name (distribution), ...

There are two other sets of parameters in the model, in the mean of and variance of the one sided disturbance. To specify random parameters in the underlying mean of the truncated normal variable, use the following:

; Fcn = variable name [distribution],
variable name [distribution], ...

(Note square brackets designate the terms in μ_{it}.) For parameters in the computation of the variance of u_{it}, use

; Fcn = variable name <distribution>,
variable name <distribution>, ...

The difference in the three formulations is in the enclosures, ( ) for production function, [ ] for mean of the truncated distribution, and <> for the variance of the one sided disturbance. This distinction is necessary because the lists might have variables in common, and this is the only way to distinguish them. In particular, it is likely that all three lists would include *one*, so this device is used to distinguish the three functions.

Three distributions may be specified All random variables have mean 0.

n = standard normal distribution, variance = 1,
t = triangular (tent shaped) distribution in [-1,+1], variance = 1/6,
u = standard uniform distribution [-1,1], variance = 1/3.

Note that each of these is scaled as it enters the distribution, so the variance is only that of the random draw before multiplication. (See Chapter R23 for discussion of this computation and for other distributions that can be specified.) The latter two distributions are provided as one may wish to reduce the amount of variation in the tails of the distribution of the parameters across individuals and to limit the range of variation. (See Train (2010) for discussion.) For example, to specify that the constant term and the coefficient on *x*1 are normally distributed with fixed mean and variance, and a normally distributed constant in the mean of the truncated distribution, you might use

; Fcn = one(n), x1(n), one[n]

This specifies that the first and second coefficients are random while the remainder are not. The parameters estimated will be the mean and standard deviations of the distributions of these two parameters and the fixed values of the other three.

NOTE: If you use the wrong enclosures for the variables, a diagnostic will appear that the program does not recognize a variable. For example:

```
FRONTIER    ; Lhs = lq ; Rhs = one,lf,lm,le,ll,lp
            ; Hfn = one,lf ; RPM ; Pds = ni
            ; Fcn = one(n),lf(n),lf[n] $
```

```
Variable in FCN=name[type] is not in RHS/RH2/HFN list.
```

The reason for the diagnostic is that the **lf[n]** would indicate a specification for the truncation model, using **; Rh2 = list**. But, this command specifies only heteroscedasticity, which is denoted with <> enclosures. Hence, when the **lf[n]** is encountered, *LIMDEP* searches for *lf* in an Rh2 list, and finding no such list, issues the diagnostic.

Correlated Random Parameters

The stochastic frontier model does not support correlated random parameters. The model is not identified with this extension.

Heterogeneity in the Means

The preceding examples have specified that the mean of the random variable is fixed over individuals. If there is measured heterogeneity in the means, in the form of

$$E[\beta_{ki}] = \beta_k + \Sigma_m \delta_{km} z_{mi}$$

where z_{mi} is a variable that is measured for each individual, then the command may be modified to

; RPM = list of variables in z

In the data set, these variables must be repeated for each observation in the group. Since the coefficients are assumed to be time invariant, the variables in $\mathbf{z}_i$ must be also.

The Parameter Vector and Retained Results

The variances of the underlying random variables are given earlier, 1 for the normal distribution, 1/3 for the uniform, and 1/6 for the tent distribution. The σ_k parameters are only the standard deviations for the normal distribution. For the other two distributions, σ_k is a scale parameter. The standard deviation is obtained as $\sigma_k/\sqrt{3}$ for the uniform distribution and $\sigma_k/\sqrt{6}$ for the triangular distribution. When the parameters are correlated, the implied covariance matrix is adjusted accordingly. The correlation matrix is unchanged by this.

Results saved by this estimator are:

Matrices:	*b*	= estimate of $\boldsymbol{\theta}$
	varb	= asymptotic covariance matrix for estimate of $\boldsymbol{\theta}$.
	beta_i	= individual specific parameters, if **; Par** is requested.
Scalars:	*kreg*	= number of variables in Rhs
	nreg	= number of observations
	logl	= log likelihood function

Last Model: *b_variables*

Last Function: None

Standard Model Specifications for the Stochastic Frontier Random Parameters Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par keeps individual specific parameter estimates.
; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Robust requests a 'sandwich' estimator or robust covariance matrix for TSCS and several discrete choice models.

Optimization Controls for Nonlinear Optimization

; Tlg[= value] sets convergence value for gradient.
; Tlf [= value] sets convergence value for function.
; Tlb[= value] sets convergence value for parameters.
; Alg = name requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n sets the maximum iterations.
; Output = n requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List displays a list of fitted values with the model estimates.
; Keep = name keeps fitted values as a new (or replacement) variable in data set.
; Res = name keeps residuals as a new (or replacement) variable.

Hypothesis Tests and Restrictions

; Test: spec defines a Wald test of linear restrictions.
; Wald: spec defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec defines a constrained maximum likelihood estimator.
; Rst = list specifies equality and fixed value restrictions.

Application

We continue the earlier application by fitting the stochastic frontier model with random parameters. The random parameters truncation model appears to be unidentified in these data, so the second model fit is with heteroscedasticity. In the first model, the constant and one of the production coefficients is specified to be random. In the second, these two coefficients and the parameter on the variable that enters the variance function are all taken to be random. The kernel density estimators compare the efficiency estimates from the random parameters model to those from the simplest pooled estimator.

The commands are:

```
NAMELIST    ; x = one,lf,lm,le,ll,lp,lk $
FRONTIER    ; Lhs = lq ; Rhs = x ; Eff = u $
FRONTIER    ; Lhs = lq ; Rhs = x
            ; RPM ; Panel ; Pts = 50 ; Halton; Fcn = one(n),lf(n) ; Eff = urp1 $
KERNEL      ; Rhs = urp1,u $
FRONTIER    ; Lhs = lq ; Rhs = x $
FRONTIER    ; Lhs = lq ; Rhs = x ; Hfn = one,loadfctr
            ; RPM ; Panel ; Pts = 50 ; Halton
            ; Fcn = one(n),lf(n),loadfctr<n> $
```

Figure E64.11 shows the distributions of the estimates of inefficiencies from the random parameters model and the simple, pooled fixed parameters model. The figure suggests that the RP formulation is moving some of the variation of the outcome variable out of the inefficiency term and into the production model, in the form of parameter variation.

E64.10 Alvarez et al. – Fixed Management Model

Alvarez, Arias and Greene (2006) suggested a production model in which an unobserved factor enters as a latent variable. The core production model is

$$y_{it} = f(x_{it,1},x_{it,2},...,x_{it,K}, m_i)$$

where the unobservable, time invariant factor, 'm_i' is labeled 'management' in their paper. By treating the unobserved factor as a random component in the model, the authors develop a stochastic frontier model in which the resultant functional form is such that all random parameters are functions of the same single random effect, v_i, and the v_i appears in squared form in the equation as well. In generic terms, this model is a random parameters stochastic frontier model with random constant term and first order terms, and nonrandom second order terms in a translog model. The functional form is

$$\begin{aligned}
\log y_{it} &= \alpha_i + \sum_{k=1}^{K}\beta_{k,i}\ln x_{it,k} + \sum_{k=1}^{K}\sum_{m=1}^{K}\gamma_{km}\ln x_{it,k}\ln x_{it,m} + v_{it} - u_{it} \\
\alpha_i &= \alpha + \theta_\alpha w_i + \theta_{\alpha\alpha}(\tfrac{1}{2}w_i^2) \\
\beta_{k,i} &= \beta_k + \lambda_k w_i \\
w_i &\sim N[0,1] \\
v_{it} &\sim N[0,\sigma_v^2] \\
u_{it} &= |N[0,\sigma_u^2]|
\end{aligned}$$

This model is specified simply by creating the necessary variables, then building a random parameters model with the two additional specifications,

; Common ; Mgt

The **; Common** specification alone is generic, and applies to all random parameters models. Use it to specify that the same random component appears in all random parameters. The **; Mgt** specification has no function outside the frontier model. It is used only with the frontier model to specify this particular form. For example, consider the following three factor translog model:

```
FRONTIER    ; Lhs = yit ; Rhs = one,x1,x2,x3,x11,x12,x13,x22,x23,x33 $
FRONTIER    ; Lhs = yit ; Rhs = one,x1,x2,x3,x11,x12,x13,x22,x23,x33
            ; RPM ; Pds = the panel specification ; Halton
            ; Fcn = one(n),x1(n),x2(n),x3(n)
            ; Common ; Mgt $
```

(It is always necessary to fit the frontier model with fixed parameters first to generate the starting values.)

An extension of this model that the authors considered was intended to ameliorate the probable correlation between the random effect w_i and the independent variables (factors). The Mundlak approach to this problem is to incorporate the group means of the variables in the model. For this model, they proposed

$$w_i = \tau + \sum_{k=1}^{K} \gamma_k \overline{\log x_{i,k}} + f_i$$

where f_i is now the structural random variable that drives the random parameters. This extension is requested with

; Means

(The program deduces internally which variables are nonconstant and should be used.)

Application

The following is the Alvarez, Arias and Greene application. The data consists of six years of observations on 247 Spanish dairy farms. The output, *yit* is milk production. The four inputs, *x*1, *x*2, *x*3 and *x*4 are feed, land, labor and cows. Commands for fitting the model are as follows: (We have restricted the number of iterations and the number of replications for purpose of this numerical illustration.) Both models (with and without the Mundlak adjustment) are shown.

```
FRONTIER    ; Lhs = yit
            ; Rhs = one,x1,x2,x3,x4,x11,x12,x13,x14,x23,x24,x34,x44 ; Par $
FRONTIER    ; Lhs = yit
            ; Rhs = one,x1,x2,x3,x4,x11,x12,x13,x14,x23,x24,x34,x44
            ; RPM ; Halton ; Pts = 25 ; Pds = 6 ; Maxit = 25 ; Common ; Mgt
            ; Fcn = one(n),x1(n),x2(n),x3(n),x4(n) $
FRONTIER    ; Lhs = yit
            ; Rhs = one,x1,x2,x3,x4,x11,x12,x13,x14,x23,x24,x34,x44 ; Par $
FRONTIER    ; Lhs = yit
            ; Rhs = one,x1,x2,x3,x4,x11,x12,x13,x14,x23,x24,x34,x44
            ; RPM ; Halton ; Pts = 25 ; Pds = 6 ; Maxit = 25
            ; Common ; Mgt ; Means
            ; Fcn = one(n),x1(n),x2(n),x3(n),x4(n) $
```

The first set of results is the pooled stochastic frontier model with no extensions or modifications.

E64.11 Latent Class Stochastic Frontier Models

The latent class framework discussed in Chapter E20 is available for the stochastic frontier model. The structural equations of the basic model are

$$y_{it} \mid j = \boldsymbol{\beta}_j'\mathbf{x}_{it} + v_{it} - u_{it},$$

$$v_i \mid j = \mathrm{N}[0, \sigma_{vj}^2]$$

$$u_i \mid j = \mid \mathrm{N}[\sigma_{uj}^2] \mid$$

where 'j' indicates class j. The truncation and heteroscedasticity models are not supported by this estimator. However, the Battese and Coelli model, in which

$$u_{it} \mid j = g(\mathbf{z}_{it})| j \times |U_i|$$

is available for both forms of $g(\mathbf{z}_{it})$.

The estimation command for the latent class stochastic frontier model is

FRONTIER ; Lhs = dependent variable
; Rhs = one, remaining variables ; Parameters $
FRONTIER ; Lhs = dependent variable
; Rhs = one, remaining variables
; Pds = fixed periods or count variable
; LCM ; Pts = number of classes (2, 3, ..., 9) $

(As in other panel data settings, it is necessary to fit the pooled model first to compute the starting values.)

The Battese and Coelli models may be specified here with

; Model = BC

for the decay model and

; Model = BC
; Hfu = one, heteroscedasticity variables

For this model, you must fit the identical Battese and Coelli model without the latent class specification first. The application below demonstrates.

The basic form of the latent class model assumes that the class probabilities are fixed values. You may make them dependent on time invariant variables, w_i with

; LCM = list of variables in w

Do not include *one* in the list.

Some particular variables computed for the latent class model are

; Group = the index of the most likely latent class
; Cprob = estimated probability for the most likely latent class

You can obtain a listing of these two results by using

; List

An example appears below. You can also use the **; Rst = list** option to structure the latent class model so that different variables appear in different classes or that certain coefficients are equal across classes. Examples are given in Chapter E20.

Estimates retained by this model include:

Matrices:	*b*	=	full parameter vector, $[\boldsymbol{\beta}_1'\lambda_1\sigma_1, \boldsymbol{\beta}_2',\lambda_2\sigma_2, \ldots F_1,\ldots,F_J]$
	varb	=	full covariance matrix
	beta_i	=	individual specific parameters, if **; Par** is requested

Note that *b* and *varb* involve $J\times(K+2)$ estimates. Two additional matrices are created,

b_class	=	a $J\times K$ matrix with each row equal to the corresponding $\boldsymbol{\beta}_j$
class_pr	=	a $J\times 1$ vector containing the estimated class probabilities

Scalars:	*kreg*	=	number of variables in Rhs list
	nreg	=	total number of observations used for estimation
	logl	=	maximized value of the log likelihood function
	exitcode	=	exit status of the estimation procedure

Standard Model Specifications for the Latent Class Stochastic Frontier Model

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Par	keeps individual specific parameter estimates.
; Partial Effects	displays marginal effects, same as **; Marginal Effects**.
; OLS	displays least squares starting values when (and if) they are computed.
; Table = name	saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix	displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.
; Robust	requests a ‘sandwich’ estimator or robust covariance matrix for TSCS and several discrete choice models.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Res = name	keeps residuals as a new (or replacement) variable.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

Application

The airline data used in the preceding examples are clearly not compatible with this model; no configuration of the equation produces meaningful results. To illustrate the estimator, we have borrowed the Spanish dairy data used in the previous section. The following commands fit a two class, Battese and Coelli decay model.

```
NAMELIST    ; x  = one,x1,x2,x3,x4 $
FRONTIER    ; Lhs = yit ; Rhs = x
            ; Model = BC
            ; Pds  = 6 $
FRONTIER    ; Lhs = yit ; Rhs = x
            ; Model = BC
            ; LCM ; Pts = 2 ; Pds = 6 ; List $
```

These are the initial results from the first command.

E65: Data Envelopment Analysis

E65.1 Introduction

There are two broad paradigms used by researchers to analyze efficiency in production, stochastic frontier analysis (SFA) and data envelopment analysis (DEA). No formulation has yet been devised that unifies SFA and DEA in a single analytical framework. Arguably, the former is a fully parameterized model whereas the latter is 'nonparametric,' albeit also atheoretical in nature. DEA is currently the conventional approach to deterministic frontier estimation. This is usually handled with linear programming techniques. The analysis assumes that there is a frontier technology (in the same spirit as the stochastic frontier production model) that can be described by a piecewise linear hull that envelopes the observed outcomes. Some (efficient) observations will be on the frontier while other (inefficient) individuals will be inside. The technique produces a deterministic frontier that is generated by the observed data, so by construction, some individuals are 'efficient.' This is one of the fundamental differences between DEA and SFA. This chapter presents *LIMDEP*'s programs for data envelopment analysis (DEA).

E65.2 Data Envelopment Analysis

Stochastic frontier modeling is based on maximum likelihood or other classical or Bayesian, parametric econometric techniques. In contrast, DEA is based on nonparametric, linear programming methods. Both paradigms are based on an underlying construct of the efficient production frontier that relates maximal output to inputs for the 'firm' (decision making unit, or DMU). Using SFA methods, the analyst defines, then estimates a continuous, regular relationship that defines the frontier. DEA uses linear programming methods to fit a piecewise linear 'hull' around the data, under the assumption that the hull adequately approximates the underlying frontier, the more so as the number of observations increases. (Since the technique is nonstatistical, this is difficult to establish analytically.) There is a vast literature on the two techniques and comparisons, none of which will be reviewed here. Our purpose here is only to document the estimator. We recommend, as a departure point in the literature, a working paper by Coelli (1996a), which describes the techniques documented here and introduces some of the theoretical notions. He also provides several useful citations.

E65.2.1 Input and Output Oriented Efficiency

The discussion of DEA efficiency measurement begins with the notion of a measure of the ratio of outputs to inputs for firm '*i*,'

$$Ratio_i = \boldsymbol{\alpha}'\mathbf{y}_i / \boldsymbol{\beta}'\mathbf{x}_i,\ i = 1,..,N,$$

where $\mathbf{y}_i$ is the vector of M outputs and $\mathbf{x}_i$ is the vector of K inputs. The optimal weights are defined by the programming problem,

$$\begin{aligned}
&\text{Maximize wrt } \boldsymbol{\alpha},\boldsymbol{\beta}: && \boldsymbol{\alpha}'\mathbf{y}_i / \boldsymbol{\beta}'\mathbf{x}_i \\
&\text{Subject to} && \boldsymbol{\alpha}'\mathbf{y}_s / \boldsymbol{\beta}'\mathbf{x}_s \leq 1,\ s = 1,...,N \\
& && \alpha_m \geq 0,\ m = 1,...,M \\
& && \beta_k \geq 0,\ k = 1,...,K
\end{aligned}$$

The optimization program seeks the optimal weights to maximize the 'efficiency' of firm *s* subject to the restriction that the efficiencies of all firms are less than or equal to one, and that all weights are nonnegative. Because the objective function is homogeneous of degree zero – any multiple of the weights produces the same solution – it is normalized with a restriction such as $\boldsymbol{\alpha}'\mathbf{x}_i = 1$. Transforming and simplifying the problem a bit produces the equivalent program,

$$
\begin{aligned}
&\text{Maximize wrt } \boldsymbol{\alpha},\boldsymbol{\beta}: && \boldsymbol{\alpha}'\mathbf{y}_i \\
&\text{Subject to} && \boldsymbol{\beta}'\mathbf{x}_i = 1 \\
& && \boldsymbol{\alpha}'\mathbf{y}_s - \boldsymbol{\beta}'\mathbf{x}_s \leq 0,\ s = 1,\ldots,N \\
& && \boldsymbol{\alpha} \geq \mathbf{0} \\
& && \boldsymbol{\beta} \geq \mathbf{0}
\end{aligned}
$$

An equivalent form of the problem is the envelopment form (hence the name),

$$
\begin{aligned}
&\text{Minimize wrt } \theta_i, \boldsymbol{\lambda}: && \theta_i \\
&\text{Subject to} && \Sigma_s\, \lambda_s\mathbf{y}_s - \mathbf{y}_i \geq \mathbf{0} \\
& && \theta_i\, \mathbf{x}_i - \Sigma\, \lambda_s\mathbf{x}_s \geq \mathbf{0} \\
& && \lambda_s \geq 0.
\end{aligned}
$$

The value of θ_i is the *input oriented technical efficiency score* for the *i*th firm

$$TE_{INPUT,i} = \theta_i.$$

It measures the extent to which the firm could reduce inputs to obtain the same output – relative to other firms in the sample. Note that the program is solved for each firm in the sample – an efficiency score θ_i is generated for each firm. For some firms in the sample, the efficiency score will be 1.0. This indicates firms deemed to be technically efficient. Otherwise, $\theta_i \leq 1$.

The preceding formulation includes an implicit assumption of constant returns to scale (CRS). The assumption is relaxed to variable returns to scale (VRS), by adding a restriction

$$\Sigma_s\, \lambda_s = 1.$$

Variable returns to scale is the standard assumption in contemporary applications. This provides a means by which the 'scale efficiency' of the firm can be measured. Let θ_{iC} denote the technical efficiency measure obtained assuming constant returns and θ_{iV} be the variable returns to scale counterpart. Then, the '*scale efficiency*' may be measured by

$$SE_i = \theta_{iC} / \theta_{iV}.$$

This can be computed using the results of the two different programs after computation. A 'nonincreasing returns to scale' (NRS) version of the program can be obtained by changing the adding up restriction to

$$\Sigma_s\, \lambda_s \leq 1.$$

An alternative view of the optimization process is to consider the extent to which outputs could conceivably be increased using the same inputs – again relative to the standard of other firms in the sample. The linear program which produces this solution is

$$\begin{aligned} &\text{Maximize wrt } \phi_i, \boldsymbol{\lambda}: && \phi_i \\ &\text{Subject to} && \Sigma_s \lambda_s \mathbf{y}_s - \phi_i \, \mathbf{y}_i \geq \mathbf{0} \\ & && \mathbf{x}_i - \Sigma \lambda_s \mathbf{x}_s \geq \mathbf{0} \\ & && \lambda_s \geq 0. \end{aligned}$$

Once again, this assumes constant returns to scale. The variable returns to scale form is obtained by adding the constraint $\Sigma_s\lambda_s = 1$. In this solution, $1 < \phi_i < \infty$. The technical efficiency measure is

$$0 < TE_{OUTPUT,i} = 1/\phi_i \leq 1$$

As before, some firms in the sample (the same firms) will be found to be technically efficient by this *output oriented efficiency measure*.

E65.2.2 Economic and Allocative Efficiency

With input price information, $\mathbf{w}_i$, (and assuming cost minimization) a cost minimization program to find the optimal inputs given the input prices is

$$\begin{aligned} &\text{Minimize wrt } \boldsymbol{\chi}_i, \boldsymbol{\lambda}: && \mathbf{w}_i' \, \boldsymbol{\chi}_i \\ &\text{Subject to} && \Sigma_s \lambda_s \mathbf{y}_s - \mathbf{y}_i \geq \mathbf{0} \\ & && \boldsymbol{\chi}_i - \Sigma \lambda_s \mathbf{x}_s \geq \mathbf{0} \\ & && \lambda_s \geq 0. \end{aligned}$$

As before, to allow for variable returns to scale (VRS), we add $\Sigma_s \lambda_s = 1$. In this program, $\boldsymbol{\chi}_i$ gives the cost minimizing vector of inputs for output $\mathbf{y}_i$ and input prices $\mathbf{w}_i$. The cost efficiency for the *i*th firm is then the ratio

$$0 < CE_i = \mathbf{w}_i \boldsymbol{\chi}_i / \mathbf{w}_i' \mathbf{x}_i < 1.$$

Allocative efficiency may be measured using

$$0 < AE_i = CE_i / TE_{INPUT,i} < 1.$$

E65.2.3 Solutions to the Optimization Problems

We note briefly the mathematical form of *LIMDEP*'s solutions to the linear programs above. The programming problem is defined in terms of

- Activity vector, $\boldsymbol{\gamma}$ = the solution vector
- Coefficient vector, $\mathbf{c}$ so that the objective function is $\mathbf{c}'\boldsymbol{\gamma}$
- Constraint matrix, $\mathbf{A}$
- Lower and upper limits for constraints, $\mathbf{b}_L$ and $\mathbf{b}_U$
- Lower and upper limits for activities, $\mathbf{d}_L$ and $\mathbf{d}_U$

The linear program solution, in general is, then,

$$\begin{aligned}
&\text{Optimize wrt } \gamma: && \mathbf{c}'\boldsymbol{\gamma} \\
&\text{Subject to} && \mathbf{b}_L < \mathbf{A}\boldsymbol{\gamma} < \mathbf{b}_U \\
& && \mathbf{d}_L < \boldsymbol{\gamma} < \mathbf{d}_U.
\end{aligned}$$

We will define the components for the three programs defined earlier. Note, first, for convenience, we define the data matrices, $\mathbf{Y}$ and $\mathbf{X}$. $\mathbf{Y}$ is an $N\times M$ matrix of outputs whose ith row is the vector of outputs for firm i; $\mathbf{X}$ is the $N\times K$ matrix of inputs, defined likewise. For an individual firm, we define $\mathbf{y}_i$ to the $M\times 1$ column vector of outputs for firm i; thus, $\mathbf{y}_i$ is the transpose of the ith row of $\mathbf{Y}$. Likewise, $\mathbf{x}_i$ is the column vector of K inputs for firm i, the transpose of the ith row of $\mathbf{X}$. Finally, the column vector of weights is $\boldsymbol{\lambda} = (\lambda_1,...,\lambda_N)'$. Thus,

$$\Sigma_s\, \lambda_s\, \mathbf{y}_s \;=\; \mathbf{Y}'\boldsymbol{\lambda} \;\text{ and }\; \Sigma_s\, \lambda_s\, \mathbf{x}_s \;=\; \mathbf{X}'\boldsymbol{\lambda}.$$

Finally, we note once again, the programs about to be defined are solved for each firm to obtain the efficiency scores. (In fact, $\boldsymbol{\lambda}$ should be indexed by firm, since it is recomputed each time. For convenience, we have omitted this subscript.) We use the symbol ∞_K and ∞_M to indicate a vector whose each element equals infinity (or sometimes minus infinity) and boldface $\mathbf{1}$ or $\mathbf{0}$ to indicate a vector of ones or zeros with a subscript to indicate the number of elements. Finally, our tableaus include the VRS restriction, which may be suppressed by the user for the CRS form.

With all this in place, we can define the solutions to the optimization problems just by identifying the components of the linear programming problems. These are as follows:

Input Oriented Technical Efficiency

$$\mathbf{d}_L = \begin{bmatrix} \mathbf{0}_N \\ 0 \end{bmatrix}, \mathbf{c} = \begin{bmatrix} \mathbf{0}_N \\ 1 \end{bmatrix}, \boldsymbol{\gamma} = \begin{bmatrix} \boldsymbol{\lambda} \\ \phi_i \end{bmatrix}, \mathbf{d}_U = \begin{bmatrix} \mathbf{1}_N \\ 1 \end{bmatrix}$$

$$\mathbf{b}_L = \begin{bmatrix} -\infty_K \\ \mathbf{y}_i \\ 1 \end{bmatrix}, \mathbf{A} = \begin{bmatrix} \mathbf{X}' & -\mathbf{x}_i \\ \mathbf{Y}' & \mathbf{0}_M \\ \mathbf{1}'_N & 0 \end{bmatrix}, \mathrm{b}_U = \begin{bmatrix} \mathbf{0}_K \\ \infty_M \\ 1 \end{bmatrix}$$

Output Oriented Technical Efficiency

$$\mathbf{d}_L = \begin{bmatrix} \mathbf{0}_N \\ 1 \end{bmatrix},\ \mathbf{c} = \begin{bmatrix} \mathbf{0}_N \\ 1 \end{bmatrix},\ \boldsymbol{\gamma} = \begin{bmatrix} \boldsymbol{\lambda} \\ \phi_i \end{bmatrix},\ \mathbf{d}_U = \begin{bmatrix} \mathbf{1}_N \\ \infty \end{bmatrix}$$

$$\mathbf{b}_L = \begin{bmatrix} -\infty_K \\ \mathbf{0}_M \\ 1 \end{bmatrix},\ \mathbf{A} = \begin{bmatrix} \mathbf{X}' & \mathbf{0}_K \\ \mathbf{Y}' & -\mathbf{y}_i \\ \mathbf{1}'_N & 0 \end{bmatrix},\ \mathbf{b}_U = \begin{bmatrix} \mathbf{x}_i \\ \infty_M \\ 1 \end{bmatrix}$$

Allocative Efficiency

$$\mathbf{d}_L = \begin{bmatrix} \mathbf{0}_N \\ \mathbf{0}_K \end{bmatrix},\ \mathbf{c} = \begin{bmatrix} \mathbf{0}_N \\ \mathbf{w}_i \end{bmatrix},\ \boldsymbol{\gamma} = \begin{bmatrix} \boldsymbol{\lambda} \\ \boldsymbol{\chi}_i \end{bmatrix},\ \mathbf{d}_U = \begin{bmatrix} \mathbf{1}_N \\ \infty_{\mathrm{K}} \end{bmatrix}$$

$$\mathbf{b}_L = \begin{bmatrix} -\infty_K \\ \text{-}\mathbf{y}_i \\ 1 \end{bmatrix},\ \mathbf{A} = \begin{bmatrix} \mathbf{X}' & \text{-}\mathbf{I}_K \\ \mathbf{Y}' & \mathbf{0}_{M\times K} \\ \mathbf{1}_N' & \mathbf{0}_K' \end{bmatrix},\ \mathbf{b}_U = \begin{bmatrix} \mathbf{0}_K \\ \infty_M \\ 1 \end{bmatrix}$$

One final note, DEA requires a fair amount of computation. The linear program involves M+K+1 constraints and N+1 activities, and it is computed once for each of the N firms in the sample. The amount of computation increases with the square of N. The particular computations are quite fast, however

E65.3 Confidence Limits for Efficiency Scores

A major shortcoming of the DEA approach to modeling production is the absence of a statistical underpinning. One approach that has been used to try to produce some statistical characterization of the estimator is to use bootstrapping to obtain confidence limits for the estimated efficiency scores. A popular method used is that of Simar and Wilson (1998). In brief, their method amounts to the following: We have in hand for each firm a θ_i estimated using the linear program defined above. To carry out the bootstrap, we use the following experiment. The data on $\mathbf{x}_m$ for all firms, including this one, are proportionally scaled using a randomly generated (see their paper for the algorithm) scale factor, θ_i/τ_{mb} for replication b. Then, $\theta_{i,b}$ is recomputed using the revised data, with the same method. The experiment is repeated B times. The 5$^{\text{th}}$ and 95$^{\text{th}}$ percentiles of the B observations provide the confidence limits. This is repeated B times for each firm. To obtain bootstrapped confidence use the command syntax described below, with the simple addition of the request for the number of bootstrap replications.

It should be noted, bootstrapping adds considerably to the amount of computation. In general, the analysis requires the computation of 2N linear programs, two for each firm, to compute the input and output oriented efficiency scores, plus one more if input prices are supplied for the allocative efficiency computation. Bootstrapping adds $B\times N$ more programs. Each program involves N+1 activities and K+M+1 constraints, so overall, the amount of computation is considerable. Nonetheless, each component of each linear program is very fast. In the example below, we have 123 observations. We requested 50 bootstrap replications, so we computed altogether 53×123 = 6,519 programs, each with 123 activities. The LP computations plus all the ancillary computations and the display took altogether only 3.84 seconds on our desktop computer.

E65.4 Command Structure

The command for the data envelopment analysis routine is simply

```
FRONTIER    ; Lhs = output variables
            ; Rhs = input variables  (will never include one)
            ; Alg  = DEA $
```

The following is the full list of specifications for this command.

The default specification uses the variable returns to scale form. If you wish to use the constant returns to scale form, add

; CRS

to the command. The nonincreasing returns to scale form ($\Sigma_i\ \lambda_i \leq 1$) is requested with

; NRS

Nondecreasing returns to scale is requested with **; NDS**.

If you wish to analyze input price data, add

; Rh2 = input price variables

The program computes the DEA efficiency scores (input and output oriented, and economic efficiency), and stores them as variables and as matrices. (See the description in the next section.) If you would like to see a listing of the scores on your screen, in the output window, add

; List

to the command. The list of 'peer' firms for each observation (see Section E65.5.1 below) may be requested by adding

; Peers

to the command. Finally, to obtain bootstrapped confidence limits for the estimator, add

; Nbt = the desired number of replications

E65.5 DEA Results

This estimator by default computes both the input and output oriented technical efficiency scores. Descriptive statistics for the results are the visible output from the estimator. The following shows an example, using the sample of 1,482 observations on Spanish dairy farms that was examined in Chapter E64. This is a one output, four input process.

FRONTIER ; Lhs = milk
; Rhs = cows,land,labor,feed
; Alg = DEA $

```
+--------------------------------------------------------------------+
| Data Envelopment Analysis                                          |
| Output Variables:  MILK                                            |
| Input Variables:   COWS     LAND     LABOR    FEED                 |
| Underlying Technology assumes VARIABLE Returns to Scale.           |
+--------------------------------------------------------------------+
| Estimated Efficiencies:     Mean     Std.Deviation     Minimum   Maximum  |
| Technical Efficiency     =======     =============     =======   =======  |
|      Input Oriented        .8301          .1416          .4823    1.0000  |
|     Output Oriented        .7388          .1268          .3875    1.0000  |
| Sample Size:           1482 Observations.    1482 Complete observations  |
| Efficiencies saved as variables DEAEFF_O, DEAEFF_I and DEAEFF_E         |
| Efficiencies saved as matrices  DEA_EFFO, DEA_EFFI and DEA_EFFE         |
| Incomplete observations are filled with zeros for efficiency values.    |
+--------------------------------------------------------------------+
```

As noted, the computed efficiency scores are saved in two places, in the data area, as variables *deaeff_i* and *deaeff_o* and *deaeff_e* if you provide input prices for the economic efficiency analysis. The same results are saved as matrices, *dea_effo*, *dea_effi*, *dea_effe*. Note that in both occurrences, the estimator is bypassing missing and bad (nonpositive) data. If any of the variables used in the analysis are missing, the observation is assigned an efficiency score of 0.0. The matrices will have row dimension equal to the original sample size, before the bypass of missing values.

The example below includes a listing of the efficiency scores. The observation identifier shows *I* = the sequence number of the observation used in the analysis. The *R* = value shows, instead, the actual location of the observation in the raw data set. *I* will not equal *R* if you have used a subset of the data (e.g., with **SAMPLE** or **REJECT)**, or if the program has bypassed missing data – the listing will only show the complete observations. If you have included observation labels, e.g., firm names, in your data set, these observation and row identifiers will be replaced with the observation names for your data set.

For a second example, the following analyzes the Christensen and Greene (1976) electricity generation data. For these data, we have the input prices, so we do the full analysis.

FRONTIER ; Alg = DEA ; List ; Nbt = 50
; Lhs = output
; Rhs = labor,capital,fuel
; Rh2 = lprice,cprice,fprice $

```

It is always interesting to compare the DEA results with those obtained using the stochastic frontier model. The following fits a translog stochastic frontier production function for the Christensen and Greene data, computes the technical efficiencies, and plots them against the DEA efficiency scores. As has been widely documented, the results are not so close to each other as one might hope.

```
FRONTIER   ; Lhs = logq
           ; Rhs = one,logcap,loglabor,logfuel,
                   loglsq,logksq,logfsq,logklogl,logklogf,logllogf
           ; Techeff = tesf $
PLOT       ; Lhs = tesf ; Rhs = deaeff_i
           ; Grid ; Title = DEA Efficiencies vs. Stochastic Frontier JLMS $
```

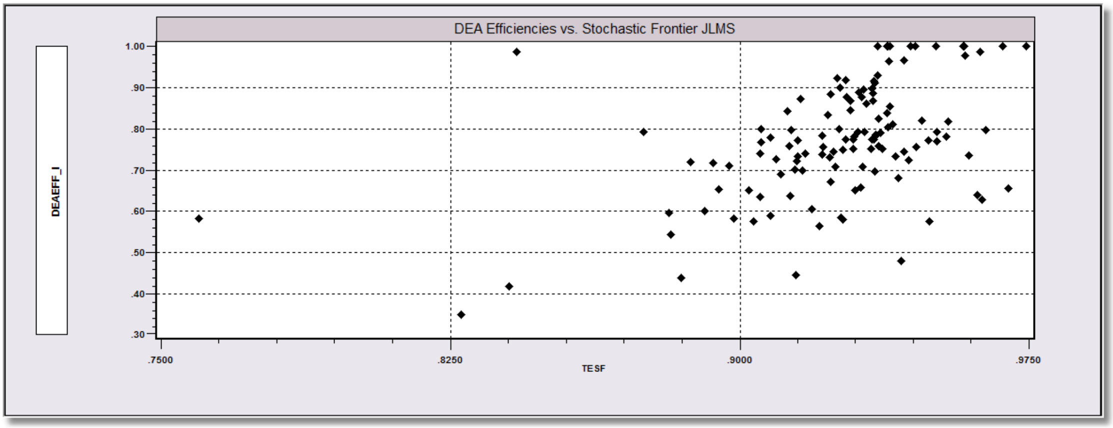

Figure E65.1 Comparison of SFA and DEA Efficiency Estimates

E65.5.1 Analysis of Peers

Part of the solution for the technical efficiency is the set of activity multipliers, $\lambda_{i,m}$ for the *i*th firm. The vector of *N* values, $\lambda_{i,m}$ will give the weights that produce the point on the efficient frontier for this firm. The firms with nonzero values of $\lambda_{i,m}$ – there will typically only be a few or one of them – will define the 'peers' for firm *i*. The listing of the peer firms can be requested by adding **; Peers** to the command. The first few observations for the sample above are shown below.

```
===============================================================================
Peers - By Firm
===============================================================================
Firm                     Orient.  TechEff  Peers
---------------------    -------  -------  ---------------------------------------
   1                     Inputs   1.00000   3  14 101
                         Outputs  1.00000   1  14 101
   2                     Inputs    .98446   4  71
                         Outputs   .92501   1  71
   3                     Inputs    .96243   3  71
                         Outputs   .88393   1  71
   4                     Inputs    .79469   4  14
                         Outputs   .73593   1  14
   5                     Inputs    .57426   4  71 118
                         Outputs   .44224   1  71
```

E65.5.2 Application

The following uses all the features of the routine save for the Malmquist TFP computation and the allocative efficiency routine. The sample data are in an *Excel* spreadsheet:

E65.6 Comparing Efficiency Values and Rankings – SFA vs. DEA

In many settings, the efficiency ratings themselves are less interesting than the ranks of the observations. The WHO study used in numerous examples throughout this chapter is an example, in which the objective of the efficiency analysis was to rank the countries in terms of their measured efficiency. A perennial question in the efficiency analysis literature focuses on whether one obtains the same qualitative results with the two methodologies. We return to the WHO data to provide an illustration.

The data used are the country means of the output, *dale*, and two inputs, health expenditure, *hexp*, and education, *educ*. After the raw data are input, we use the following

```
SAMPLE      ; All $
REJECT      ; Small > 0 $
CREATE      ; dalebar  = Group Mean(dale, Str = country) $
CREATE      ; hexpbar = Group Mean(hexp, Str = country) $
CREATE      ; educbar = Group Mean(educ, Str = country) $
REJECT      ; year # 1997 $
CREATE      ; logdbar = Log(dalebar) $
CREATE      ; loghbar = Log(hexpbar) $
CREATE      ; logebar = Log(educbar) $

E65.7 Malmquist Index of Total Factor Productivity

(Once again, the user is referred to the relevant literature, such as the numerous papers by Fare and Grosskopf) for background details. Fare's 1994 output based Malmquist productivity change may be written

$$M_{i,O}(t,t+1) = \sqrt{\frac{TE_i(t+1\,|\,t)\times TE_i(t+1\,|\,t+1)}{TE_i(t\,|\,t)\times TE_i(t\,|\,t+1)}}$$

where $TE(r|s)$ indicates the earlier defined output oriented technical efficiency index for firm i, using inputs $\mathbf{x}_{i,r}$ and producing outputs $\mathbf{y}_{i,r}$ relative to production (and input usage) for firms based in period s. This index is computed using the following program:

$$\mathbf{d}_L = \begin{bmatrix} \mathbf{0}_N \\ 0 \end{bmatrix},\ \mathbf{c} = \begin{bmatrix} \mathbf{0}_N \\ 1 \end{bmatrix},\ \boldsymbol{\gamma} = \begin{bmatrix} \boldsymbol{\lambda} \\ \phi_{ir} \end{bmatrix},\ \mathbf{d}_U = \begin{bmatrix} \mathbf{1}_N \\ \infty \end{bmatrix}$$

$$\mathbf{b}_L = \begin{bmatrix} -\infty_K \\ \mathbf{0}_M \end{bmatrix},\ \mathbf{A} = \begin{bmatrix} \mathbf{X}_s' & \mathbf{0}_K \\ \mathbf{Y}_s' & \text{-}\mathbf{y}_{ir} \end{bmatrix},\ \mathbf{b}_U = \begin{bmatrix} \mathbf{x}_i \\ \infty_M \end{bmatrix}$$

This uses the constant returns to scale form. Also, since the period r output and input vectors for firm i will not appear in $\mathbf{Y}_s$ and $\mathbf{X}_s$ when r does not equal s, ϕ_{ir} need not be larger than one. Note that this requires solution of four linear programs for each firm in each period, so the total number of programs to solve will be $4\times N\times T$. Each is quite fast, so overall, the computations do not take long. In the sample of 247 firms and six periods, the nearly 6,000 programs, each involving 248 activities and six constraints, took about 10 seconds.

These computations are carried out for each firm in each period save the last one, and produce an $N\times T$ matrix of TFP values, one row for each firm, one column for each period. The TFP value for the last period is recorded as 1.0, though this is just a space filler.

To compute the Malmquist TFP indices, you will require a panel of data, at least two periods, for each of N firms. Unlike other panel data routines in *LIMDEP*, *this computation always requires a balanced panel*. Every firm must be observed in the same T periods. Also, this routine has no procedures for avoiding missing or invalid data such as zero values for inputs or outputs. The balanced panel must be 'clean' before computation begins. To request the computations, just add

; Pds = t, the fixed number of periods.

Nothing else need be changed. There is no bootstrap feature (**; Nbt = 0**); the computations assume constant returns to scale (**; CRS** is the default and cannot be changed) and no allocative efficiency (**; Rh2** is ignored).

Malmquist TFP Index Application

To illustrate the Malmquist computations, we reexamine the sample of 247 Spanish dairy farms observed for six years. The output is *milk* production. Inputs are *cows, land, labor* and *feed*.

```
FRONTIER    ; Lhs = milk
            ; Rhs = cows,land,labor,feed
            ; Alg = DEA ; Pds = 6
            ; List $
```

The following results are displayed. In addition, a matrix containing the full table, named *malmquist*, is created.

```

E66: MAXIMIZE – Nonlinear Optimization

E66.1 Introduction

Chapters E14 and E21 presented programs for computing nonlinear least squares, nonlinear two and three stage least squares and GMM estimators. The discussion continued in Chapter E25 with a discussion of **NLSUR** for estimation of nonlinear systems of equations. The **NLSQ** and **NLSUR** procedures are parts of a package that allows you to define your own minimization or maximization problem. This will allow you to set up your own maximum likelihood problems for models which are not included in the program already.

The estimation criteria defined in Chapters E14 and E21 are:

Nonlinear Least Squares	Minimize$_\beta$ $\sum_{i=1}^{N} w_i \times [y_i - f(\boldsymbol{\beta},\mathbf{x}_i)]^2 = \sum_{i=1}^{N} w_i\, \varepsilon_i^2$
Nonlinear IV	Minimize$_\beta$ $\boldsymbol{\varepsilon}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\boldsymbol{\varepsilon}$ where $\varepsilon_i = y_i - \mathrm{f}(\boldsymbol{\beta},\mathbf{x}_i)$
GMM	Minimize$_\beta$ $\mathrm{M}(\boldsymbol{\beta}) = \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\boldsymbol{\varepsilon}(\boldsymbol{\beta})$
GMME	Minimize$_\beta$ $q = \overline{\mathbf{m}}'\mathbf{W}^{-1}\overline{\mathbf{m}}$, $\overline{\mathbf{m}} = \frac{1}{N}\sum_{i=1}^{N}\mathbf{m}(\mathbf{x}_i,\boldsymbol{\beta})$, $\mathbf{W} = \text{a weighting matrix}$

MAXIMIZE/MINIMIZE adds to these a general program that allows you to optimize:

Single Function of a Set of Parameters	Minimize or maximize$_\beta$ $\mathrm{F}(\boldsymbol{\beta})$
Sum of Terms	Minimize or maximize$_\beta$ $\sum_{i=1}^{N} w_i \times F(\boldsymbol{\beta},\mathbf{x}_i)$

LIMDEP's **MINIMIZE/MAXIMIZE** procedure will allow you to set up your own log likelihood or method of moments criterion functions. Most of the necessary information about **MINIMIZE/MAXIMIZE** was given in Chapters E14 and E21. Users will find it useful to review these chapters with the discussion below.

NOTE: This program may be used to estimate up to 150 parameters.

NOTE: Use **MAXIMIZE** to create new models that are not in the menu of available models in the program. An example appears in Section E66.8.3.

E66.2 The MINIMIZE/MAXIMIZE Commands

For convenience, we will assume at this point that you wish to **MAXIMIZE** a function. (If appropriate, change the command to **MINIMIZE**.) The **MAXIMIZE** command is the same as **NLSQ** discussed in Chapter E14,

NLSQ ; Lhs = y
; Fcn = ...
; Labels = ...
; Start = starting values $

with two exceptions. To maximize a general function, the command is **MAXIMIZE** and there is no Lhs variable. The basic command is, then,

MAXIMIZE ; Labels = list of labels for parameters being computed
; Fcn = function definition
; Start = list of starting values $

The basic format of the command, as shown above, is used to maximize a sum of terms. The function definition defines a function that is summed over the sample observations. Here is an example that computes maximum likelihood estimates of the parameters of a probit model using 500 artificially generated observations that conform exactly to the assumptions of the model.

CALC ; Ran(12345) $
SAMPLE ; 1-500 $
CREATE ; x = Rnu(-.5,.5) ; y = (.2 - .2*x + Rnn(0,1)) > 0 $
CREATE ; q = 2*y - 1 $
MAXIMIZE ; Fcn = Log(Phi(q * (b0 + b1*x))) ; Labels = b0,b1 ; Start = 0,0
; Output = 3 $
PROBIT ; Lhs = y ; Rhs = one,x ; Output = 3 $

E66.2.1 Function Definitions

The following describes the various components of the function definition. The next section describes a very important variation of this specification, the use of subfunctions. Users should be sure to read all of both these sections before using this program.

Labels for Parameters

The labels definition is optional. If you do not provide labels, the defaults are **b1**, **b2**, ..., **bk**. The number of parameters in the model, *k*, is the number of starting values you provide. Thus, for example, a linear regression could be requested with

MINIMIZE ; Fcn = (y - b1 - b2*x) ^ 2 ; Start = 0,0 $

Because there are a variety of named entities which can appear in the function, you should use the

; Labels = list of labels

part of the command to identify which of them are the parameters being estimated. You must then use these labels in the function you specify. Labels may be anything you like, up to eight characters.

WARNING: Use new names! Do not use program names that are in use otherwise, such as *s*, *rho*, *sigma*, *b*, etc., and the names of existing scalars or matrices. Such labels would be accepted when your command is translated, because you are free to use these entities in your function definition to supply specific values. But, later, when *LIMDEP* scans your expression to see what you have specified, it checks all other tables first, and your label list last. For example, if you use **s** as a label, and this command is the first model command that you have given, **s** will simply be taken as the as yet undefined result of a regression. The actual value would, in fact, always be fixed at 0. An attempt is made to prevent you from doing this at the time your function definition is translated. For example, here is what happens if we try to use **s** instead of **b0** in the probit model estimator above

MAXIMIZE ; Fcn = Log(Phi(q * (s + b1*x))) ; Labels = s,b1 ; Start = 0,0 $

```
Conflict: param. and scalar have the same name: S.
```

For large problems, you may use a shortcut for the labels definition,

; Labels = number_label

produces ‘number’ sequentially numbered repetitions of the label. For example, **5_b** gives **b1,b2,b3,b4,b5**. The number may be a literal value or a scalar. With this device, you can make your model command independent of the size of the model, and you can accommodate a model of any size. For example:

```
NAMELIST    ; xa = ... (up to 100 names)
            ; xb = ... (up to 100 names) $
CALC        ; ka = Col(xa) ; kb = Col(xb) $
MATRIX      ; ca = Init(ka,1,0.) ; cb = Init(kb,1,0.0) $
MINIMIZE    ; Start = ca,cb, ... any other parameters
            ; Labels = ka_ba, kb_bb, any other labels
            ; Fcn = Index = ba1’xa  +  bb1’xb | ... the rest of the function $
```

This template could be used for a model of any size. Only the namelists would have to be changed from one specification to another.

LIMDEP will ensure that there is a correspondence between your labels and your starting values. However, it is not possible for the program to ensure that you have used all of the parameters in your function specification. If you define a parameter, but you do not use it in your function definition, then one of two things will occur. Either the iterations will never converge and they will exit on maximum iterations, with one of the parameters not changing from its initial value, or what appears to be convergence will be reached, but the estimated covariance matrix of the estimated parameters will be singular, as it will contain a row and column of zeros corresponding to the unused parameter.

Here is an example. Note that the defined model parameter *c*3 does not appear in the function.

MINIMIZE ; Fcn = (y - c0 - c1*x1 - c2*x2)^2
; Start = 0,0,0,0
; Labels = c0,c1,c2,c3 $

```

Algebraic Form of the Function

The **; Fcn** specification is written using the rules and operators of algebra (+, -, *, /), ^ (for raise to the power), and @ (for the Box-Cox transformation). The usual rules are observed; ^ and @ are computed first, then * and /, and finally + and -. Two additional operators which have the same precedence as multiplication are ! for maximum (5 ! 6 = 6) and ~ for minimum (5 ~ 6 = 5). Parentheses may be used freely to force the order of evaluation of expressions. Use as many levels of parentheses as required. Entities which may appear in the specification include:

- numbers,
- variable names,
- namelists,
- any existing scalars,
- matrix elements,
- your parameters, using your labels.

To use a subscripted matrix element, enclose the subscript in curled brackets, **{ }**, not parentheses. I.e., **gamma(1,1)** will confuse the compiler, use **gamma{1,1}**.

NOTE: This construction, with curled brackets, is specific to the function definition part of the **NLSQ**, **NLSUR**, **MAXIMIZE**, **MINIMIZE** and **GMME** commands. Elsewhere, such as in **CALC** and **CREATE**, matrix subscripts are indicated with ordinary parentheses.

The function is evaluated by 'looping' through your current sample, computing the function at each observation, and summing the terms. Let **Z**(*i*) denote all the variables in your data set where '*i*' denotes a specific observation. It is assumed that some variables appear in your function definition, so the function is computed by summing all observations. If no variables actually appear in the function, then the same function will simply be summed *N* times. Thus, in the preceding probit example, the function evaluated is

$$F = \sum_{i=1}^{N} \text{Log}\ (\ \text{Phi}\ (\ (2y_i - 1) * (\beta_0 + \beta_1 x_i))) = \sum_{i=1}^{N} g[\mathbf{Z}(i)].$$

An example that appears below is a four dimensional Rosenbrock function,

$$F(\mathbf{c}) = (c_1+10c_2)^2 + 5(c_3 - c_4)^2 + (c_2 - 2c_3)^4 + 10(c_1 - c_4)^4.$$

The function definition for this minimization problem would be

; Fcn = (c1+10*c2)^2 + 5*(c3-c4)^2 + (c2-2*c3)^4 + 10*(c1-c4)^4

Since this function does not involve any variables, the function value each time this is calculated would be just *N* times the value shown in the actual function. Since this would be a waste of time and effort, one would normally precede this kind of optimization problem with

SAMPLE ; 1 $

so that it would be evaluated only once.

Functions that May Appear in the Definition

The following functions may be used in your function definition

Abs(*z*)	= absolute value, $\lvert z \rvert$
Atn(*z*)	= arctangent, atan(*z*)
Cos(*z*)	= cosine, cos(*z*)
Exp(*z*)	= exponent, exp(*z*)
Gma(*z*)	= gamma, $\Gamma(z) = \int_0^\infty t^{z-1}e^{-t}dt$
Inp(*z*)	= inverse normal probability = $\Phi^{-1}(z)$, $0 < z < 1$
Lgd(*z*)	= logit density = Lgp*(1-Lgp)
Lgm(*z*)	= log of gamma
Lgt(*z*)	= logit = log(z/(1-z)), $0 < z < 1$
Lgp(*z*)	= logit probability = Exp(z)/(1+Exp(z)) = Prob($Z \le z$)
Lmm(*z*)	= -N01(z)/Phi(z) = E[$z \mid z \le 0$] for $z \sim$ N[0,1]
Lmp(*z*)	= N01(z)/Phi(-z) = E[$z \mid z \ge 0$] for $z \sim$ N[0,1], Lmp(-z)=$\phi(z)/\Phi(z)$
Log(*z*)	= natural logarithm, log(z)
N01(*z*)	= standard normal density, $\phi(z)$
Phi(*z*)	= standard normal CDF, $\Phi(z)$
Psi(*z*)	= log derivative of Gma, $\Psi(z) = \Gamma'(z)/\Gamma(z)$, (digamma function)
Psp(*z*)	= $\Psi'(z) = \Gamma''(z)/\Gamma(z) - \Psi^2(z)$, (trigamma function)
Sgn(*z*)	= signum(*z*) = -1,0,+1 if z <, =, > 0
Sin(*z*)	= sine, sin(*z*)
Tvm(*z*)	= 1 - Lmm $\times$ (*z* + Lmm) = Var[$z \mid z < 0$] for $z \sim$ N[0,1]
Tvp(*z*)	= 1 - Lmp $\times$ (*z* + Lmp) = Var[$z \mid z < 0$] for $z \sim$ N[0,1]
Bds(*z*,*a*,*c*)	= incomplete beta function; (Bds(0,*a*,*c*) = 0, Bds(1,*a*,*c*) = 1)
Gmp(*z*,*p*,*a*)	= incomplete gamma integral, normalized to the probability
Bvn(*z*1,*z*2,ρ)	= bivariate normal CDF
Bvd(*z*1,*z*2,ρ)	= bivariate normal density
Min(*z*1,*z*2)	= minimum of *z*1 and *z*2
Max(*z*1,*z*2)	= maximum of *z*1 and *z*2
Ash(*z*)	= hyperbolic arc sin(*z*) = $\log(z + (1 + z^2)^{1/2})$
As1(*z*)	= derivative of Ash(*z*) = $(1 + z^2)^{-1/2}$
Ach(*z*)	= hyperbolic arc cos(*z*) = $\log(z + (z^2 - 1))$
Ac1(*z*)	= derivative of Ach(*z*) = $(z^2 - 1)^{-1/2}$
Ath(*z*)	= hyperbolic arc tan(*z*) = $.5\log((1 + z)/(1 - z))$
At1(*z*)	= derivative of Ath(*z*) = $(1 - z^2)^{-1}$
Hsn(*z*)	= hyperbolic sin(*z*) = .5(exp(2*z*)-1)/exp(*z*)
Hs1(*z*)	= derivative of Hsn(*z*) = Hcs(*z*)
Hcs(*z*)	= hyperbolic cos(*z*) = .5(exp(2*z*)+1)/exp(*z*)
Hc1(*z*)	= derivative of Hcs(*z*) = Hsn(*z*)
Htn(*z*)	= hyperbolic tan(*z*) = Hsn(*z*)/Hcs(*z*)
Ht1(*z*)	= derivative of Htn(*z*) = $1/\mathrm{Hcs}^2(z)$

The incomplete beta function is

$$\text{Bds}(z,a,c) \;=\; [\Gamma(a)\Gamma(c)/\Gamma(a+c)] \int_0^z t^{a-1}(1-t)^{b-1}dt \text{ for } 0 < z < 1.$$

The normalized incomplete gamma function is

$$\text{Gmp}(z,p,a) \;=\; [a^p / \Gamma(p)] \int_0^z t^{P-1}\, e^{-at}\, dt.$$

Note that this returns a probability; $\text{Lim}_{z\to 0}$ Gmp(z,p,a) = 0, $\text{Lim}_{z\to\infty}$ Gmp(z,p,a) = 1, 0 < Gmp < 1, ∂Gmp/∂z > 0. To get the unnormalized gamma integral, you may use the construction

$$\text{Gma}(p) \;/\; a\text{\^{}}p \;\mathbf{*}\; \text{Gmp}(z,p,a) \;=\; \int_0^z t^{p-1}\, e^{-at}\, dt.$$

Do note, however, that this integral can become very large. This function is a generalization of p! for noninteger p. Some particular values to note, Gmp(z,p,a) = 0 if $z \le 0$; Gmp(z,p,a) = 1 if $p \le 0$, and Gmp(z,p,a) = 0 if $a \le 0$ and, finally, Gma(.5) = $\sqrt{\pi}$.

In the beta, gamma and bivariate normal functions, if any of the parameters separated by commas are expressions, it is necessary to enclose them in parentheses. E.g., use **Bvn((1+x'b),z,r)**, not **Bvn(1+x'b,z,r)**. The list may contain variables, labels, scalars, and expressions contained in parentheses. Functions may be nested to any depth and expressions may appear as arguments in the functions, as in

Log (Phi (a1 + a2 * (x/y)^2)).

This would be a valid expression and would evaluate exactly as given.

Linear Functions and Dot Products

Many expressions in econometric models will involve dot products of parameters and variables. For example, a model built as an extension of a probit model will likely involve an expression of the form **Phi(b'x)**. Dot products may appear in exactly this form in your function definitions. Typically, the '**x**' would be a namelist. To use the parameter vector, use the first name in your labels list. For example, in

```
NAMELIST    ; x = one,x1,z,p  $
MAXIMIZE    ; ...  ; Labels = b0,b1,b2,b3
                   ; Fcn = ... Phi(b0'x) $
```

the term **b0'x** is evaluated as $b0\times one + b1\times x1 + b2\times z + b3\times p$. Once again, in a dot product, the sum is evaluated from left to right using your list of labels in the order in which they appear in **; Labels = list**.

NOTE: If the namelist and the labels list do not have the same number of elements, then the dot product is simply evaluated out to the shorter of the two lists. In the example, if there were additional names in **x**, they would not change **b0'x** because starting at *b*0, there are only four parameters.

NOTE: This replaces the function Dot[.] used in earlier versions of *LIMDEP*. The Dot[.] function is retained for backwards compatibility, but you will find it easier to use the more natural syntax. Also, the operation described above does allow a bit more flexibility. For completeness, we note the counterparts to the constructions described above are **Dot[x]** = **b0'x** and **Dot[b3,second]** = **b3'second**. You may use either form.

Suppose you want to pick up just a few of the parameters in a dot product. For example, suppose your parameters are **; Labels = b1,b2,b3,b4,b5,b6,b7** and as part of your function, you want **b3*x14 + b4*xyz + b5*wvs**. You could first define the namelist for the dot function, with, say, **NAMELIST ; second = x14,xyz,wvs $**. Then, to obtain that function, just begin the dot product with *b*3 instead of *b*1. Thus, **b3'second** evaluates exactly to the sum given above.

It is also possible to skip over parameters in dot products, by putting columns of zeros in your namelists. This may be convenient in specifying your function, especially if it involves many parameters. For example, using the list above, you could obtain $b2 \times x14 + b5 \times xyz$

```
CREATE     ; zero = 0 $
NAMELIST   ; second = x14,zero,zero,xyz $
MAXIMIZE   ; ... b2'second ...
```

Dot products need not be only a mix of variables and parameters. They may also include vectors (matrices) that do not appear elsewhere in the function, and they may be products of variables or parameters. When you are specifying your functions, there are several ways you can shorten your commands by making use of the dot product notation, and using lists. The following constructions can all be used in specifying your functions: Let

a,d = the names of any vectors in your matrix work area
x,y = the names of any namelists
cj = any of the labels in your **; Labels = ...** specification

Then, any of the following can appear in your function

a'a = inner product of the vector
a'd = dot product of two vectors
a'x = linear combination of variables, at the *i*th observation
x'y = sum of cross products of the variables, at *i*th observation
x'x = sum of squares
cj'a = product of vector elements and parameters
cj'x = the familiar product of coefficients and variables.

This product can be computed beginning with any of the parameters in the list. For example, consider fitting a probit model:

```
MAXIMIZE    ; Labels = a1,a2,a3
            ; Start = 0,0,0
            ; Fcn = Log(Phi((2*y-1)*(a1+a2*x1+a3*x2))) $
```

Alternatively, if you define a namelist with

```
NAMELIST    ; xa = one,x1,x2  ; xb = x1,x2 $
```

Then, **; Fcn = Log(Phi((2*y-1) * a1'xa))**

is the same as **; Fcn = Log(Phi((2*y-1) * (a1 + xb'a2)))**.

Bilinear and Quadratic Forms

Bilinear and quadratic forms may also appear in function definitions. Suppose that *c* and *d* indicate elements of the parameter vector, which point to specific parts of the vector, and **z** is a namelist and **A** is a matrix. The following forms may appear in your function definition

(bilinear) **c'[z]d** $= \Sigma_j c_j d_j z_j$,

c'[z]c $= \Sigma_j c_j^2 z_j$

(quadratic) **c'[A]c** $= \Sigma_j \Sigma_l c_j c_l A_{jl}$

In the quadratic form, **A** may denote a namelist. In this case, you must indicate how many rows and columns are to appear in the matrix. Thus, suppose the namelist contains 12 variables. These could be arranged in a 2×6, 3×4, 4×3, or other matrix. To indicate how many rows the matrix has, you append the number of rows in the name between backslashes. For example, if

```
NAMELIST    ; x = x1,x2,x3,x4,x5,x6,x7,x8,x9,x10,x11,x12 $
```

then, **c**'[**X** \ 4\]**d** is the bilinear form $\begin{pmatrix} c1 & c2 & c3 & c4 \end{pmatrix} \begin{bmatrix} x1 & x2 & x3 \\ x4 & x5 & x6 \\ x7 & x8 & x9 \\ x10 & x11 & x12 \end{bmatrix} \begin{pmatrix} d1 \\ d2 \\ d3 \end{pmatrix}$.

Each observation is inserted in turn into the matrix in order to set up the computation. The function evaluation then involves summing (possibly functions of) the quadratic forms.

E66.2.2 Gauss-Hermite and Gauss-Laguerre Quadrature in Functions

The function optimization programs such as **MAXIMIZE** or **MINIMIZE** may use functions that contain integrals of the form

$$F(\boldsymbol{\beta}) \;=\; \int_{-\infty}^{\infty} \exp(-v^2)G(\boldsymbol{\beta},v)dv$$

by using Gauss-Hermite quadrature. This is a very accurate approximation which is computed using

$$F(\boldsymbol{\beta}) \;\approx\; \sum_{h=1}^{H} w_h G(\boldsymbol{\beta},z_h)$$

where H is the number of points for the quadrature, w_h is the weight and z_h is the node at point h of the quadrature. You set the number of points, H for the quadrature. The $G(.)$ function is unrestricted – it can be any function that is allowable in **MINIMIZE/MAXIMIZE**. The variable of the integration, v, may or may not actually appear in the function. You can also include functions of the form

$$F(\boldsymbol{\beta}) \;=\; \int_{0}^{\infty} \exp(-v\;)G(\boldsymbol{\beta},v)dv\,.$$

(Notice that the exponent is exp(-v) rather than exp(-v^2), and the range of integration is from 0 to +∞ rather than from -∞ to ∞. Integrals of this form are accurately approximated using Gauss-Laguerre integration, rather than Gauss-Hermite integration.) Commands that use quadrature are of the form

MAXIMIZE **; Fcn = name = Ntg(the function to be integrated) |**
the rest of the function, which will probably involve 'name'
; Hrq = the name of the variable over which integration is done
for Hermite integration
or **; Glq = the name** of the variable over which integration is done
for Gauss-Laguerre integration

The accuracy of the quadrature is directly a function of the number of quadrature points, the more the better. You may set the number of points with

; Hpt = one of 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 16, 20, 32, 48, 96 for the Hermite quadrature
and **; Lpt** = one of 2, 3, 4, 5, 6, 7, 8, 9, 10, 12, 15, 20, 40, 68 for the Laguerre quadrature

As noted, more points are better than less. However, the amount of computation varies linearly with the number of quadrature points, so if time is a consideration, you may wish to choose a lower number. The default values for the numbers of quadrature points are 20 for Hermite and 40 for Laguerre.

To use one of these integrals in your function to be maximized, you must set up the operation as follows: The command will include

; Hrq = **the name** of the variable over which the integration is done for integration by Hermite quadrature

or **; Glq =** **the name** of the variable over which the integration is done for integration by Laguerre quadrature

and **; Start =** parameter values, as usual
; Labels = labels for parameters in the model, as usual
; other options $

Note the following requirements:

- You can have more than one integral in the final function, but each must be a named subfunction. If you specify 'Ntg(...)' within a function definition, an error will occur during compilation claiming that you have an unidentified symbol.
- Integrals should not be functions of other integrals. The results will be unpredictable, but almost certainly incorrect.
- You may have only one kind of integral in your function definition. Each Hrq, Glq, (or Sim, see below) which appears in a command overrides previous ones.

Two examples follow. Note that neither of these are 'good models,' and unless the data actually do satisfy the assumptions of the model, estimation of these will not produce very appealing results. For the first one, in particular, for a cross section formulation, without multiplying *v* by *x*, the variance term diverges; it is not identified.) The examples are intended only to illustrate use of the tools.

Heterogeneity in a Probit Model

Consider a probit model in which there is normally distributed, unobserved individual heterogeneity which multiplies one of the variables in the model,

$$y = 0 \text{ or } 1,$$

$$\text{Prob}[\, y = 1 \mid v\,] = \Phi(\boldsymbol{\beta}'\mathbf{z} + \theta\, x\, v) \text{ where } v \text{ is standard normally distributed.}$$

(A nonunitary standard deviation of v would be absorbed into the free parameter θ.) The probability that enters the log likelihood is Prob[$y = j$] = E_v [Prob[$y = j \mid v$]], j = 0,1. The expectation is exactly equal to

$$\text{Prob}\,[\, y = j\,] = \int_{-\infty}^{\infty} (1/\sqrt{2\pi})\exp(-v^2/2)\Phi[(2j-1)(\boldsymbol{\beta}'\mathbf{z}+\theta xv)]dv = P(y).$$

In the integral, let $u = v/\sqrt{2}$, so $v = u\sqrt{2}$ and the Jacobian is $dv/du = \sqrt{2}$. Make the change of variable in the integral, to produce

$$\text{Prob}\,[\, y = j\,] = \int_{-\infty}^{\infty} (1/\sqrt{\pi})\exp(-u^2)\Phi[(2j-1)(\boldsymbol{\beta}'\mathbf{z}+\sqrt{2}\theta xu)]du = P(y).$$

This is now exactly in the form noted earlier for Hermite quadrature. (It can be simplified a bit more by defining $\gamma = \sqrt{2}\,\theta$.) The following commands simulate and estimate this model: (The command uses a subfunction, which is described in the next section.)

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-200 $
CREATE      ; z1 = Rnn(0,1) ; z2 = Rnn(0,1) ; v = Rnn(0,1) ; x = Rnu(-.5,.5) $
CREATE      ; y = ( .2 + z1 + z2 + v*x + Rnn(0,1) ) > 0 ; q = 2*y - 1 $
NAMELIST    ; z = one,z1,z2$
CALC        ; kz = Col(z) $
PROBIT      ; Lhs = y ; Rhs = z $
MAXIMIZE    ; Fcn = Prob = Ntg(1/Sqr(pi) * Phi(q*(b1'z + t*u*x))) | Log(Prob)
            ; Start = b,.1
            ; Labels = kz_b,t
            ; Hrq = u ; Hpt = 20 ; Output = 3 $
```

The following output results. (The probit results for the starting values are omitted.)

A Gamma Integral

(This is, admittedly, a bit contrived.) The gamma integral is

$$\Gamma(P) = \int_0^\infty \exp(-v)v^{P-1}dv = (P\text{-}1)! \text{ if } P \text{ is a positive integer.}$$

Consider the following trivial modification of a probit log likelihood function:

$$F = \Sigma \{ \log \Phi(q * \boldsymbol{\beta}'\mathbf{x}) + \frac{1}{\Gamma(P)} \int_0^\infty \exp(-v)v^{P-1}dv \}.$$

Since the second term is exactly equal to one, the end result of maximizing the function shown above should be identical to the simple probit estimates, though the function value will equal the probit log likelihood plus the sample size. This could be done with **MAXIMIZE** as follows:

```
CALC        ; Ran(12345) $
SAMPLE      ; 1-200 $
CREATE      ; z1= Rnn(0,1) ; z2 = Rnn(0,1) $
NAMELIST    ; z = one,z1,z2 $
CREATE      ; y = ( .2 + z1 + z2 + Rnn(0,1) ) > 0 ; q = 2*y - 1 $
CALC        ; p = 2 ; k = Col(z)  $
MAXIMIZE    ; Fcn = gamma = Ntg(u^(p-1)) | Log(Phi(q * b1'z)) - gamma/Gma(P)
            ; Start = k_0 ; Labels = k_b ; Glq = u ; Pts = 24 $
PROBIT      ; Lhs = y ; Rhs = z $
```

To illustrate this program, we used the data from the previous example, and set $P = 2$ in the gamma function. As expected, the coefficients are identical to the probit model and the function differs by 200. (Our maximizer translates the problem into a minimization, so the sign changes.)

E66.2.3 Integration by Simulation

You can include functions that include expectations of the form

$$F(\beta) = E_v\,[F(\beta,v)]$$

$$= \int_{-\infty}^{\infty} \frac{1}{\sqrt{2\pi}} e^{-v^2/2} F(\beta,v)\,dv$$

where v is distributed as standard normal. These can be approximated reasonably accurately by simulation, by using

$$F(\beta) \approx (1/R) \sum_{r=1}^{R} F(\beta,v_r)$$

where v_r is one of R random draws from the standard normal distribution. To replace the Hermite integration with this integration by simulation, change **; Hrq = name** to

; Sim = name

To set R, the number of points for the approximation, you will use (as with other applications)

; Pts = number of points for simulations.

NOTE: The seed for the random number generator is set to the same value each time a computation is done for a specific individual. Thus, you can replicate a computation done earlier by setting the main seed for the program before estimation.

Consider the first example above. A second way to approximate the expected value would be by simulation and averaging. That is, the probability can be approximated by averaging the probabilities obtained with a sample of random draws from the distribution of v. The change in the preceding would be only to the method of integration.

The commands are:

CALC	**; Ran(12345) $**
SAMPLE	**; 1-200 $**
CREATE	**; z1 = Rnn(0,1) ; z2 = Rnn(0,1) $**
NAMELIST	**; z = one,z1,z2 $**
CREATE	**; y = (.2 + z1 + z2 + Rnn(0,1)) > 0 ; q = 2*y - 1 $**
PROBIT	**; Lhs = y ; Rhs = z $**
MAXIMIZE	**; Fcn = Prob = Ntg(Phi(q*(b1'z + t*u*x))) | Log(Prob)**
	; Start = b,.1 ; Labels = kz_b,t ; Sim = u ; Pts = 50 ; Output = 3 $

We also drop the scaling in the integral by $1/\pi^{1/2}$, since that is specific to the change of variable for the Hermite integration. The results are shown below.

```

```

Note the results are nearly the same as those computed using Hermite quadrature. The difference in the fourth coefficient results from the scaling by $\sqrt{2}$. The differences across the other coefficients can be partly explained by the relatively small number of simulation points (50). Of course, the Hermite integral is also only an approximation.

E66.2.4 Maximum Simulated Likelihood Estimation

The simulation procedure described above can be extended to a vector of up to five standard normally distributed variables. The function is defined as

$$F(\beta) = \sum_{i=1}^{N} \frac{1}{R} \sum\nolimits_{r=1}^{R} g[\beta, \mathbf{Z}(i), v_{1ir}, v_{2ir}, ..., v_{Mir}].$$

(M may be up to five.) The variables in the simulated function may be freely correlated. The specification is as follows:

MAXIMIZE **; Labels** = the list of labels for the parameters
; Start = the starting values for the parameters
; Sim = a symbol for the draws
; Sdv = M specifications for the standard deviations of the *v*s
; Pts = the number of draws, R
; Fcn = the function definition
; ... any other options $

The number of variables simulated will equal the number of specifications you provide in the **; Sdv** list. Use a ‘1’ for a fixed (at 1.0) standard deviation or a ‘*’ for a free standard deviation, to be estimated. The names for the variables will then be the symbol you place in the **; Sim** specification plus the integer index.

For example,

; Sdv = *,*,*
; Sim = uab

produces a vector of three random draws with unrestricted standard deviation, named *uab*1, *uab*2, *uab*3. Optional features include

; Cor	to allow the *M* variables to be freely correlated
; Halton	to use Halton draws (see Chapter R24) instead of uniform random numbers to power the simulation
; Antithetic	to use pairs of draws, *v* and **-***v*.

E66.3 Subfunctions in Functions

Functions for **MINIMIZE** may be built up recursively by using subfunctions. The **; Fcn** part of the command will consist of

; Fcn = name1 = expression |
name2 = expression ... |
expression $

The last expression is the one being minimized, so it does not have a name. Any expression can use the name of any previous expression, as many times as desired. For examples:

; Fcn = bx = c0 + c1*x | (y-bx)^2
; Fcn = bx = c0 + c1*x | e = y - bx | e^2
; Fcn = bx = c0 + c1*x | e = y - bx | e^2 + e^4
; Fcn = d = (2*y-1)*b'x| Log(Phi(d)) (log likelihood for a probit model).

This may bring enormous gains in simplifying expressions. Functions often involve repeated use of the same function. For an example, consider the probit model, which might be inefficiently set up as

; Fcn = y*Log(Phi (b'x)) + (1-y)*Log(1 - Phi(b'x))

This can be written

; Fcn = bx = b'x |
fbx = Phi(bx) |
lfbx = Log(fbx) |
y * lfbx + (1-y)*(1-lfbx)

(Obviously, there are yet more efficient ways to do this, but this illustrates the point.) This feature will never increase the amount of computation, and will usually decrease it. It reduces the chance for error in lengthy functions. And, it will reduce overall the length of your commands. You should take advantage of this feature of the command whenever possible.

Note that functions are compiled from left to right (or, top to bottom). That means if you try to use a name which is defined after the function you are defining, an error will occur in which the name you are using does not appear to be defined.

E66.4 Supplying Derivatives for Functions

All optimizations for user defined problems (**NLSQ**, **NLSUR**, **MINIMIZE**, **MAXIMIZE, GMME**) use first difference approximations to obtain derivatives of the functions. This provides sufficient accuracy to obtain appropriate solutions to most problems. However, it is relatively slow (sometimes extremely so) compared to using analytic derivatives and, for some problems, may not be sufficiently accurate.

The subfunctions defined as above may be the derivatives of the function you are optimizing. This can speed up the computations. To indicate that a subfunction is a derivative, you just precede the name with an underscore, then the name of the parameter. For example:

```
MINIMIZE    ; Start = 0,0
            ; Labels = c0,c1
            ; Fcn = e = y - c0 - c1*x |
                    _c0 = -2*e         |
                    _c1 = -2*e*x       |
                    e^2 $
```

NOTE: If the derivatives you provide do not match the function, the optimization procedure will eventually break down, claiming to be unable to minimize the function. The optimizer cannot check your differentiation for you by any other way. However, if you have not differentiated the function correctly, the optimization will break down eventually.

Any derivatives that you do not provide are evaluated numerically as usual.

For an example, the following shows three ways to estimate the parameters of a simple probit model.

```
TIMER $
CALC        ; Ran(12345) $
SAMPLE      ; 1-2000 $
CREATE      ; x = Rnn(0,1) ; y = x + Rnn(0,1) ; y = y>0 ; q = 2*y-1 $
PROBIT      ; Lhs = y ; Rhs = one,x $
MAXIMIZE    ; Labels = b0,b1 ; Start = 0,0
            ; Fcn = Log(Phi(q*(b0+b1*x))) $
MAXIMIZE    ; Labels = b0,b1 ; Start = 0,0
            ; Fcn = bx = q*(b0+b1*x)         |
                    d = q*N01(bx)/Phi(bx)    |
                    _b0 = d                  |
                    _b1 = d*x                |
                    Log(Phi(bx)) $
```

Absolute timings are not particularly meaningful as they are specific to computers. But, for the three methods shown, on the same machine, we find identical results to six decimal places, while the formal probit estimator requires 0.04 seconds, the solver with numerical derivatives took 0.33 seconds, and the analytical derivatives reduced this to 0.23 seconds. On a comparable basis, the time savings could be substantial.

Derivatives for an Index Function

If your function contains an 'index' function, such as the **β′x** that appears in a probit model, then there is a shortcut whereby you can give a full set of derivatives with a very small amount of programming. To illustrate, consider the following example which uses this 'trick' for a probit model:

```
NAMELIST    ; xvars = a namelist of  up to 100 variable names $
CREATE      ; y = the dependent variable $
CREATE      ; q = 2*y-1 $
CALC        ; kvars = Col(xvars) $
MAXIMIZE    ; Labels = kvars_c ? labels are c1,c2,...,c100
            ; Start = the set of starting values (might be a matrix)
            ; Fcn = index = q*c1'xvars                         |
                    _d(c1'xvars) = q*N01(index)/Phi(index) |
                    Log(Phi(index)) $
```

This **MAXIMIZE** command specifies the log likelihood function. The middle specification of the function definition provides analytic derivatives for all 100 variables in the model. The specification **_d(c1'xvars)** contains the label of the desired first parameter for which the derivatives are provided, then an apostrophe, followed by a namelist. An expression appears after the equals sign. This shorthand states that the analytic derivatives are obtained by multiplying the variables in the namelist by the expression. This produces derivatives for as many parameters as there are variables in the namelist. A small, specific example would be

```
NAMELIST    ; x = one,x1,x2,x3 $
MAXIMIZE    ; Labels = b1,b2,b3,b4
            ; Start = 0,0,0,0
            ; Fcn = bx = q*b1'x                  |
                    _d(b1'x) = q*N01(bx)/Phi(bx)  |
                    Log(Phi(bx)) $
```

The second line is equivalent to the four lines

```
_dc1  = q*N01(bx)/Phi(bx) * 1
_dc2  = q*N01(bx)/Phi(bx) * x1
_dc1  = q*N01(bx)/Phi(bx) * x2
_dc1  = q*N01(bx)/Phi(bx) * x3
```

E66.5 Model Specifications for the MAXIMIZE Command

This is the full list of general specifications that are applicable to this model estimator.

Controlling Output from Model Commands

; Table = name saves model results to be combined later in output tables.

Robust Asymptotic Covariance Matrices

; Covariance Matrix displays estimated asymptotic covariance matrix (normally not shown), same as **; Printvc**.

Optimization Controls for Nonlinear Optimization

; Start = list	gives starting values for a nonlinear model.
; Tlg[= value]	sets convergence value for gradient.
; Tlf [= value]	sets convergence value for function.
; Tlb[= value]	sets convergence value for parameters.
; Alg = name	requests a particular algorithm, Newton, DFP, BFGS, etc.
; Maxit = n	sets the maximum iterations.
; Output = n	requests technical output during iterations; the level '**n**' is 1, 2, 3 or 4.
; Lpt = n	sets the number of points to use Laguerre quadrature.
; Hpt = n	sets the number of points to use for Hermite quadrature.
; Set	keeps current setting of optimization parameters as permanent.

Predictions and Residuals

; List	displays a list of fitted values with the model estimates.
; Keep = name	keeps fitted values as a new (or replacement) variable in data set.
; Fill	fills missing values (outside estimating sample) for fitted values.

Hypothesis Tests and Restrictions

; Test: spec	defines a Wald test of linear restrictions.
; Wald: spec	defines a Wald test of linear restrictions, same as **; Test: spec**.
; CML: spec	defines a constrained maximum likelihood estimator.
; Rst = list	specifies equality and fixed value restrictions.

; Maxit = 0 ; Start = the restricted values specifies Lagrange multiplier test.

Predictions requested with **; List, ; Keep** and **; Fill** are the individual values of the function. There are no residuals. You may also compute a weighted log likelihood (or any other function) with

; Wts = weighting variable

Parameters may be fixed at the starting values with

; Fix = list of labels

E66.6 Output from MINIMIZE/MAXIMIZE

The results from this procedure consist of the minimized function value, and, if a sum of terms was minimized, estimates of the standard errors and asymptotic 't ratios'. If you have computed a simple function, not a sum of terms, *LIMDEP* reports 1.0 for the estimated standard errors. The asymptotic covariance matrix is estimated by the BHHH method if BFGS, DFP or steepest descent is used, or with the estimated Hessian if you request Newton's method. The latter can occasionally be problematic because the second differencing method used to estimate the Hessian does not insure positive definiteness.

Results saved by the **MINIMIZE** procedure are:

Matrices: *b* and *varb* for all parameters, including those fixed,
gradient = the first derivative vector.

Scalars: *logl* = function value,
nreg and *kreg* = the dimensions of the problem,
exitcode = the termination status for the procedure.

Last Model: The labels in your **; Labels = list** specification.

Last Function: Your function as defined.

You can obtain simulations of the function you have maximized, or functions of the parameters you have computed as well as partial effects of any function based on those parameters using **SIMULATE** and **PARTIALS**. An example appears in Section E66.8.3.

E66.7 Types of Optimization Problems

There are broadly two types of functions, one that does not require summing over a sample of observations and one that does, in the manner of a log likelihood function. You can also use **MAXIMIZE** to find the zeros of an equation and to solve a linear programming problem.

E66.7.1 Simple Function of Parameters

If the function you are minimizing or maximizing is not a sum of terms, just specify it as described above. Then, be sure to precede your command with

SAMPLE ; 1 $

For instance, one of the examples, from Goldfeld and Quandt (1972) is this four dimensional Rosenbrock function:

$$F(\boldsymbol{\beta}) = (\beta_1+10*\beta_2)^2 + 5*(\beta_3 - \beta_4)^2 + (\beta_2 - 2*\beta_3)^4 + 10*(\beta_1 - \beta_4)^4.$$

The correct function minimizing values of all four parameters are 0.0. The **; Fcn** part of the command is exactly as it is shown above. The commands for minimizing this function are:

```
SAMPLE      ; 1 $
MINIMIZE    ; Labels = b1,b2,b3,b4 ; Start = .1,-.1,.3,.05
            ; Fcn = (b1+10*b2)^2 + 5*(b3-b4)^2 + (b2-2*b3)^4 + 10*(b1-b4)^4 $
```

```
-----------------------------------------------------------------------------
User Defined Optimization
Dependent variable               Function
Log likelihood function            .00000
Estimation based on N =      1, K =   4
Inf.Cr.AIC  =      8.0 AIC/N =    8.000
--------+--------------------------------------------------------------------
        |                Standard            Prob.      95% Confidence
UserFunc|  Coefficient       Error       z    |z|>Z*         Interval
--------+--------------------------------------------------------------------
      B1|-.20178D-05    .....(Fixed Parameter).....
      B2| .20178D-06    .....(Fixed Parameter).....
      B3|-.83743D-06    .....(Fixed Parameter).....
      B4|-.83743D-06    .....(Fixed Parameter).....
--------+--------------------------------------------------------------------
```

If you forget to set the sample, you can still get the right answer. But, it will take longer because you will be minimizing

$$F_N = \sum_{i=1}^{N} \mathrm{F}(\beta) = N\times\mathrm{F}(\beta)$$

where N is your current sample size. This would be (wastefully) computed by summation, so the function and derivatives would be computed N separate times to obtain the identical function. However, the program will not actually report the results in the normal output table. You will receive a message of the sort

```
Normal exit:  44 iterations. Status=0, F=    .2774660E-24
Error   143: Models - estimated variance matrix of estimates is singular
Error   447: Current estimated covariance matrix for slopes is singular
```

which is produced by the example above when we change **SAMPLE ; 1 $** to **SAMPLE ; 1-200 $**. The covariance matrix truly is singular. It is a 4×4 matrix that has rank 1, equal to 200 times the outer product of the derivative vector.

E66.7.2 Solutions to Equations

The preceding suggests a method of finding a solution to an equation or the set of solutions to a set of equations. If the equation in one variable can be written in the form '$f(x) = c$' then, one way to find the value of x is to use

```
SAMPLE      ; 1 $
MINIMIZE    ; Start = a guess such that f(x) is computable
            ; Labels = x
            ; Fcn = (f(x) -  c )^2  $
```

(where you insert the definition of the function in the last line). The solution to the equation occurs where the squared difference equals zero. (Note that this need not be unique.) If there is a second equation, '$g(z) = d$,' you could use

```
            ; Labels = x,z
            ; Fcn = (f(x) - c)^2 + (g(z) - d)^2 $
```

The extension to M equations is direct. The equations may also be simultaneous, as in the example below.

The following example appears in Greene (2011, p. 460). For random sampling from a gamma population with parameters λ and P and observations x_i, $i = 1,...,N$, $E[x_i] = P/\lambda$ and $E[1/x_i] = \lambda/(P-1)$. Thus, one (admittedly inefficient) way to estimate P and λ would be to equate these sample moments to their population counterparts. Thus, we wish to solve the two equations

$$(1/N)\sum_{i=1}^{N} x_i = P/\lambda$$

and

$$(1/N)\sum_{i=1}^{N} 1/x_i = \lambda/(P-1).$$

One might proceed as follows, assuming the variable x already exists:

```
CALC        ; Ran (12345) $
SAMPLE      ; 1-100 $
CREATE      ; x = Rni(5) $
CREATE      ; x1  = 1/x $
CALC        ; m1= Xbr(x) ; m0 = Xbr(x1) $
SAMPLE      ; 1 $
MINIMIZE    ; Labels = l,p
            ; Start = 1,10
            ; Fcn = (m1 - p/l)^2 + (m0 - l/(p-1))^2
            ; Output = 3 $
```

(Note, this is not the optimal way to solve this problem. The sufficient statistics based on the log likelihood are $\Sigma_i\, x_i$ and $\Sigma_i \log x_i$, so the efficient estimator will be a function of these two moments.)

> **NOTE:** The **SOLVE** command described in Chapter E68 may also be used to search for the roots of an equation using a grid search rather than the type of minimization used here.

E66.7.3 Sum of Terms

Optimizing a sum of terms is identical to the preceding except that your **; Fcn** expression will involve one or more variables, and you will not reset the sample to just one observation. For example, the following sets up the log likelihood function for a probit model, where *y* is the dependent variable and *x*1 and *x*2 are the independent variables.

MAXIMIZE ; Labels = a1,a2,a3 ; Start = 0,0,0
; Fcn = Log(Phi((2*y-1)*(a1+a2*x1+a3*x2))) $

> **NOTE:** The number of observations in the current sample *always* controls the number of terms in a sum. Function values are summed over the sample, even if no variables actually appear in the function.

E66.7.4 Linear Programming

MINIMIZE and **MAXIMIZE** will also solve a linear programming problem. The general form of the problem is

MINIMIZE or **MAXIMIZE** **c’x**

Subject to **xl** $\leq$ **x** $\leq$ **xu**

and **bl** $\leq$ **Ax** $\leq$ **xu**

where all terms are vectors save for **A** which is a conformable matrix of coefficients (some of which may be zero). The necessary command is

```
MAXIMIZE   ; Alg  = Simplex
           ; Lhs = c
           ; Rhs = a
           ; Limits = xl,xu $
```

The vectors *c*, *xl* and *xu* and matrix *a* must be created with **MATRIX**. Any element in *a* can be zero. For one sided limits, you may use large values such as 1.D15 in *xl* or *xu*. Matrix *a* has the same number of columns as there are activities to be solved for. There is one row for each constraint. The first element in the *j*th row is *bl*(*j*). This is followed by the row of *a*. The last element in each row is *bu*(*j*). There are no other options for this procedure. An example appears below.

Results from this procedure are the solution itself and retained values

Matrices:	*b*	= the solution vector, **x**
	lpweight	= the vector **c**
Scalars:	*lpfunctn*	= the value of the criterion
	klp	= the number of activities
	exitcode	= 0 if the problem is solved
		3 if the problem cannot be solved
		5 if an error occurs in setting up the problem

For example, we solve the problem

Maximize $F = x1 + 3x2$

Subject to $0 \leq x1 \leq 1$

$0 \leq x2 \leq 1$

$x1 + x2 \leq 1.5$

$.5 \leq x1 + x2$

The command syntax is

```
MATRIX      ; xl  = [       0,     0        ]
            ; xu  = [       1,     1        ]
            ; c   = [       1,     3        ]
            ; a   = [-1.d15,    1,     1,        1.5  /
                         .5,      1,     1,     1.d15  ] $
MAXIMIZE    ; Lhs = c ; Rhs = a
            ; Limits = xl, xu
            ; Alg = Simplex $
```

The solution is $x1 = .5$, $x2 = 1$, *function* = 3.5

```

E66.8 Applications

We show several applications that use **MAXIMIZE** or **MINIMIZE** to optimize a user defined function.

E66.8.1 Simple Function

The following set of commands demonstrates several features of the **MINIMIZE** program. The technical output from the program is omitted. We show only the final results of each command. The first is from Goldfeld and Quandt (1972).

$$F(\mathbf{c}) = (c_1+10c_2)^2 + 5(c_3-c_4)^2 + (c_2-2c_3)^4 + 10(c_1-c_4)^4.$$

The correct values of all four parameters are 0.0. The Fcn part is exactly as it is shown above. The unrestricted optimum is found using

```
SAMPLE      ; 1 $
MINIMIZE    ; Labels = c1,c2,c3,c4 ; Start = .1,-.1,.3,.05
            ; Fcn = (c1+10*c2)^2 + 5*(c3-c4)^2 + (c2-2*c3)^4 + 10*(c1-c4)^4 $
```

```
-----------------------------------------------------------------------------
User Defined Optimization
Dependent variable              Function
Log likelihood function           .00000
--------+--------------------------------------------------------------------
        |                 Standard            Prob.      95% Confidence

      B2| .20178D-06    .....(Fixed Parameter).....
      B3|-.83743D-06    .....(Fixed Parameter).....
      B4|-.83743D-06    .....(Fixed Parameter).....
--------+--------------------------------------------------------------------
```

We now repeat the preceding while holding two of the parameters fixed at the starting values.

MINIMIZE ; Labels = c1,c2,c3,c4 ; Start = .1,-.1,.3,.05 ; Fix = c2,c4
; Fcn = (c1+10*c2)^2 + 5*(c3-c4)^2 + (c2-2*c3)^4 + 10*(c1-c4)^4 $

```

--------+--------------------------------------------------------------------
```

E66.8.2 Sum of Terms

For the sum of terms functions, we create some data.

```
CALC      ; Ran (12345) $
SAMPLE    ; 1-25 $
CREATE    ; z1 = Rnn(0,1)                    ? correlated regressors
          ; z2 = .5*(z1+Rnn(0,1))
          ; z3 = (z1 + z2 + Rnn(0,1))/3
          ; ys =  z1 + z2 + z3 + Rnn(0,2)
          ; d = ys > 0                       ? probit dependent variable
          ; t  = (d=1) * ys $                ? tobit dependent variable
NAMES     ; z  = one,z1,z2,z3 $
```

We now estimate a tobit and a probit model. Starting values are based on OLS. We use Olsen's formulation for the tobit model.

```
REGRESS   ; Lhs = t ; Rhs = z $
CALC      ; thet = 1/s   $
MATRIX    ; beta = thet * b $
```

```
-----------------------------------------------------------------------------

E66.8.3 Model Estimator – Canonical NB Regression Model

The following uses **MAXIMIZE** to create a new count data model in *LIMDEP* that is not in the menu of supported, built in specifications.

Hilbe (2011) recommends an alternative form of the negative binomial that he labels the ‘canonical negative binomial’ model. The signature feature of the model is that it applies to a discrete random variable with a formal negative binomial distribution – it is not obtained by integrating heterogeneity out of a mixed distribution. Hence the name ‘canonical’ – it derives from first principles. The conditional (on x_i) density of the random variable is

$$f(y_i \mid \mathbf{x}_i) = \frac{\Gamma(y_i + \theta)\lambda_i^{y_i}(1-\lambda_i)^{\theta}}{\Gamma(y_i+1)\Gamma(\theta)}, \ \lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$$

The conditional mean function for this model is

$$E[y_i \mid \mathbf{x}_i] = -\theta\frac{\lambda_i}{\lambda_i - 1}.$$

The resemblance to the more familiar NB2 model is only superficial. It can be seen from the conditional mean function that the parameters in the models are very different. A more transparent way to examine the difference is to examine the partial effects. In the NB2 model,

$$\partial \mathrm{E}[y_i|\mathbf{x}_i]/\partial\mathbf{x}_i \ = \ \lambda_i\boldsymbol{\beta} \ = \ E[y_i|\mathbf{x}_i]\ \boldsymbol{\beta}.$$

In the CNB model,

$$\frac{\partial E[y_i \mid \mathbf{x}_i]}{\partial \mathbf{x}_i} = -\theta\frac{-\lambda_i}{(\lambda_i-1)^2}\boldsymbol{\beta} = -E[y_i \mid \mathbf{x}_i]\left(\frac{\lambda_i}{\lambda_i-1}\right)\boldsymbol{\beta}.$$

This is a completely different scaling of the parameter vector. The implication seems likely to be that the parameters themselves from the two models will differ substantially if, as is common, the differences tend to even out in the partial effects. We will explore this in an example below.

The canonical NB model is not a built in procedure in *LIMDEP*. However, it is a very straightforward application of the **MAXIMIZE** command to obtain the estimates followed by **PARTIALS** and **SIMULATE** to obtain the partial effects and model simulations. The program below is written in the form of a template that requires only the specification of the dependent variable and the namelist containing the regressors. A substantive complication for this estimator is the starting values. The ordinary NB estimates might seem natural, but as the analysis above suggests, the parameters in the NB2 and the CNB models are likely to be quite different. Hilbe suggests - 1 for the constant term, zeros for the slopes, and 2 for θ (i.e., .5 for $\alpha = 1/\theta$).

The procedure is generic save for a single line that is modified for the specific application

```
PROC = CNBModel(y,x) $
CALC        ; k = Col(x) $
? MAXIMIZE Estimates the model parameters
MAXIMIZE    ; Start = -1,k_0,2
            ; Labels = b0,k_b,theta
            ; Fcn = bx = b0+b1'x          |
                    lambdai = Exp(bx)  |
                    y*bx + theta*Log(1-lambdai)
                    + Lgm(y+theta) - Lgm(y+1) - Lgm(theta) $
? PARTIALS computes the partial effects for the variables in the namelist
PARTIALS    ; Parameters = b
            ; Labels = b0,k_b,theta
            ; Covariance = varb
            ; Function = bx = b0+b1'x  |
                    lambdai = exp(bx)  |
                    -theta*lambdai/(lambdai-1)
            ; Effects: x ; Summary $
? We compare the results to the NB2 model. Partials are comparable APEs
NEGBIN      ; Lhs = y ; Rhs = one,x $
PARTIALS    ; Effects: x ; Summary $
ENDPROC $
```

To execute the procedure, we use the health care data, and commands

```
SAMPLE      ; All $
NAMELIST    ; x = age,educ,hhninc,female$
EXECUTE     ; Proc = CNBModel(docvis,x) $
```

The results are as follows: Notice that they begin with several warnings about the computation of the function. Unlike other models that we have examined thus far, this model does involve a computation that is quite likely to produce this result. One of the terms in the log likelihood is $\log(1-\lambda_i)$. The implication is that λ_i must be between zero and one. Since $\lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i)$, there is no constraint that can be placed on the parameters that will enforce this boundary. It is not unlikely that for some observations, this error will occur. The solver will draw the iterations on the parameters away from these values as it gets closer to a solution.

Maximum repetitions of PROC
```

We note, finally, a possible extension of the model. In the NB1 and NB2 formulations, we allow for heterogeneity in the scale parameter, θ. In particular, the generalized model specifies

$$\theta_i = \theta \exp(\boldsymbol{\delta}'\mathbf{z}_i).$$

It is straightforward to incorporate the same extension in the canonical model, as shown in the revised procedure below:

```
PROC = CNBModel(y,x,z) $
CALC  ; k = Col(x) ; m = Col(z) $
? MAXIMIZE Estimates the model parameters

E67: GMM Estimation

E67.1 Introduction

LIMDEP can be used for GMM estimation of econometric models. Although the methodology is common to all of them, we provide several approaches. The nonlinear least squares estimator presented in the Chapter E14 is based on the least squares criterion

$$M(\boldsymbol{\beta}) = \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\boldsymbol{\varepsilon}(\boldsymbol{\beta})$$

which minimizes the simple sum of squares of a set of residuals. As noted earlier, different weighting schemes and the use of instrumental variables extends this to more general GMM interpretations. Thus, the more general estimation criterion,

$$M(\boldsymbol{\beta}) = \boldsymbol{\varepsilon}(\boldsymbol{\beta})'\mathbf{Z}(\mathbf{Z}'\boldsymbol{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\boldsymbol{\varepsilon}(\boldsymbol{\beta})$$

allows for instrumental variables and a weighting matrix. Depending on the choice of the weighting matrix, this will produce GMM estimators of various sorts. Section E21.5 and Chapter E25 extend this nonlinear least squares or instrumental variables approach to multiple equations. Finally, consider the less structured GMM criterion:

$$\text{q} = \overline{\mathbf{m}}'\boldsymbol{\Sigma}\,\overline{\mathbf{m}}$$

where $$\overline{\mathbf{m}} = \frac{1}{n}\sum_{i=1}^{n}\mathbf{m}_i(\boldsymbol{\beta},\mathbf{x}_i)$$

based on a set of L ‘orthogonality conditions,’

$$E[\mathbf{m}_i(\boldsymbol{\beta},\mathbf{x}_i)] = \mathbf{0}.$$

E67.2 General Specifications of the GMM Estimator

The GMM estimation procedure departs from a set of ‘orthogonality conditions,’

$$E[m_{il}(\boldsymbol{\beta},\mathbf{x}_i)] = 0$$

where $\boldsymbol{\beta}$ is the vector of parameters to be estimated, $\mathbf{x}_i$ is a set of variables that is assumed to be in the set of information that defines the ‘moment condition,’ and $m_{il}(.)$ is one of L expectations that the model specifies to equal zero. The GMM estimator is obtained by finding the estimator, **b**, that makes the empirical moment,

$$\overline{m}_l = \frac{1}{n}\sum_{i=1}^{n} m_{il}(\mathbf{b},\mathbf{x}_i)$$

mimic the population expectation as closely as possible.

There are three possible cases:

- If there are L functionally independent conditions specified and $K = L$ parameters to be estimated, it will generally be possible to find a **b** that makes the empirical moments match the population expectations.

- If $L > K$, then it will generally not be possible to make the moments all equal zero, and we will have, instead, to minimize some criterion which makes the moments 'close' to zero. This is the GMM estimation problem.

- If $L < K$, then there are more parameters to be estimated than there are moment conditions specified, and, since they are functionally independent, the L moment conditions will not be sufficient to identify the parameters, and estimation will be impossible.

E67.3 GMM Estimation

Collect the L moment specifications in the column vector

$$\bar{\mathbf{m}} = \frac{1}{n}\sum_{i=1}^{n}\mathbf{m}_i(\boldsymbol{\beta},\mathbf{x}_i)\,.$$

The GMM estimator is the minimum distance estimator which minimizes the quadratic form

$$q = \bar{\mathbf{m}}'\boldsymbol{\Sigma}\,\bar{\mathbf{m}}$$

for some choice of positive definite matrix $\boldsymbol{\Sigma}$. Different choices of $\boldsymbol{\Sigma}$ will produce different estimators. At this point, we turn to formulating the command for the GMM estimator. A brief application will be shown next, then the remaining details of using the estimator will be given. Some technical details will follow.

The essential command structure for the GMM estimator is

GMME	**; Fn1**	=	definition of the first moment condition
	; Fn2	=	definition of the second moment condition
	; ...		up to 50 orthogonality conditions
	; Labels	=	the symbols used for the parameters,
	; Start	=	starting values for the optimization **$**

This basic command – note that $\boldsymbol{\Sigma}$ is not specified, requests minimization of the simple sum of squares. The default specification, therefore, is $\boldsymbol{\Sigma} = \mathbf{I}$. Notice that the number of parameters may not exceed the number of functions. The function definitions can make use of all the tools discussed earlier for specifying nonlinear regressions. They may also specify instrumental variables, as shown in the examples below.

Example 1:

Suppose $y_1...,y_n$ are a sample of n independent observations from the gamma distribution,

$$f(y) = \frac{\lambda^P}{\Gamma(P)} e^{-\lambda y} y^{P-1}, y \geq 0, \lambda, P > 0.$$

Then, the following expectations hold

$$\begin{aligned}
E[y] &= P/\lambda \\
E[y^2] &= P(P+1)/\lambda^2 \\
E[1/y] &= \lambda/(P-1), P > 1 \\
E[\log y] &= \Psi(P) - \log\lambda
\end{aligned}$$

where $\Psi(P)$ is the Psi function, $d\log\Gamma(P)/dP$. Any two moments could be used for estimation of the parameters. To use the two which, it turns out, define the maximum likelihood estimator, consider the first and the fourth. The command would be

```
GMME        ; Fn1 = y - p/lambda
            ; Fn2 = Log(y) - Psi(p) + Log(lambda)
            ; Start = ... the starting values
            ; Labels = p,lambda  $
```

Example 2: (This example is from Ruud (2000)

Hansen and Singleton's classic (1982) paper on consumption and asset pricing suggests the moment equations

$$E\left[z_{tj} \left\{ \left(\frac{1+r_t}{1+\delta}\right)\left(\frac{C_t}{C_{t-1}}\right)^{\gamma-1} - 1 \right\} \middle| t-1 \right] = 0$$

for a set of instrumental variables z_{tj} where t indexes periods, C_t is consumption, r_t is return, and δ and γ are the parameters to be estimated. Ruud suggests the instrumental variables obtained by differentiating the function in brackets with respect to $1/(1+\delta)$ and γ, which produces,

$$z_{t1} = (1+r_{t-1})\left(\frac{C_{t-1}}{C_{t-2}}\right)^{\gamma-1}$$

and

$$z_{t2} = z_{t1} \times \log\left(\frac{C_{t-1}}{C_{t-2}}\right)$$

We could set this up for estimation as follows:

```
SAMPLE    ; 1 - whatever is appropriate $
CREATE    ; ct1 = c / c[-1]
          ; lagct1 = ct1[-1]
          ; If(_obsno > 2) loglag = Log(lagct1)
          ; r1 = 1+r
          ; lagr1 = r1[-1] $
SAMPLE    ; 3 - whatever is appropriate
GMME      ; Labels = delta,gamma
          ; Start = 0,0
          ; Fn1 = (r/(1+delta) * ct1^(gamma-1) - 1) * lagr1 * ctl^(gamma-1)
          ; Fn2 = (r/(1+delta) * ct1^(gamma-1) - 1) * lagr1 * ctl^(gamma-1) * loglag $
```

We note, this can be made simpler to specify and to estimate by slightly reparameterizing the function. Let $\theta = 1/(1+\delta)$ and $\tau = \gamma - 1$. Making the substitutions, we would obtain the same results with

```
GMME      ; Labels = delta,gamma
          ; Start = 0,0
          ; Fn1 = ( r1 * theta * ct1^tau-1) * lagr1 * ctl^tau
          ; Fn2 = ( r1 * theta * ct1^tau-1) * lagr1 * ctl^tau * loglag $
WALD      ; Fn1 = 1/theta - 1
          ; Fn2 = tau + 1 $ (We do this to see our original parameters.)
```

E67.4 The Weighting Matrix

The GMM estimator defined earlier is consistent regardless of what matrix **Σ** is used in the minimization. (Indeed, if the problem is 'exactly identified,' that is, if there are the same number of equations as parameters), than, as has been widely documented elsewhere, the identical solution will be obtained for all matrices **Σ**. However, in terms of the efficiency of the estimator, not all choices are the same – in this discussion, we now consider only 'overidentified' problems, in which there are more equations than parameters. You may specify any matrix you like to be used in the optimization by adding

; Sigma = the name of the matrix

to the command. The name given must be that of a positive definite matrix with number of rows and columns equal to the number of moment equations.

The Optimal Weighting Matrix

As noted, you may specify any matrix you wish for the weighting in the criterion function. For GMM estimation, the 'optimal' weighting matrix is

$$\mathbf{\Sigma}^* = \{\text{Var}[\overline{\mathbf{m}}]\}^{-1}$$

This matrix can be estimated if one has in hand any consistent estimator of the model parameters. Thus, let **b** be that estimator. Then, the estimator would be

$$\mathbf{S}^* = \left(\frac{1}{n}\right)\left(\frac{1}{n}\right)\sum_{i=1}^{n}\mathbf{m}_i(\mathbf{b},\mathbf{x}_i)\mathbf{m}_i(\mathbf{b},\mathbf{x}_i)'$$

A natural way to proceed, then, would be to use two steps:

Step 1. Use the default $\mathbf{\Sigma} = \mathbf{I}$ to obtain the initial consistent estimates of the parameters,

Step 2. After computing **S***, redo the estimation while specifying $\mathbf{\Sigma}$ to be the inverse of this estimate.

When you use the **GMME** command, *LIMDEP* automatically saves **S*** for you as a matrix named *sigma*. So, to do the two steps, you would proceed as follows:

GMME	**; Fn1**	= definition of the first moment condition
	; Fn2	= definition of the second moment condition
	; ...	up to 20 orthogonality conditions
	; Labels	= the symbols used for the parameters,
	; Start	= starting values for the optimization **$**
MATRIX	**; optimalw = <sigma> $**	
GMME	**; Fn1**	= definition of the first moment condition
	; Fn2	= definition of the second moment condition
	; ...	up to 20 orthogonality conditions
	; Labels	= the symbols used for the parameters,
	; Start	= starting values for the optimization
	; Sigma	= **optimalw $**

E67.5 Output – Displayed Results

The **GMME** command is a particular form of **MINIMIZE**, so the results and displays are almost identical. The initial table of results will contain additional results that are specific to GMM estimation, as shown in the example below. The value of the GMM criterion is displayed as the function value. The 'degrees of freedom' is the difference between the number of moment equations specified and the number of parameters estimated. If this is positive, so that the model is overidentified, then a chi squared statistic can be computed to test the overidentifying restrictions – this equals the criterion function. This test is reported as part of the output.

E67.6 Other Options

GMME is an optimization command that is largely the same as **NLSQ** and **MINIMIZE**. All other options that are available for the nonlinear optimization procedures, including output display and convergence are useable here as well. Moreover, the full range of specification options are available for defining the moment equations; that is, all functions, using quadrature, linear, bilinear, and quadratic forms, use of namelists, and so on, may all be used as they are in other optimization problems.

E67.7 Application

The following example appears in Chapter 18 of Greene (2011). It is based on 20 observations on a random variable '*y*' to which we fit a gamma distribution with parameters λ and P (see Example 1 above). The data are

y = 20.5, 31.5, 47.7, 26.2, 44, 8.28, 30.8, 17.2, 19.9, 9.96, 55.8, 25.2, 29, 85.5, 15.1, 28.5, 21.4, 17.7, 6.42, 84.9

We first obtain the maximum likelihood estimates by maximizing the log likelihood function directly:

```
MAXIMIZE    ; Fcn = p*Log(l) - Lgm(p) - l*y + (p-1)*Log(y)
            ; Labels = l,p
            ; Start = .1,2 $
```

The GMM estimator based on the first and fourth moments will replicate the maximum likelihood estimator.

```
GMME        ; Labels = l,p
            ; Start =.1,2
            ; Fn1 = p/l - y  ? We changed the sign of this, for convenience.
            ; Fn2 = Log(y) - Psi(p) + Log(l) $
```

Note, however, that the asymptotic covariance matrix will differ – a finite sample difference – because of the different formulas used to do the computations. It seems useful to pursue that difference here, as we can derive the results in full detail for this simple problem. We use the BHHH estimator for the asymptotic covariance matrix for the MLE. For the gamma model above,

$$\partial \log L/\partial\lambda \;=\; \Sigma_i\,(P/\lambda\; - \;y)$$

$$\partial \log L/\partial P \;=\; \Sigma_i\,(\log\lambda - \Psi(P) + \log y).$$

Note that the first order conditions for the MLE are $n\bar{\mathbf{m}} = \mathbf{0}$. Let $\mathbf{M}$ be the 20×2 matrix whose *i*th row is the derivative shown above for the *i*th observation. Then, the estimator of the asymptotic covariance matrix for the MLE is

$$\text{Est.Asy.Var[MLE]} \;=\; (\mathbf{M}'\mathbf{M})^{-1}.$$

For the GMM estimator, $\mathbf{\Sigma} = \mathbf{I}$ while $\mathbf{G}$ turns out to be a sum of constants, so the n disappears;

$$\mathbf{G} = \begin{bmatrix} -P/\lambda^2 & 1/\lambda \\ 1/\lambda & -\Psi'(P) \end{bmatrix}.$$

Inserting these in the formula for the asymptotic covariance matrix of the GMM estimator, we obtain after canceling

$$\text{Est.Asy.Var}[GMM] = (\mathbf{G}'\mathbf{G})^{-1}\mathbf{G}'\mathbf{M}'\mathbf{M}\mathbf{G}(\mathbf{G}'\mathbf{G})^{-1}.$$

As can be seen, this differs from the formula for the MLE. Since **G'G** and (1/n)**M′M** converge to the same matrix, we see that the difference is due to finite sample variation. Finally, we obtain the full GMM estimator, using all four moment equations, and two steps to obtain the efficient estimator at the second step.

This is the maximum likelihood estimator

```
MAXIMIZE    ; Fcn = p*Log(l) - Lgm(p) - l*y + (p-1)*Log(y)
            ; Labels = l,p
            ; Start = .1,2 $
```

```

E67.8 Technical Details for the GMM Estimator

The underlying theory for the GMM estimator is well documented in the current literature, including the current textbooks such as Greene (2011), Ruud (2000), and Hayashi (2000), so it will be omitted here, and only final results will be shown.

The estimation criterion used is

$$q \quad = (1/2)\ \bar{\mathbf{m}}'\, \boldsymbol{\Sigma}\ \bar{\mathbf{m}}\,.$$

(The 1/2 is purely for convenience – it allows the ‘2’ to disappear from the derivatives.)

NOTE: The output displayed by the program reports $2q$, not q. That is, your final results will report the value of the quadratic form, not one half times it.

The first order conditions for minimizing q are

$$\frac{\partial q}{\partial \boldsymbol{\beta}} \ = \ \mathbf{G}'\, \boldsymbol{\Sigma}\ \overline{\mathbf{m}} \ = \ \mathbf{0},\ \text{where}\ \ \mathbf{G} = \frac{\partial \overline{\mathbf{m}}}{\partial \boldsymbol{\beta}'}\,.$$

Note that there are L equations and K parameters and $L \geq K$. Thus, $\mathbf{G}$ is an $L\times K$ matrix of partial derivatives. (Note, as well, that $\mathbf{G}$ is a sample mean.) If there are K moment equations used to identify the K parameters, then assuming that $\boldsymbol{\Sigma}$ is positive definite and that the moment equations are functionally independent so that $\mathbf{G}$ has an inverse, then we can premultiply the first order condition by $(\mathbf{G}'\ \boldsymbol{\Sigma})^{-1}$ and obtain the simpler necessary condition, $\overline{\mathbf{m}} = \mathbf{0}$. The solution to this is independent of $\boldsymbol{\Sigma}$, which establishes the earlier claim that $\boldsymbol{\Sigma}$ is irrelevant to the solution to an exactly identified problem.

The asymptotic covariance matrix is computed using the estimated parameters, and

$$\text{Est.Var}[\mathbf{b}] \ = \ \left[\mathbf{G}'\, \boldsymbol{\Sigma}\, \mathbf{G}\right]^{-1} \mathbf{G}'\, \boldsymbol{\Sigma}\, \mathbf{S}^*\, \boldsymbol{\Sigma}\, \mathbf{G} \left[\mathbf{G}'\, \boldsymbol{\Sigma}\, \mathbf{G}\right]^{-1}$$

where $\mathbf{S}^*$ was defined earlier. Note that if you have specified the optimal weighting matrix, $\boldsymbol{\Sigma} = (\mathbf{S}^*)^{-1}$, then the estimated variance reduces to the familiar result,

$$\text{Est.Var}[\mathbf{b}] \ = \ \left[\mathbf{G}'\, (\mathbf{S}^*)^{-1}\, \mathbf{G}\right]^{-1}.$$

If the model is exactly identified, then q is minimized at zero. (See the example above.) If not, then q will be positive. The theoretical result that $2q$ will have a limiting chi squared distribution with degrees of freedom equal to the number of overidentifying restrictions (equations minus parameters) can be used to test restrictions in this framework. (The multiplier, 2, appears because in our formulation of the problem, we initially divided by 2.) For two nested models, with $q0$ being the unrestricted one and $q1$ embodying the restrictions, $2(q1 - q0)$ can be used to test the restrictions – refer this statistic to the chi squared table with degrees of freedom equal to the number of restrictions.

E68: Numerical Analysis

E68.1 Introduction

This chapter describes some features for examining nonlinear functions. The six commands described here are:

WALD	for obtaining variances and covariances for nonlinear functions,
FPLOT	for plotting a nonlinear function,
MINIMIZE	for computing first and second derivatives of a function,
FINTEGRAL	for obtaining the integral of a function
SOLVE	for finding the zeros of a function,
FUNCTION	for evaluating a function.

All of these features are modifications of the **MINIMIZE** command. Relevant information which you should examine before using these features is given in Chapter E66 (the **MINIMIZE** and **MAXIMIZE** commands), Chapter E14 (the **NLSQ** command and most of the information needed to use **MINIMIZE**), and in Section R14.4 which describes the **WALD** command in full detail.

NOTE: After the estimation programs, we would expect the **WALD** command to be one of the most useful tools that you will find in *LIMDEP*. Analysts often devote large amounts of time and effort to obtaining standard errors and confidence intervals for functions of things that they estimate (such as parameters). **WALD** automates this entire procedure. In particular, you will not have to obtain and program any derivatives for applying the delta method. This is all done automatically.

E68.2 Variances for Nonlinear Functions

The **WALD** command for analyzing nonlinear functions of parameters is described in full in Chapter R14. It is provided primarily for testing hypotheses, but you can use **WALD** simply to compute the variances and covariances of a set of functions (or, just the functions themselves). To avoid duplication, we will merely reproduce the essential format of the command here:

```
WALD        ; Fn1 =  first nonlinear function
            ; Fn2 = second function
            ; ... up to 50 functions of 100 parameters
            ; Labels = list of labels
            ; Start = values of underlying parameters
            ; Var = covariance matrix for parameters  $
```

WALD computes the sample averages of the functions if the command contains

```
            ; Average
```

You would use this, for example, for analyzing average partial effects. (You might use **PARTIALS** instead for this function, however **WALD** might be simpler for a general function of the model parameters that is not a conditional mean.)

Output from this command is the set of function values, estimates of their standard errors, asymptotic ‘t ratios’ and the probability that a standard normal variable would exceed that value in absolute value. *LIMDEP* will also attempt to compute a Wald statistic for the null hypothesis that all the functions are zero, which would be

$$Wald = \mathbf{f}' [\mathbf{Var(f)}]^{-1}\mathbf{f}$$

where **f** is the set of functions, and the covariance matrix is that of the estimated functions. If the matrix is not positive definite, a warning will be issued. This can be ignored if your only intent is to compute a set of nonlinear functions. In this case, there is no requirement that the functions be independent, so singularity of the estimated covariance matrix should not be taken as indicative of any problem. In addition to the display, *LIMDEP* retains matrices *waldfns* containing the matrix of functions and *varwald* with the estimated asymptotic covariance matrix. If the Wald statistic is computable, a scalar named *wald* will contain the value.

Kmenta’s (1967) method of estimating the CES production provides a useful example. The production function is

$$\log y = \log \gamma - (\nu/\rho)\log[\delta K^{-\rho} + (1-\delta)L^{-\rho}].$$

Kmenta derives the approximation

$$\text{Log} y \approx \beta_1 + \beta_2 \log K + \beta_3 \log L + \beta_4 \log^2(K/L) + \varepsilon,$$

where

$$\beta_1 = \log\gamma, \qquad \gamma = e^{\beta_1},$$

$$\beta_2 = \nu\delta, \qquad \delta = \beta_2 / (\beta_2 + \beta_3),$$

$$\beta_3 = \nu(1 - \delta), \qquad \nu = \beta_2 + \beta_3,$$

$$\beta_4 = -\rho\nu\delta(1-\delta)/2, \qquad \rho = -2\beta_4(\beta_2 + \beta_3) / (\beta_2\beta_3).$$

The results below show the application of Kmenta’s estimator to Greene’s (Table A7.1) data on the SIC 33, primary metals. Note that **WALD** requires nothing more than the formulas for the nonlinear functions. Everything else needed for the computation is found internally.

The commands are:

CREATE ; ly = Log(y) ; lk = Log(k) ; ll = Log(l) ; lkl = (Log(k/l))^2 $

Compute the regression coefficients.

REGRESS ; Lhs = ly ; Rhs = one,lk,ll,lkl $

There are two ways to specify the command. The first is the generic method, in which you supply all the information needed to do the analysis:

WALD ; Fn1 = gamma = Exp(b1) **?** Functions to analyze
; Fn2 = delta = b2/(b2+b3)
; Fn3 = nu = b2+b3
; Fn4 = rho_kl = -2*b4*(b2+b3)/(b2*b3)
; Start = b **?** Values of the parameters
; Var = varb **?** Asymptotic covariance matrix
; Labels = b1,b2,b3,b4 $ **?** Labels for the parameters.

If the analysis is based on the most recently fit model, then all the information needed has been saved as *b*, *varb*, and the *last model* names. All you must provide is the functions.

```
WALD    ; Fn1 = gamma = Exp(b_one)
        ; Fn2 = delta = b_lk / (b_lk+b_ll)
        ; Fn3 = nu = b_lk + b_ll
        ; Fn4 = rho_kl = -2 * b_lkl * (b_lk + b_ll) / (b_lk * b_ll) $
```

The second set of results is identical to the first, so it is not presented.

```

E68.2.1 The Delta Method

Suppose $\mathbf{b}$ is an estimator of parameter vector $\boldsymbol{\beta}$, with asymptotic covariance matrix $\boldsymbol{\Sigma}$, and $\mathbf{g}(\mathbf{b})$ is an estimator of J continuous, differentiable functions of $\boldsymbol{\beta}$. We make the following assumptions about the estimators:

- The estimator $\mathbf{b}$ is asymptotically normally distributed with mean vector $\boldsymbol{\beta}$ and asymptotic covariance matrix $\boldsymbol{\Sigma}$,
- The vector function $\mathbf{g}(\boldsymbol{\beta})$ is continuous and continuously differentiable,
- The vector function $\mathbf{g}(\boldsymbol{\beta})$ is not a function of the sample size,
- The conditions underlying the Slutsky theorem are met so that plim $\mathbf{g}(\mathbf{b}) = \mathbf{g}(\boldsymbol{\beta})$.

Then, the vector $\mathbf{g}(\mathbf{b})$ is asymptotically normally distributed with mean $\mathbf{g}(\boldsymbol{\beta})$ and asymptotically normally distributed with asymptotic covariance matrix

$$\text{Asy.Var}[\mathbf{g}(\mathbf{b})] = \boldsymbol{\Gamma}(\boldsymbol{\beta})\,\boldsymbol{\Sigma}\,\boldsymbol{\Gamma}(\boldsymbol{\beta})'$$

where $$\boldsymbol{\Gamma}(\boldsymbol{\beta}) = \partial\mathbf{g}(\boldsymbol{\beta}) / \partial\boldsymbol{\beta}'.$$

The empirical estimators of $\boldsymbol{\beta}$ and $\boldsymbol{\Sigma}$ are $\mathbf{b}$ and $\mathbf{S}$, the results of estimation. The Jacobian, $\boldsymbol{\Gamma}(\mathbf{b})$ is estimated with $\boldsymbol{\Gamma}(\mathbf{b})$, the matrix of derivatives computed at the estimator of $\boldsymbol{\beta}$. This is precisely the set of computations done with **WALD** described in the preceding section. Your **; Start = b** provides the estimated parameters, **; Var = varb** provides **S** and the list of functions defines $\mathbf{g}(\mathbf{b})$. The matrix of derivatives is estimated by two sided numerical derivatives, which we compute using

$$\frac{\partial g_j}{\partial b_k} = \frac{g_j(\mathbf{b}+\delta_k\mathbf{e}_k) - g_j(\mathbf{b}-\delta_k\mathbf{e}_k)}{2\delta_k}$$

where $$\delta_k = \max(.0001, .00001|\mathrm{b}_k|)$$

and $\mathbf{e}_k$ is a vector with zeros save for a one in the kth position.

E68.2.2 Krinsky and Robb Simulation Method

The method of Krinsky and Robb (1986, 1990) is based on the claimed asymptotic normality of the estimator. The technique involves simply simulating draws from the distribution of the structural parameters, then using the empirical variance of the functions of the draws to estimate the desired variances. Thus, the Krinsky and Robb estimator is

$$\text{Est.Asy.Var}[g(b)] = \frac{1}{R}\sum_{r=1}^{R} [\mathbf{g}(\mathbf{b}_r) - \mathbf{g}(\mathbf{b})][\mathbf{g}(\mathbf{b}_r) - \mathbf{g}(\mathbf{b})]'.$$

We simulate the draws by drawing R primitive K variate standard normal vectors, $\mathbf{v}_r$, then computing

$$\mathbf{b}_r = \text{b} + \mathbf{C}\mathbf{v}_r$$

where **C** is the Cholesky square root of **S**.

Request this with the following addition to the **WALD** command:

; K&R ; Pts = number of draws

The **; Pts** specification is optional. The default is 1,000 draws. Replicability of Krinsky and Robb results can be obtained by setting the seed for the random number generator before the WALD command with

CALC ; Ran (value) $

We repeated the computations of the previous example using the Krinsky and Robb method. The results are below. In two of the cases, the standard errors change substantially. (We note for users of this technique, the second, apparently lesser known Krinsky and Robb paper cited above reports that the large differences found in the first paper could be mostly attributed to a programming error. As the estimates below show, differences do arise. Whether they are substantive enough to warrant reconsideration of the delta method remains to be settled.)

E68.3 Plotting a Function

The **FPLOT** command is used to examine a general function G(**x,β**). The function may be a simple function (i.e., not a sum of terms), the minimand of a **MINIMIZE** command, or some other kind of sum of terms. **FPLOT** is used to plot the function when one of the parameters varies and the remaining parameters stay fixed at the preset values. One use of this feature might be to examine the slope of a likelihood surface.

Setup for this command is identical to **MINIMIZE** or **NLSQ**. Specify the function to be plotted exactly as if it were to be optimized with one of these commands. (Note, though, that it is not necessary that this actually be a minimization problem, or even that the function you define have a minimum.) With the problem fully specified, add:

; Plot(one of the parameters in ; Labels)
; Limits = range of the parameter over which to plot the function
; Pts = number of points to plot

Two values must be specified for **; Limits**. Starting values must be given for all parameters of the function which appear in the **; Labels** list. The **; Limits** values must bracket the starting value for the variable being plotted. The function will be evaluated at the starting values to ensure that this is possible.

We illustrate with two examples. In the first, we plot the normal CDF over -4 to 4 using 100 points. Since the function does not involve any data, and is not a sum, we set the sample to one observation for the plot. (Otherwise, the function is $\Sigma_i f_i = Nf$ as f does not vary with i.)

```
SAMPLE   ; 1 $
FPLOT    ; Fcn = Phi(x) ; Title = Standard Normal CDF
         ; Labels = x ; Start = 0
         ; Plot(x) ; Limits = -4,4 ; Pts = 100 $
```

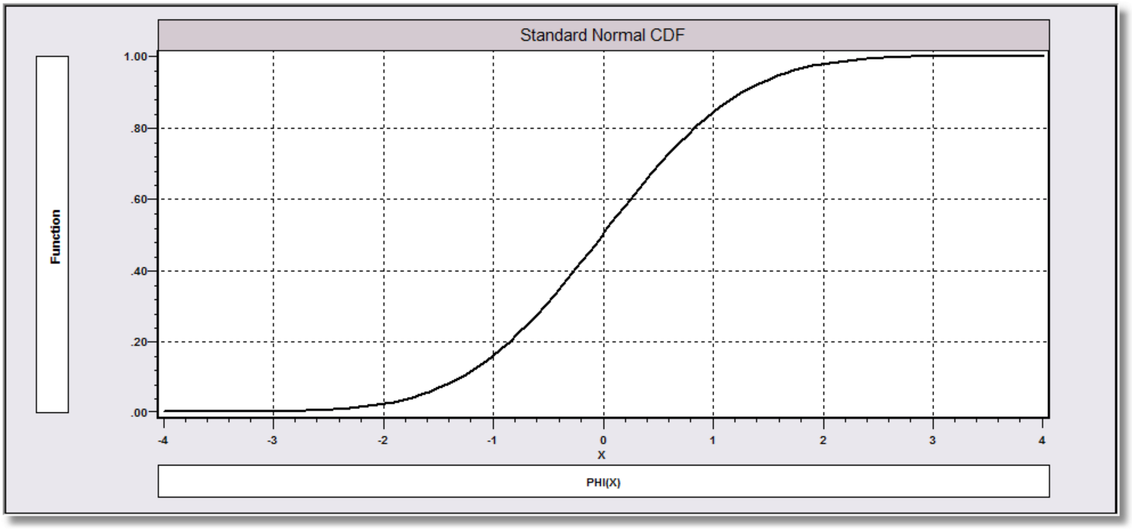

Figure E68.1 Normal CDF Produced with FPLOT

For the second example, we plot the sum of squared residuals from a regression after **REGRESS**, varying one of the slopes between -2 and +2 estimated standard errors of that slope. Note in the experiment below, the sum of squares is computed varying *b*1, the slope on *x*1. The function plotted is the sum of squares for the 100 observations – the **; Fcn** specification defines a computation that is summed over the current sample.

```
CALC        ; Ran (123579) $
SAMPLE      ; 1-100 $
CREATE      ; x1 = Rnn(0,1) ; x2 = x1 + Rnn(0,1)
            ; x3 = .5*x1 + 1.5*x2 + Rnn(0,1) $
CREATE      ; y = x1 - x2 + .5*x3 + Rnn(0,3) $
REGRESS     ; Quietly ; Lhs = y ; Rhs= x1,x2,x3,one $
CALC        ; Lower = b(1) - 2*Sqr(varb(1,1))
            ; Upper = b(1) + 2*Sqr(varb(1,1)) $
FPLOT       ; Fcn = b1 * x1 + b2 * x2 + b3 * x3 + b4
            ; Lhs = y
            ; Start = b ; Labels = b1,b2,b3,b4
            ; Plot(b1) ; Pts = 200 ; Limits = Lower,Upper $
```

NOTE: Specifying a function and an Lhs variable requests a sum of squared residuals. When there is an Lhs variable specified, the function is computed as $\Sigma_i (y_i - function_i)^2$. The function need not be linear; it can be any function definition you like.

Also, the preceding does not recompute the least squares slopes with the new values of *b*1. That is, the sum of squares is not the minimum sum of squares with each *b*1 at the set value and the others recomputed. It is the sum of squares which results when *b*1 is varied and the other slopes remain at their original least squares values. Thus, the minimum in the figure below occurs where *b*1 equals the original least squares value.

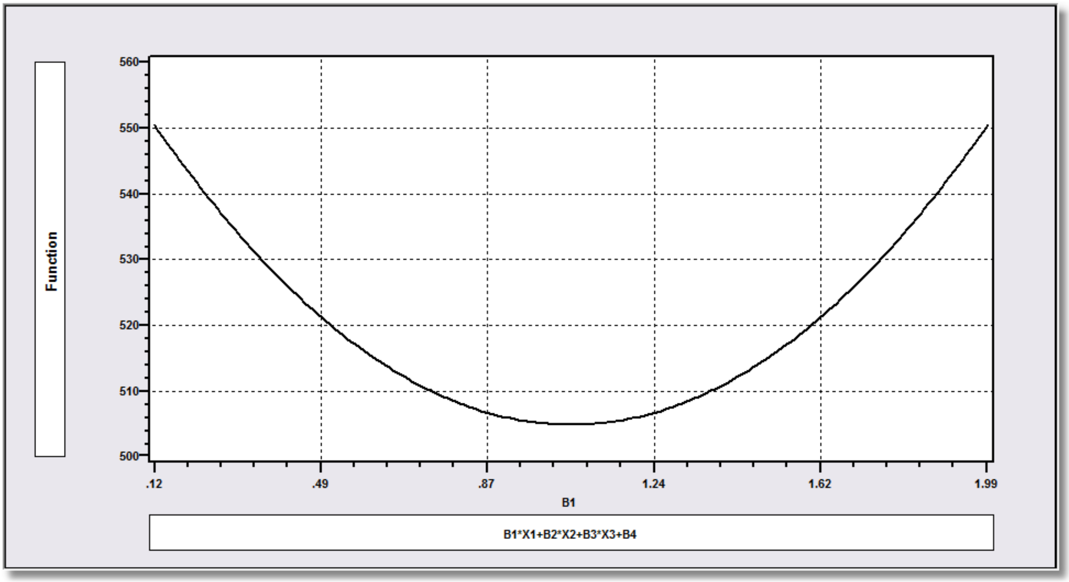

Figure E68.2 Function Plot of OLS Sum of Squared Residuals

E68.3.1 Retaining the Results from FPLOT

Two options for keeping the results are

; Keep = name to retain the function values
and **; Res = name** to keep the values of the changing variable.

E68.3.2 Application – Plotting a Log Likelihood Function

For another illustration of **FPLOT**, we use a small data set based on the Poisson model.

IMPORT $

ENDDATA
```

NAMELIST ; x = one,x1,x2,x3 $

The log likelihood for the Poisson model is

$$\log L = \Sigma_i -\log\Gamma(y_i + 1) - \lambda_i + y_i\, \boldsymbol{\beta}'\mathbf{x}_i,\ \ \lambda_i = \exp(\boldsymbol{\beta}'\mathbf{x}_i),\ \Gamma(y_i + 1) = y_i!.$$

The log likelihood function is maximized. We then plot the function for various values of β_4. The maximizing value of $b4$ is -.46, which is at the top of the hill below.

```
MAXIMIZE    ; Start = 0,0,0,0
            ; Labels = b1,b2,b3,b4
            ; Alg = N

E68.4 Evaluating a Function

The command

```
FUNCTION   ; Labels = list of labels
           ; Start = list of values to use to evaluate function
           ; Fcn = the function definition
           ; Keep = variable name $
```

will evaluate the function you define and store the function values in the variable named. You can also save the derivatives of the function with respect to the named parameters as follows: Before the **FUNCTION** command, define the place to store the derivatives with

```
NAMELIST   ; name = a list of variables to store the derivatives in $
```

The namelist must contain the same number of variables as there are parameters in the **; Labels** definition in the **FUNCTION** command. Then, you can add

```
           ; Derivatives = namelist
```

to store the derivatives.

As an example, we use the function in the previous application.

```
MAXIMIZE   ; Start = 0,0,0,0 ; Labels = b1,b2,b3,b4 ; Alg = N
           ; Fcn = -Lgm(y+1) - Exp(b1'x) + y*b1'x $
CREATE     ; dfdb1 = 0 ; dfdb2 = 0 ; dfdb3 = 0 ; dfdb4 = 0 $
NAMELIST   ; dfdb = dfdb1, dfdb2, dfdb3, dfdb4 $
FUNCTION   ; Labels = b1,b2,b3,b4 ; Start = b ; Fcn = Exp(b1'x)
           ; Keep = condmean ; Derivatives = dfdb $
```

This produces the following results:

```
==== [Evaluation of User Specified Function] ====
Function values were saved in variable  CONDMEAN
Derivatives were saved in variable list DFDB
     Parameter  Derivative
   1 B1          DFDB1
   2 B2          DFDB2
   3 B3          DFDB3
   4 B4          DFDB4
```

NOTE: This procedure produces the same results as **SIMULATE** for the function evaluation, and has some overlap with the differentiation routine described for **MAXIMIZE** in the next section. The difference here is that the derivatives saved here are observation specific whereas the next section shows how to obtain the gradient of the function which will usually be a sum of terms.

E68.5 Function Differentiation

If you wish only to obtain the derivatives of a function, set up **MINIMIZE** or **MAXIMIZE** exactly as if you were going to optimize that function *even if the function is not one which could be optimized*. You can set it up as a simple function or as a sum of terms. The function will be evaluated at the points you specify with **; Start = list**. To obtain the first and second derivatives, add

```
; Fix
; Alg = N
```

with no other specification to the command. Note that **; Fix all** and **; Fix = list** are alternative forms that request different computations. With **; Fix** as above, the output from this command will be as follows: The usual output for **MINIMIZE** or **MAXIMIZE** will be given. With the exception of the reported function value, this output can be ignored. The function and derivatives are found in scalar *logl* which contains the function value, matrix *gradient* which contains the vector of first derivatives, and *varb* which contains the Hessian, not a covariance matrix.

For example, to obtain the derivatives of the sum of squares for a nonlinear regression model, you might proceed as follows:

```
MINIMIZE    ; Fcn = (y - the function) ^ 2
            ; Labels = ...
            ; Start = ... list
            ; Fix
            ; Alg = N $
```

Another example to illustrate the computation is shown below for a Poisson regression model in the previous section. The function is first maximized. Then, the first and second derivatives are computed at the maximizing values. The results confirm what we would know about the derivatives – they are zero at the maximum. The function and Hessian are also listed. The log likelihood is maximized first.

```
MINIMIZE    ; Start = 4_0 ; Labels = b1,b2,b3,b4 ; Alg = N
            ; Fcn = Exp(b1'x) - y*b1'x $
```

The results of this step appear above Figure E68.3 above. The next command computes the function, gradient and Hessian. Since *b* is already the MLE, the main results are identical to those shown above.

```
MINIMIZE    ; Start = b ; Labels = b1,b2,b3,b4 ; Alg = N
            ; Fcn = Exp(b1'x) - y*b1'x ; Fix $
```

We now display the first derivatives (essentially zero) and the Hessian. The **; Stat** command below verifies that *varb* is the inverse of the matrix used in the first output to obtain the standard errors of the estimated parameters.

```
MATRIX      ; List ; gradient ; varb $
```

```

E68.6 Integration

You can compute integrals of the form

$$F = \int_L^U f(x)\mathrm{d}x.$$

The function may be any function that you can set up with the **MINIMIZE/MAXIMIZE** command, which would include

$$F = \int_L^U f(\theta_1, \theta_2, ..., x)\mathrm{d}x,$$

where we pull one of the variables out of the list and name it x, or, even

$$F = \int_L^U \Sigma_i w_i F(\mathbf{x}_i, \theta_1, \theta_2, ..., z)\mathrm{d}z.$$

In this case, we simply set up the sum of terms, and name one of the variables in the function ‘z.’

Integration is set up essentially the same as **FPLOT**. The command is

FINTEGRATE ; Fcn = the function
; Labels = ... the full set of labels for function arguments
; Start = the values of all the parameters
; Limits = L,U
; Pts = number of points in grid (see below)
; Vary (variable) $

The last part specifies the variable of integration. This must be one of the variables in your **; Labels** list. The starting values given provide values for all the variables in the function. One of them will be an interior value for the variable being varied. Suppose, for example, your function is over $x1$,$x2$ and $x3$, with $x1 = 9$, $x2$ ranging from 0 to 1 and $x3 = -.7$. Then you might use **; Start = 9,.5,-.7**. The value for the changing variable is given so that it can be assessed before the computation is done whether the function evaluation is possible at all.

E68.6.1 The Trapezoid Rule

The method used is the trapezoid rule with first order correction (which is also the Newton-Cotes method). The integral is approximated as follows: We divide the range from L to U into N-1 equal length intervals. The interval length is

$$\Delta = (U - L) / (N\text{-}1).$$

Then,

$$F = \int_L^U f(x)\mathrm{d}x \approx \frac{1}{2}\Delta[f(L) + f(U)] + \sum_{i=2}^{N-1} \Delta f(L + i\Delta)$$

For example, a moderately accurate method of obtaining probabilities for the normal distribution would be

SAMPLE ; 1 $
FINTEGRATE ; Fcn = N01(x)
; Labels = x
; Start = some intermediate value
; Limits = Lower,Upper ; Vary(x)
; Pts = 100 $

The result of the calculation will be displayed in your output and kept in a scalar named *integral*.

The accuracy of the approximation improves with the number of points. However, the amount of computation does as well. If the function is a simple function which is not a sum of terms, several hundred points may not be overly time consuming. But, if you are summing functions of many observations, you may want to limit the number of points.

To continue the example above, using

CALC ; List ; Phi(1) - Phi(-1) $

produces an answer of .68269. Using the method above with 100 points and limits of -1,1 produces a value of .68267.

The commands are:

```
SAMPLE       ; 1 $
FINTEGRATE   ; Fcn = N01(t)
             ; Labels = t
             ; Start = 0
             ; Limits = -1,1 ; Vary(t)
             ; Pts = 100 $
```

```
+----------------------------------------------------+
| Function integration:                              |
| Grid is  100 points in [    -1.000 to      1.000] |
| Value of the integral is          .68267           |
+----------------------------------------------------+
```

E68.6.2 Quadrature

For some integrals which are improper in both tails and of the form

$$\int_{-\infty}^{+\infty} f(x)e^{-x^2}dx$$

the value can be well approximated by Hermite quadrature:

$$\int_{-\infty}^{+\infty} f(x)e^{-x^2}dx \approx \sum_{s=-1,+1}\sum_{m=1}^{K} w(m)[f(s\times z(m))]$$

where $w(m)$ is a weight and $z(m)$ is the abscissa of the Hermite polynomial. (See Abramovitz and Stegun(1971).) A 20 point quadrature is used (K=10) by default. For integrals which can be written

$$\int_{0}^{\infty} f(x)e^{-x}dx$$

we can use Gauss-Laguerre quadrature, instead,

$$\int_{0}^{+\infty} f(x)e^{-x}dx \approx \sum_{m=1}^{K} w(m)f(z(m)) .$$

For this procedure, a 40 point quadrature is used. To request these procedures, the commands are

```
FINTEGRAL  ; Fcn = ... as before
           ; Start = ... as before
           ; Labels = ... as before
           ; Vary (variable that is varying)
           ; [integral type] $
```

where [integral type] is **HR1** for the Hermite quadrature or **GL1** for the Gauss-Laguerre quadrature.

You can set the number of points for the Hermite quadrature by including

; Hpt = n

where *n* is one of (4,6,8,10,12,14,16,18,20,24,32,40,64,96). You can reset the number of points for the Gauss-Laguerre quadrature to one of (2,3,4,5,6,7,8,9,10,12,15,20,40,68) by using

; Lpt = n

More points provides a more accurate approximation, but takes longer to compute. If you are not summing over a sample to compute the function, the difference will be trivial, and you should use a large value.

To illustrate the procedure, we will approximate the gamma function over the range 0.5 to 2.5 with a 40 point Gauss-Laguerre quadrature. We compute the function at 21 points, then list and plot the results. For comparison, the value of the function computed with the internal program is given as well. (Note that for small P, the function is not very well approximated.)

```
SAMPLE        ; 1 $
CALC          ; i = 0 $
MATRIX        ; gammafn = Init(21,1,0) ; p = gammafn $
PROCEDURE
CALC          ; ap = .5 + i * .1 $
FINTEGRAL     ; Fcn = x^(ap - 1) ; Labels = x ; Start = 1 ; GL1 ; Vary(x) $
CALC          ; i = i + 1 ; List ; ap ; integral ; Gma(ap) $
MATRIX        ; p(i) = ap ; gammafn(i) = integral $
ENDPROCEDURE
EXECUTE       ; n = 21 $
MPLOT         ; Lhs = p ; Rhs = gammafn ; Grid ; Fill
              ; Title = Gamma Function Values $
```

Each execution of the procedure produces a result such as the following: This is the first one.

```
+-----------------------------------------------------+
| Function integration:                               |
| Laguerre quadrature; 40 pts from    0 to +inf       |
| Value of the integral is         1.63524            |
+-----------------------------------------------------+
+--------------------------------------+

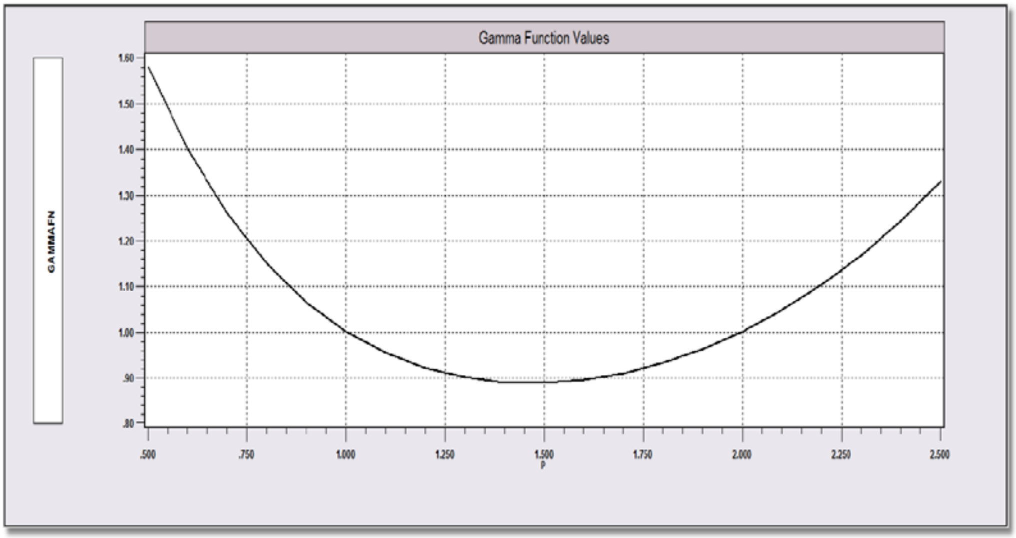

Figure E68.4 Gamma Function

E68.6.3 Monte Carlo Integration

Consider an integral that is of the form of an expected value of a function

$$f(.) = \int_u g(u)\, f(u) d\iota$$

where $f(u)$ is the density of the random variable u. In particular, a case typically of interest arises when u has a normal distribution with mean zero and variance σ^2, in which case the preceding can be written

$$f(.) = \int_u g(\sigma v) \phi(v) dv$$

where $v \sim N[0,1]$. The 'Monte Carlo' integration method amounts to replacing the integration above with averaging over a set of draws from the assumed population;

$$\hat{f}(.) = \frac{1}{R} \sum\nolimits_{r=1}^{R} g(u_r).$$

So long as the function is smooth and well behaved, an appeal to the law of large numbers will produce plim $\hat{f}(.) = f(.)$. You can use this method of integration by using

; Simulation (or just ; Sim)
; Pts = the number of draws, R

in your **FINTEGRAL** command. The number of points may be from 10 to 10,000. Since you are not integrating over a range, you may omit the **; Limits = Lower, Upper** from the command when you do Monte Carlo integration.

As an example, consider the integral

$$f(u) = \int_{-\infty}^{\infty} \Phi(u)\phi(u)du\ .$$

If we randomly draw values of u, the values of $\Phi(u)$ should vary randomly in the interval from zero to one, with center at one half. The expected value should be one half. (That is the exact theoretical result.) We use the command

```
SAMPLE      ; 1 $
CALC        ; Ran (12347) $
FINTEGRAL   ; Labels = z ; Start = 0 ; Vary(z) ; Simulation
            ; Pts = 3000 ; Fcn = Phi(z) $
```

```
+---------------------------------------------------+
| Function integration:                             |
| Monte Carlo integral with 3000 draws              |
| Value of the integral is          .50013          |
+---------------------------------------------------+
```

E68.7 Finding the Roots of a Function

To find the zeros of a function, use

```
SOLVE       ; Labels =  list of labels for parameters
            ; Start  =  an interior point of the function for nonvarying parameters
            ; Fcn    =  the function definition
            ; Vary      (the label of the parameter that varies)
            ; Limits =  low, high = the range over which the function is computed
            ; Pts    =  the number of points in the range to evaluate
            ; Plot      this is optional  $
```

The last specification will produce a plot of the function in the dimension of the label of the varying parameter holding the others fixed at their start values. This procedure uses a simple grid search to search the range from low to high for the values at which f(x) = 0. When two points in the grid search bracket a zero value, several Newton iterations are used to find the actual x at which f(x)=0.

The following builds on the earlier example to create a function to analyze:

```
MAXIMIZE    ; Start = 0,0,0,0
            ; Labels = b1,b2,b3,b4
            ; Alg = N
            ; Fcn = -Lgm(y+1) - Exp(b1'x) + y*b1'x $
SOLVE       ; Labels = b1,b2,b3,b4
            ; Start = b
            ; Fcn =  -Lgm(y+1) -Exp(b1'x) + y*b1'x + 18/15
            ; Vary (b1)  ; Limits = -1.2,.1 ; Pts  = 500 ; Plot $
```

The function is the one plotted in Figure E68.3 plus 18/15 which produces two zeros in the range specified. (Your function will be better defined – we have put this together to produce an uncomplicated example.) The search locates two roots in the range specified.

```
Newton iterations to search for any root near    -.595370
Iteration  B1        Function   Newton Step
Iteration  B1        Function   Newton Step
Found  2 roots in the range B1      =   -1.2000 to      .1000
    -.986736    -.249137
```

The figure shows the results of the search.
